In the Propaganda department of this issue is another report of the Council on Pharmacy and Chemistry on the widely advertised products—"Lactopeptine" and "Elixir Lactopeptine." These preparations are supposed to contain, as their two main ingredients, pepsin and pancreatin and this, in the light of present-day knowledge, brands these products — especially the elixir — as therapeutic absurdities. It is axiomatic that pepsin and pancreatin are never indicated at one and the same time and it is practically impossible for the two substances to act together; in fact, in a liquid medium the ingredients are mutually destructive. Eight years ago The Journal published the results of an investigation showing that Lactopeptine contained "but small amounts of pepsin," and "neither diastase nor pancreatin"; two years ago another report was published confirming the earlier one. The present report still further clinches the previous findings. It is worthy of note that the manufacturers in protesting against this report have uttered not a word in defense of the "Elixir Lactopeptine," although, in probably nine out of ten prescriptions for Lactopeptine, it is the elixir that is called for. The reason for ignoring their most widely used product is evident—Elixir Lactopeptine is an indefensible therapeutic and pharmacologic absurdity. The company in its protest, however, does claim that tryptic activity can be found in fresh specimens of Lactopeptine powder and Lactopeptine tablets. Further investigation, made after this protest was received, showed that while a few specimens of Lactopeptine in the dry form possessed some—therapeutically negligible—tryptic activity, there was no activity whatever in most of the specimens examined. Briefly, the facts regarding this "ethical proprietary" may be summed up thus: (1) Lactopeptine, whether in the form of an elixir, powder or tablets, is a therapeutic absurdity. (2) Lactopeptine in the dry form (powder or tablets) may, when strictly fresh, possess some slight—although therapeutically negligible—tryptic activity, a fact that is of merely academic interest because pepsin and pancreatin are never indicated at the same time. (3) Even if fresh specimens have any advantage over the old, there is no way of telling which the patient is likely to get, as the trade packages of Lactopeptine are undated. (4) The form in which Lactopeptine is usually prescribed is the "Elixir," a liquid preparation in which the pancreatin and pepsin destroy each other. (5) Lactopeptine has not the composition claimed for it and if it did have, it would still be of no value.

THE N. F. IMITATION OF ELIXIR LACTOPEPTINE

Nearly forty years ago — to be exact, in 1876 — the essential worthlessness of Lactopeptine was brought to the attention of the pharmaceutical profession. This was done in a paper, contributed to the American Pharmaceutical Association by Prof. Emil Scheffer, reporting some experiments made with Lactopeptine and proving that it had no greater digestive value than the saccharated pepsin then in vogue. This paper, which appeared in the Proceedings of the American Pharmaceutical Association, was called to the attention of The Journal's readers by the president of the American Pharmaceutical Association[1] soon after the appearance of the Council's first report on Lactopeptine.[2] When scientific fact runs counter to popular fancy, and especially when popular fancy is supported by heavy advertising, science inevitably gets the worst of it. This is what occurred in the Lactopeptine matter, for Professor Scheffer's paper was ignored by pharmacists and was not brought to the attention of physicians. Not only did an extensive advertising campaign force Lactopeptine and Elixir Lactopeptine into popular favor, but the very demand thus created was an inducement for druggists to imitate the products. As a result, we find the Compound Powder of Pepsin and also Compound Digestive Elixir in the National Formulary. Compound Digestive Elixir, as manifestly worthless as its prototype, Elixir Lactopeptine, has, like its prototype, proved to be a "good seller." It is not surprising to find a journal devoted to the business rather than the professional side of pharmacy (*N. A. R. D. Journal*) earnestly defending the Compound Digestive Elixir on the ground that "physicians keep right on prescribing it, and they say they get the results they are looking for, and what more does any one want?" Even more naively the *N. A. R. D. Journal* goes on to argue that "while the action of one or more of the ingredients in the N. F. formula may be 'killed,' as some writers have expressed it, and that, therefore, the presence of such is superfluous, it has never been mentioned what the resulting compound will be, nor what its therapeutic action." Thus the druggist is invited to emulate the followers of Mrs. Eddy in substituting for inconvenient knowledge a cheerful faith which seeks not to dissolve a profitable mystery. Pharmacists should not be too severely blamed, however, for adopting such an attitude; manufacturers and dealers in drugs are, after all, merchants, whose profits are in a general way directly proportionate to the amount of goods they sell. The pharmaceutical profession, however, will do well to remember that pharmacists themselves will suffer in the end from the reaction in the minds of the medical profession and the public if they persist in disregarding what they know to be true for the sake of what they find to be profitable.

ALABAMA OPTOMETRY BILL VETOED

During its recent session, the Alabama legislature passed a law providing for a board of optometry examiners. The opposition was largely disarmed, owing to the fact that, at the last meeting of the medical society of the state of Alabama, through a general misunderstanding, this bill was recorded as receiving the endorsement of the state association. When it went to Governor Henderson, the facts regarding the measure and its dangers to the public were placed before him, and in spite of considerable pressure he wisely refused to permit it to become a law. Usually the advocates of these measures are able to secure a considerable amount of political backing and influence. The endorsement of the state association, however secured or through whatever misunderstanding it may have occurred, only increased the difficulty of the governor's position. Probably most state executives under these circumstances would have felt fully justified in signing the bill. These facts only increase the appreciation of Governor Henderson's independence and courage in refusing to allow this measure to become a law. In the ten years in which this question has been before legislatures, some definite principles thereon have been evolved. Beyond question, the public is in danger of being imposed on and injured by dishonest or incompetent spectacle fitters. Unquestionably, if in the opinion of the legislature this is a question of sufficient importance to demand regulation, there should be adequate regulation of those who follow this business. It is true that too little time is given to the instruction of medical students on this subject, and that to become a competent oculist or ophthalmologist requires postgraduate instruction. These facts have all been taken advantage of in promoting the passage of optometry bills in the various states. But it does not follow that the only remedy or best remedy is the creation of a separate, independent board of "optometrists" and the legal recognition of a pseudoscientific sect, which, by its incompetent encroachment on the field of medical practice, will do quite as much, if not more, harm to the public than the unregulated spectacle fitter. Each of our states has a state board for the examination and licensing of physicians. A bill extending the powers of the medical examining board, authorizing it to examine, either directly or through an appropriately constituted examining committee, those desiring to fit glasses, to issue to them a proper license to do so and to prevent all unlicensed persons from preying on the public, would meet all the indications as far as public safety is concerned, and would avoid the evils and dangers of a separate board.

[2] The Journal A. M. A., March 16, 1907, p. 959.

"CARDUI: THE STORY OF A NOSTRUM"

Those who have followed The Journal's articles on "Wine of Cardui" and are conversant with the fact that the suits resulting from the exposures have resolved themselves into a fight by the combined "patent medicine" interests of the country against the American Medical Association will read with interest an article that appears in the current (October 23) issue of *Harper's Weekly*. This article, under the title quoted above, is announced as the first of three to appear in *Harper's* on the subject of "Wine of Cardui" and "Black Draught," two nostrums put out by the Chattanooga Medicine Company. These articles are written by a Dr. Bicknell, who is said to have been in the employ of the Chattanooga Medicine Company for some years as their chemist. Certainly the details he gives indicate a familiarity with the business that could be expected only from one who had been employed in some such capacity. The current article traces the growth of the Wine of Cardui business, and illustrations are used to show the evolution of the nostrum label from "Nature's Great Emmenagogue" to "20 Per Cent. Alcohol." While the author denies that the Chattanooga Medicine Company's nostrum will perform the many wonders claimed for it by its manufacturers, he says "there is one miracle that Cardui can perform—a miracle quite as wonderful, perhaps, as the regulation of the menstrual function; it can make money." According to Bicknell, Wine of Cardui contains blessed thistle and an insignificant amount of black haw. These herbs, says the author, "whatever their life-giving potentialities, are at least conveniently inexpensive." Then follows a computation of the cost of making and marketing a gallon of Wine of Cardui. This shows that the contents of each bottle "cost a trifle over 4 cents." For the bottle, corks, labels, carton, packing case, etc., he computes an amount that makes the cost of a bottle of Wine of Cardui, packed ready for shipment, total a little less than eleven cents. To this he adds the "patent medicine" maker's largest item of expense, advertising, bringing up the total gross cost of the nostrum to a trifle under 26 cents a bottle. It sells for $1.00 a bottle. These statements prepare one for the claim made by Dr. Bicknell that during the past year "the *net profit* of the year's sale of Cardui amounted to $949,200.00!" These figures are enlightening. They help one to understand the lavish expenditure of money that followed the filing of the suits by the Chattanooga Medicine Company against The Journal and its editor. Those engaged in a business whose *net* profits were even one-half million dollars annually are not likely to be over particular in the methods of defending the business. The fact that the two and a half million dollars, representing the gross sales, based on the Bicknell figures, comes out of the pockets of those who can least afford it, is but an incident in a sordid business.

THE DEATH OF A GREAT NATURALIST

Henri Fabre has just died at his home in France. Only toward the close of his long, laborious life had the careless world begun to realize that in this unpretentious son of peasants, waging a heartbreaking struggle against grinding poverty and humiliating neglect, it had been ignoring a unique genius. For this long failure to obtain fitting recognition there were many reasons. Fabre possessed none of the arts of the self-advertiser. Entomology, when he embraced it as a career, was a neglected science, and the phase of it to which he intuitively turned, the study of instinct, was especially neglected. Then, too, though versed in several sciences, Fabre was impatient of booklore in his own field and refused to bow to the theories of the day, preferring to interrogate Nature alone. Finally, it may be that even his delightful prose, with flashes of fancy and quaint humor, inspired in the Gradgrinds of science a certain distrust. This distrust, if it existed, Fabre was at no pains to allay, for he declared that he hated the barbarous jargon which made science so thorny and repellant to the young. In his youth Fabre felt a strong inclination toward medicine. Had he followed that inclination, he surely would have made notable contributions to medical science. As Legros says, he had in high degree "that gift, properly speaking poetic, which is known as the clinical eye, which at the first glance perceives and confirms the diagnosis in all its detail." He also had the gift of untiring observation, the thirst for knowledge, the capacity for unlimited work and the illuminating imagination which mark the scientific discoverer. Yet we can scarcely reproach the fate which gave his faculties their own peculiar trend. Darwin styled him "the inimitable observer"; Maeterlinck called him "one of the most profound and inventive scholars . . . one of the purest writers, and . . . one of the finest poets of the century that is just past"; Edmond Rostand characterized him as "this great scientist, who thinks as a philosopher, sees as an artist, and feels and expresses himself as a poet."

A JOURNAL OF LABORATORY MEDICINE

The *Journal of Laboratory and Clinical Medicine* is a new venture in the field of medical journalism. As the title indicates, the journal is to be devoted to the laboratory in its relation to medicine and surgery. Its object is to publish reports of recent discoveries made in research institutions, and to suggest to the practitioner how he may apply these discoveries in his daily work. The first function is to be fulfilled by original contributions, the second by editorials contributed by the editorial staff; several pages are also to be devoted to laboratory methods. Dr. Victor C.

Vaughan is the editor-in-chief, and the associate editors are: Drs. Dennis E. Jackson, St. Louis; Frederick P. Gay, San Francisco; Hans Zinsser, New York; Paul G. Woolley, Cincinnati; J. J. R. MacLeod, Cleveland; Roy G. Pearce, Chicago, and Roger S. Morris, Cincinnati. The journal takes advertising, but makes the following announcement: "The advertising policy of the journal will conform to the standard set by the Council on Pharmacy and Chemistry of the American Medical Association." Among the contributors to the first number are: Drs. Dennis E. Jackson, St. Louis; Frederick P. Gay, San Francisco; George Dock, St. Louis; Roger S. Morris, Cincinnati; Martin E. Engman, St. Louis; Louis B. Wilson, Rochester, Minn., and Paul G. Woolley, Cincinnati. The first number is creditable to all concerned.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST; SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ARKANSAS

Staff Physicians Appointed.—The boards of control of the state charitable institutions, on September 23, elected Dr. William T. McCurry, Little Rock, oculist for the Arkansas Deaf Institute and the Arkansas School for the Blind, Little Rock; Dr. Luther D. Reagan, physician for the School for the Blind, and Dr. Sherman B. Hickman, physician for the Deaf Mutes Institute.

Free Treatment.—The Pope County Medical Society at its meeting in Russellville, October 6, held a series of free clinics.——Plans are under way for the three-story hospital and clinic building to be erected in the rear of the Medical College, Little Rock. The hospital is being constructed with the $20,000 and interest of the Dr. Isaac Folsom Free Clinic Fund founded about fifteen years ago.

CALIFORNIA

State Medical Society Meeting.—It is announced that the Medical Society of the State of California will hold its annual meeting in Fresno, in April of next year.

Quack Indicted.—"Dr." S. R. Chamley, the "Cancer Specialist," is reported to have been indicted by the grand jury in San Francisco, recently, but had disappeared when detectives were sent to arrest him. He is said to have charged a patient $2,300 for an operation for cancer when, as testified by witnesses, he knew the patient had no cancer "but meant to get all the money he could."

Going After the Irregulars.—The State Board of Medical Examiners announces that it will start an aggressive campaign in southern California directed particularly against the advertising "quacks" and other individuals who prey on the credulous public. It is intended to eradicate from the southern section of California the flagrant violators of the medical practice act who have heretofore openly defied regulation.

COLORADO

Medical Reserve Corps Officers Meet.—A meeting of all Denver physicians who are on the inactive list of the Medical Reserve Corps of the Army was held October 11 in the office of Dr. William W. Grant, for organization and to study the correspondence courses which have recently been authorized by the war department.

Personal.—Dr. William A. Jolley, Boulder, formerly major in the Medical Corps of the Colorado National Guard, who has been in service with the American Red Cross in Belgrade, returns home this month.——The resignation of Dr. William P. Harlow, dean of the medical school of the University of Colorado, Boulder, has been presented to the board of regents.——Dr. Samuel R. McKelvey, Denver, has been appointed secretary and executive officer of the State Board of Health.——Dr. James W. Purcell, Denver, who has been seriously ill for ten months, is reported to be convalescent.

New State Society Officers.—At the annual meeting of the Colorado State Medical Society held in Denver, October 5 to 7, under the presidency of Dr. George B. Packard, Denver, the following officers were elected: president, Dr. John R. Espey, Trinidad; vice presidents, Drs. Chauncey E. Tennant, Denver; Jesse U. Sickenberger, Grand Junction; William A. Kickland, Fort Collins, and Henry W. Averill, Evans; councilors, Drs. Will H. Swan, Colorado Springs, second district, and Hampton S. Henderson, Grand Junction, fourth district; delegate to the American Medical Association, Dr. Lewis H. McKinnie, Colorado Springs; and alternate, Dr. George A. Moleen, Denver. Glenwood Springs was selected as the next place of meeting.

GEORGIA.

Dinner to Dr. Murray.—In honor of Dr. George S. Murray, Columbus, who left September 23 to serve in the Medical Corps of the British Army at the front, the Muscogee Medical Society gave a dinner, September 21.

Battey Bust Presented.—A marble bust to the late Dr. Robert Battey, Rome, was presented to the Wesley Memorial Building of Emory University by Mrs. Martha Smith Battey. The ceremony took place October 15. Dr. George H. Noble, Atlanta, presented the bust on behalf of the family and Bishop Warren A. Candler, chancellor of the university, made the address of acceptance.

ILLINOIS

State Antituberculosis Meeting.—The seventh annual meeting of the Illinois Association for the Prevention of Tuberculosis will be held in Danville, October 23, in conjunction with the meeting of the state conference of charities.

Personal.—Dr. William Jayne, Springfield, who is still prominent in business life and is a director in the First National Bank, recently celebrated his eighty-ninth birthday anniversary.——Dr. J. H. Riley, DeKalb, is reported to be seriously ill.

Chicago

Needs of Psychopathic Hospital.—The advisory attending staff of the Psychopathic Hospital, after an investigation of the needs of the institution, recommend that more beds are needed and that the hospital shall be so arranged that patients can be segregated according to their diseases.

Tuberculosis Expert Gives Clinic.—Dr. Francis M. Pottenger, Monrovia, Calif., gave a clinic and demonstration in the amphitheater of Rush Medical College, October 16, on "Tuberculosis," under the auspices of the Rush Medical College Ambulatorium of the Chicago Municipal Tuberculosis Sanatorium.

INDIANA

Disease Prevention Day.—The second annual observance of Disease Prevention Day in Indiana, October 1, was a marked success.

Test Case.—O. L. Burgener, a chiropractor, is being tried in Indiana for practicing medicine, surgery and obstetrics without a license. The charge was filed by Dr. William T. Gott, Crawfordsville, secretary of the Indiana State Board of Medical Examiners.

Personal.—Dr. William N. Wishard, Indianapolis, is reported to be seriously ill with septicemia.——Dr. Edwin W. Poinier, Andrews, has been appointed physician of Huntington County, succeeding Dr. William R. Beck.——Dr. George H. Hockett, Anderson, is recovering after a tonsillectomy.——Dr. David L. Kahn, Indianapolis, has been appointed local surgeon for the Lake Erie and Western Railway, succeeding Dr. Paul F. Robinson, Indianapolis, resigned.——Dr. J. McLean Moulder, [illegible] accepted the superintendency of the new [illegible] hospital, Kansas City, Kan.——Dr. John P. Franz, Indianapolis, was painfully injured in a collision between his automobile and a street car, recently.

KENTUCKY

Personal.—Dr. Granville S. Hanes, Louisville, is seriously ill with septicemia as the result of an infection of the finger. The axillary glands became infected and were removed, October 11.

Dinner to Dr. Vance.—A dinner was given to Dr. Ap Morgan Vance by the Medico-Chirurgical Society of Louisville, October 14, at the Tavern Club, to celebrate the election of Dr. Vance to the presidency of the Kentucky State Medical Association.

MAINE

Personal.—Dr. Theodore E. Hardy, Waterville, has had conferred on him the honorary degree of A.M. by Colby University, Waterville.

New Sanatoriums.—An order was passed by the governor, September 1, providing for the purchase of the Hebron Sanatorium for Tuberculosis at a cost of $15,000 and for the purchase of the Fairfield Institution, at the same figure. The former institution will be known as the Western Maine Sanatorium, and the latter as the General Maine Sanatorium.——Dr. Theodore E. Hardy, Waterville, has been elected president of the board of trustees of the state sanatoriums and Dr. Olin S. Pettingil, Wallum Lake, R. I., assistant superintendent of the Rhode Island Sanatorium, has been offered the position of superintendent of the Hebron Institution.

MARYLAND

Typhoid in Maryland.—During the month of September, 609 cases of typhoid fever occurred in Maryland, according to reports made to the State Department of Health. Of these, 186 were reported in Baltimore, the remainder being distributed throughout the counties. Baltimore County leads the list, 68 cases having been reported from there. Of the towns outside of Baltimore, Cumberland had the largest number of cases, 13 being reported. There were 6 cases in Annapolis.

Surgeons Tell of War Abroad.—War experiences of Baltimore surgeons in German, French and English hospitals were related recently at the regular meeting of the Baltimore City Medical Society. The subject of the evening was "Medical Lessons of the War." Dr. Henry N. Shaw, Baltimore, stationed in England; Dr. Robert H. Crawford, stationed at the American Red Cross Hospital at Glerwitz, Galicia, and Dr. John A. C. Colston, recently from Pau, France, were among the speakers.

Cost of Mosquito War.—The campaign against mosquitoes closed recently. It cost the city of Baltimore about $25,000, and is said to have been successful. William D. Wrightson of the Public Health Service said that the inspecorts had found two kinds of malarial fever mosquitoes in Baltimore, in addition to the ordinary culex, or domestic insect. It is thought that the campaign will be made a part of the work of the health department, which may have a sanitary engineer added to its staff.

Personal.—The State Board of Health has appointed Dr. C. Hampson Jones, assistant commissioner of health of Baltimore for nearly twenty years, chief of the bureau of communicable diseases in the State Health Department. Dr. Jones will take charge of the bureau November 1.——Dr. Frank J. Powers, Baltimore, has been appointed by the mayor physician to the city jail, to succeed Dr. George L. Wilkins, who for fifteen years had held this position.——Dr. Nathaniel G. Keirle, chief of the Pasteur department of Mercy Hospital and city medical examiner, passed his eighty-second birthday, October 10.

Hopkins Extends Work.—An important branch of the department of pathology in the Johns Hopkins University, to be devoted entirely to research work, will be opened within the next six weeks in the pathologic building, after Dr. William H. Welch returns from China. Dr. Welch is chief pathologist of the university and is now in the Far East on work for the Rockefeller Foundation. The rooms to be occupied in the new work have been equipped with scientific appliances and instruments costing several thousand dollars. A fund aggregating $22,000 has been raised for supporting the work for three years. At the end of this time a larger endowment will be necessary. In the absence of Dr. Welch, Dr. Milton C. Winternitz, his first assistant, has been directing the work. Dr. Welch will probably name the director soon after his return. It is probable that the director of the laboratory will have two assistants. All branches of research work in pathology will be followed. This includes bacteriology, immunology, and problems arising from postmortem examinations.

MISSOURI

Personal.—Dr. William P. Camp, Springfield, is reported to be critically ill at his home.——Dr. D. R. McCue, Trenton, a member of the State Board of Pardons and Paroles, has resigned.——Dr. Leroi Beck, South St. Joseph, was seriously injured by the overturning of his automobile while making an emergency call, September 4.

Chiropractors Barred.—The Missouri State Board of Health has ruled that chiropractors have no legal standing and are open to prosecution for practicing as physicians without a license.

Health Lectures of State Fair.—At the State Fair, Sedalia, September 25 to October 2, a program of lectures on public health topics was aranged under the auspices of the Missouri State Medical Association and the state commissioner of food and drugs. The program included addresses by Dr. Robert M. Funkhouser, St. Louis, on eugenics; Mr. F. H. Fricke, state pure food and drug commission, on food and drugs; Dr. Robert E. Schlueter, St. Louis, on cancer; Mr. H. E. Wiedeman, state chemist, household tests; Dr. Frank G. Nifong, Columbia, on the economic value of medical science and its service to the world today; Dr. Mazyck P. Ravenel, Columbia, on "Every Man His Own Life Insurance Agent"; Dr. Francis H. Matthews, Liberty, on contagious diseases; Dr. Guy Titsworth, Sedalia, on how to keep the eyes well. Motion pictures on health protection were shown after each lecture.

St. Louis

Bartlett's Guests.—Dr. William J. Mayo, Rochester, Minn.; Dr. Victor C. Vaughan, Ann Arbor, Mich.; Dr. Richard H. Harte, Philadelphia, and Dr. Donald C. Balfour, Rochester, Minn., were guests of Dr. Willard Bartlett on October 11. The visitors were making a trip down the Mississippi River in Dr. Mayo's yacht.

Biologic Research.—Note has previously been made of the expedition undertaken under the auspices of St. Louis University for the purpose of establishing a biologic research station in British Honduras. The preliminary survey which was made by Dr. Edward N. Tobey, Dr. John P. Coony and Mr. Alphonse M. Schwitalla was unfortunately saddened by the tragic loss of the United Fruit Company's steamer *Marowijne* with Dr. Tobey on board as has been already reported. As for the results of the expedition, Mr. Schwitalla reports that a detailed program can now be submitted to the university for the prosecution of research in those regions. It is clear that a great abundance of material can be found for studying some of the outstanding problems connected with malaria and uncinariasis. A large amount of material can also be obtained for studying pinta, sprue, climatic bubo, and the so-called "tropical ulcers." In several cases it was suspected that fevers of hitherto undescribed character have been encountered. During this year's trip only the coast towns were visited. The villages of the interior are sure to yield even richer results. Altogether it may be considered as certain that a further study of this promising field will yield results that will be beneficial not only to the people of those regions but will also prove a distinct advance in tropical medicine.

NEW HAMPSHIRE

New Officers for State Surgeons.—At the annual meeting of the New Hampshire Surgical Club, held in Hanover, October 8, Dr. William H. A. Lyons, Manchester, was elected president; Dr. George C. Wilkins, Manchester, vice president, and Dr. Charles E. Congdon, Nashua, secretary-treasurer.

Dartmouth Alumni Elect.—At the annual meeting of the Dartmouth Medical Alumni Association held in Hanover, October 8, under the presidency of Dr. Elmer H. Carleton, Hanover, the following officers were elected: president, Dr. Elmer H. Carleton, Hanover (reelected); vice presidents, Drs. Alexander A. Beaton, Franklin, and Walter A. Bartlett, Manchester; and secretary-treasurer, Dr. Howard N. Kingsford, Hanover.

NEW JERSEY

Medical Talks to Pupils.—Arrangements have been made by the board of education of Montclair to have lectures to be given to the pupils of the evening schools of the city on hygiene, first aid, etc.

State Board Sustained.—The Supreme Court of New Jersey in a decision rendered Oct. 6, 1915, partially sustained the State Board of Medical Examiners in refusing to license "graduates" of the New Jersey College of Osteopathy in regard to which it was charged that diplomas had been sold at from $25 to $300 each.

Personal.—Dr. Edward Guion, for twelve years chief of the Bureau of Health of Atlantic City, has resigned to enter private practice.——Dr. John C. Felty, first assistant to the medical superintendent of the New Jersey State Hospital for the Insane, Trenton, who has been a member of the medical staff of the hospital for twenty-five years, resigned and relinquished his duties, October 4, and will make his home in Gettysburg, Pa. A dinner was given in honor of Dr. Felty, at the Country Club, October 4, at which he was presented with a clock.——Dr. Edgar B. Funkhouser has succeeded Dr. Felty.

NEW YORK

Psychopathic Ward.—The finance committee of the Buffalo Common Council has recommended that Health Commissioner Francis E. Fronczak be authorized to spend $2,000 in fitting out a ward in the East Ferry Street Hospital, Buffalo, for alcoholics and persons suspected of being of unsound mind.

Sanatorium Opened.—The J. N. Adam Memorial Hospital, Perrysburg, was formally opened October 9. This institution has been erected at a cost of $120,000 and is under the charge of the Buffalo Association for the Relief and Control of Tuberculosis. At the opening exercises the work of the schoolchildren of Buffalo, who raised $10,000 for the institution, will be commemorated by the unveiling of tablets.

New York City

Correction.—In the personal items of the issue of October 9, it was stated that Dr. and Mrs. H. Holbrook Curtis had sailed for Europe. Dr. Curtis telegraphs that it is a misstatement.

"Safety First" Shows Results.—A report compiled by the Safety First Society states that during September, 1915, there were only twenty-eight deaths from accidents involving vehicles in Manhattan as against forty-nine for the same month of 1914. Motor vehicles of all types killed eighteen persons last month, as against thirty in September, 1914.

Four Anthrax Cases.—During the past three weeks there have been four deaths from anthrax in this vicinity. The most recent, that of Mr. Stackpole, has excited much public interest because he was treated with the new serum prepared by A. Eichhorn of the Bureau of Animal Industry and lived for about a week after the disease manifested itself.

Changes in the Medical Faculty at Columbia.—Dr. Francis R. Fraser has been granted leave of absence while rendering service with the French army. Dr. Francis Carter Wood has been elected by the medical faculty to be delegate to the university council for the unexpired term of Dr. M. Allen Starr, retired. It is announced by the trustees of the university that the registration in the medical department is 345 as against 323 last year.

Many Shops Still Sell Wood Alcohol.—An investigation by the health department of 2,400 places in which it was suspected that wood alcohol was being sold has brought to light the fact that 764 shops were selling wood alcohol not properly labeled. Of these places, 466 were drug stores and saloons and the others were paint shops. The result of the discovery that so many shops were using and selling wood alcohol illegally has caused the health department to issue a warning to citizens against the use of any alcohol that is not properly labeled.

Health Department Encourages Use of Schick Test.—The bureau of laboratories of the health department announces that it is prepared to supply an outfit for applying the Schick test which will make the application of the test a simple procedure for the general practitioner. This outfit consists of a capillary tube and a small rubber bulb, such as is employed in the distribution of vaccine virus, and a bottle containing 10 c.c. of sterile physiologic saline solution to which 0.025 per cent. phenol has been added. The capillary tube contains one minimum lethal dose (for the guinea-pig) of undiluted diphtheria toxin. The outfit is accompanied by directions for its use and the health department believes that it will be found both convenient and reliable.

NORTH CAROLINA

Dairy Inspection Inaugurated.—Greensboro is inaugurating a system of dairy inspection including the publication from month to month of the standing of the respective dairies which supply milk to the city.

Personal.—Dr. Samuel Westray Battle, Asheville, sailed for England, October 4.——Dr. John Thames, Wilmington, assistant county health officer of New Hanover County, has been completely exonerated on the charge of official negligence, recently preferred against him.

The Murphy Memorial.—The P. L. Murphy Memorial Association, of which Colonel P. M. Pearsall, Newbern, is secretary, has issued in book form the addresses made on the occasion of the presentation of the portrait of the late Dr. Patrick Livingston Murphy to the state library, Raleigh, and on the dedication of the bronze memorial tablet to Dr. Murphy at the State Hospital for the Insane, Morganton.

Deaver in Charlotte.—Dr. John B. Deaver, Philadelphia, was entertained at luncheon at the Charlotte Sanitarium by Dr. Edward C. Register, September 22, and at dinner by the Mecklenburg County Medical Society at the Country Club in the evening. During the day Dr. Deaver gave clinics at the Charlotte Sanitarium and the Presbyterian and other hospitals of the city. In the evening he delivered a lecture on "Symptoms of Disease in the Upper Abdomen."

Health Officers Confer.—The four recently installed whole-time county health officers, Drs. Darius C. Absher of Henderson, Vance County; Milton T. Edgerton of Greenville, Pitt County; James C. Braswell of Nash County and Eugene R. Hardin of Clinton, Sampson County, met at Raleigh, September 18, at the office of the State Board of Health, to arrange uniformity of system and method in the control of infectious diseases in their respective counties.

Hospital Notes.—Dr. Addison G. Brenizer, Jr., has leased the old Brenizer Home in Charlotte and will establish a private hospital in the building.——Contracts have been let at Tarboro for the Edgecombe County General Hospital.——Drs. William P. and Charles R. Reaves, Greensboro, are building a three-story and basement building which will be ready in a short time. The basement will be given over to the treatment of colored patients; the first floor will be used for offices and the third floor as an infirmary for white patients.——Miss Lorene Johnson, Statesville, has leased the Billingsley Hospital and will conduct it for the benefit of patients of all physicians of the city and county.

PENNSYLVANIA

Personal.—Dr. Walter J. Cathrall, South Bethlehem, after an illness of eleven months contracted in the United States government service in the Far East, is again able to resume his practice.

Dedication of Hospital.—The dedication of the Elizabeth Steel Magee Hospital and the conferring of honorary degrees by the University of Pittsburgh will take place in Memorial Hall, that city, October 27. There will be a number of addresses relating to the hospital and its founder, Christopher Lyman Magee, and an address on "The Teacher's Inheritance" by Dr. William Walter Chipman of Montreal, after which the degrees will be conferred. The new hospital, located at Forbes and Halket streets, will be inspected in the afternoon and there will be a dinner at the Hotel Schenley in the evening.

Optometrists to Fight.—The institution of mandamus proceedings to test the legality of Governor Brumbaugh's veto of the house bill creating a separate board for licensing optometrists, was the principal topic of discussion before the annual convention of the optical society of Pennsylvania, which opened its meetings at the Hotel Adelphia, Philadelphia, October 12. Although their reason for fighting the veto is to escape the domination of the state medical board of optometrists, they base their fight on a technicality. It is their contention that the governor vetoed the bill after the ten day limit allowed for vetoes and that the bill, therefore, became law automatically.

Philadelphia

Personal.—Dr. John B. Carnett, who has been seriously ill for four months, is convalescing.——Dr. Malcolm C. Grow is now en route to Archangel to serve in a Russian military hospital.——Dr. Luther C. Peter has been made associate professor of diseases of the eye in the Philadelphia Polyclinic.——Dr. William B. Swartley has just gone on service for three months at the American Ambulance Hospital at Paris.——Dr. Charles H. Frazier was elected president of the Mask and Wig Club of the University of Pennsylvania, October 13.——Dr. Daniel J. McCarthy, professor of medical jurisprudence in the University of Pennsylvania, has returned from the American Ambulance Hospital in Paris and will make a report on the influence of the war on the nervous system and mental future of the soldiers, the result of high explosives and other problems of scientific interest to the medical profession.

WISCONSIN

New State Officers.—At the annual meeting of the State Medical Society of Wisconsin, held in Milwaukee, October 5 to 7, under the presidency of Dr. Theodore J. Readelings, Marinette, the following officers were elected: president, Dr. Louis F. Jermain, Milwaukee; vice presidents, Drs. Michael R. Filkinson, Oconomowoc; Mathew S. Hosmer, Ashland, and Robert W. Blumenthal, Milwaukee; secretary, Dr. L. Rock Sleyster, Waupun (reelected); treasurer, Dr. Sidney S. Hall, Ripon; delegate to the American Medical Association, Dr. Thomas H. Hay, Stevens Point; alternate, Dr. L. Rock Sleyster, Waupun; delegate to the National Legislative Council, Dr. Gustave Windesheim, Kenosha; delegate to the council on medical education, Dr. Arthur J. Patek, Milwaukee.

CANADA

Personal.—Lieut.-Col. Henry R. Casgrain, Windsor, Ont., in command of one of the stationary hospitals in Egypt or the Dardanelles, is seriously ill at Alexandria.——Dr. Henry J. Stephens, London, Ont., has been appointed medical officer of the Seventieth Overseas Battalion.——Drs. Jim B. Jupp and Samuel M. McLay, Woodstock, Ont., have joined the Royal Army Medical Corps.——Surg.-Gen. George A. S. Ryerson was the guest of honor at the first regular monthly dinner of The Aesculapian Club, Toronto, the evening of October 14. Dr. Ryerson was the founder of the society. He gave a very interesting address on his recent trip to northern France, recounting many striking incidents.——The American consul in Toronto, Dr. Julius D. Dreber, was recently banqueted by members of the American colony in that city at the American Club.

Ontario Medical Inquiry Under Way.—The preliminary hearing of the government commission relative to medical education and practice in Ontario was held in Toronto, October 16, but after a half hour's session adjourned until Thursday, Friday and Saturday, October 21, 22 and 23. The chiropractors will be heard at the Thursday session. There were about 200 medical men at the session. The Academy of Medicine, Toronto, was represented by the president, Dr. William H. B. Aikins, and treasurer, Dr. William A. Young. The academy will act with the Ontario Medical Council whose solicitor is Mr. H. S. Osler, K. C. The Ontario Medical Association is represented by Dr. Richard A. Reeve. The University of Toronto was represented by President Falconer and Mr. J. B. Clark, K. C. It is understood that the university will take the stand that all shall take a prescribed course of four years and practice whatsoever method of therapeutics they may choose.

Hospital News.—Official word has been received by Dean Charles K. Clarke of the medical faculty of the University of Toronto that No. 4 Base Hospital, under command of Lieut.-Col. James A. Roberts, has departed for the Mediterranean. The hospital was organized by the University of Toronto in March and April last, and left for England early in May. Since that time it has been doing work in England. It is composed of forty-four medical men, many prominent in practice in Toronto, and seventy-three nurses. Miss Beatrice Bartlett, an Anglican Sister of the Church of England, lectured recently in Montreal on the need of help for the hospitals in France. She has organized several hospitals for the French government. She spoke of thousands of men blinded by gas fumes, thousands made insane. She has made fifty-two trips across the English Channel since the beginning of the war. At one time she saw 10,000 wounded around one base hospital and 40,000 refugees. She took a munition worker on one occasion to France to show him the war conditions, and had showed him tables whereon 9,000 amputations had been performed. His report to 140,000 of his mates had made them all workers for the cause.——McGill's Tent Town Hospital at the front is said to be a model hospital. It is under command of Lieut.-Col. Herbert S. Birkett, Montreal.

GENERAL

Ohio Valley Meeting.—The annual meeting of the Ohio Valley Medical Association will be held in Evansville, November 3 and 4.

Tuberculosis Examination.—An announcement has been made by the National Association for the Study and Prevention of Tuberculosis, that a national medical examination day is to be made a part of the plans for Tuberculosis Week, December 6 to 12. December 8 is set for medical examination day and this is the first step toward the securing of an annual physical examination for every one in the United States. Children's Health Crusade Day is planned for December 10.

Health Education.—The United States Public Health Service, believing that "education is the road to sanitary progress," has establish a loan library with stereopticon slides which it sends out on request of sanitarians, educators, and others interested in the promulgation of the doctrines of hygiene and public sanitation. There are special sets of slides on diseases of children, hookworm, leprosy, malaria, milk production, mouth hygiene, pellagra, bubonic plague, rural schools, smallpox, tropical diseases, tuberculosis and typhoid fever.

Prevention of Infant Mortality.—The sixth annual meeting of the American Association for the Study and Prevention of Infant Mortality will be held in Philadelphia, November 12 to 15. The subjects to be taken up at the meeting include eugenics, effect of the economic standing of the family on infant mortality; infant welfare nursing in small cities, towns and rural districts; institutional mortality; midwifery conditions and prevention of respiratory diseases. The topic of "Economic Aspects of Infant Welfare" will be discussed at a joint session with the Philadelphia County Medical Society at the Philadelphia College of Physicians. Other sessions will take place at the Bellevue-Stratford.

Bequests and Donations.—The following bequests and donations have recently been announced:

St. Joseph's Hospital, Alton, Ill., $3,000, as the result of a bazaar recently held.

Michael Reese Hospital, Chicago, $25,000; Chicago-Winfield Tuberculosis Sanatorium, Winfield, Ill., $5,000, by the will of Edwin G. Foreman.

Methodist Hospital, Philadelphia, a contingent bequest of $3,600 or more, dependent on the death of direct beneficiaries by a codicil to the will of Charles Fox.

St. Vincent's Charity Hospital, Cleveland, $25,000, for the equipment of the operating department of a new wing to the hospital, by the will of Dr. Dudley Peter Allen, Cleveland.

Subscription Swindlers Still at Work.—Every few months we are compelled to warn our readers against fraudulent canvassers and collectors. Seven weeks ago we referred specifically to a scheme operated under the title of the "Cornell Educational Association." In this an individual *presents himself as a contestant for a prize in the form of a scholarship* awarded by Cornell Educational Association to the one sending the most business in a certain length of time. The scheme is a successful one because it appeals to the sympathies of the good nature of the average man—to the one who wants to help the student get an education.

422 Elm st

New Haven

Hence it is worked under different names. One to which we have already called attention is the National Educational Association; the latest is the Michigan Educational Association. In spite of our repeated warnings, evidence is received every day or two that some of our readers are being caught. To distinctly emphasize this warning, we are reproducing in a reduced form a blank that caught some of our readers within the last two or three weeks. The same names appear as officers on the various blanks—the name of the alleged institution and the canvasser changes.

FOREIGN

Control of Vaccination at Vienna.—The Vienna authorities are utilizing the opportunity afforded by distribution of the bread and flour tickets to householders to gather data in regard to vaccination. Question blanks regarding vaccination are given out with the tickets and they are required to be filled in for each inmate of the building.

Nipiology—the Science of Infant Welfare.—Prof. E. Cacace of the University of Naples has coined this term, "nipiology," to express that branch of pediatrics dealing with young infants. The term is from the Greek "nepios," and he has organized a Nipiologic Society in connection with the Instituto Nipioigienico, of which he is director. The scope of the institute and society is the study of early infancy from the biologic, psychologic and clinical standpoints, and for records and welfare work of all kinds for infants, and for training mothers and prospective mothers. The society in question accepts lay members on payment of small annual dues, and both local and national women's organizations are taking an active interest in the work of the new Societa di nipiologia.

Scarcity of Physicians in Galicia.—The Austrian department of the interior has ordered all physicians who have occupied official positions in Galicia to return to their posts at once, regardless of what they may be doing at the time. If serving in hospitals or prisoners' camps they must be relieved of their duties at once and all proceed to Galicia without delay to aid in combating epidemic diseases. All the medical men of Galicia, general practitioners, hospital physicians and surgeons and others who have left Galicia since the war began are urged to return to aid in the pressing work in Galicia unless they are serving now in hospitals or other branches of the sanitary service and the local political authorities certify that their services are indispensable. The word indispensable must be used in its strictest sense. Women physicians are exempted from these orders to return to Galicia. The journey back to Galicia being in the interests of the public safety, the authorities along the way are required to facilitate the journey in every way. Official records are to be kept of the medical men of Galicia and those still missing from their posts may be appealed to through the daily papers. The official decree concludes with provisions to insure registration and a more equable supply of physicians throughout the country, combating the tendency for medical men to gravitate to the cities and leave large areas with inadequate medical attendance. The Runderlass is addressed to all the "district captains" throughout lower Austria; it is published in full in the *Klinisch-therapeutische Wochenschrift* just received.

PARIS LETTER

Paris, Sept. 30, 1915.

The War

EARLY DISINFECTION OF WOUNDS OF WAR

At a recent session of the Académie de médecine, Dr. Tuffier, agrégé professor at the Faculté de médecine de Paris and surgeon of the hospitals, read a paper in which he particularly emphasized the importance of complete and early disinfection of wounds of war, since infections constitute for the wounded a considerable aggravation of their condition, producing a mortality which may run from 6.1 per cent., which is that of wounds in general in the first twelve hours, to 32.1 per cent. if the treatment begins after twelve hours. To be efficacious, disinfection should be early. It should therefore be performed by experienced surgeons at the first-aid posts (which, being too much neglected, have need of improvement) and in the ambulances of the first line.

According to Tuffier, there are three zones in the medical organizations: the first where life is saved; the second where limbs are saved, and the third where they are repaired. If the first of these zones operates well, the other two are relieved of much of their burdens. In the first-aid posts, the skin of the wounded patients should be disinfected by tincture of iodin; then visible foreign bodies should be removed from the wound, the flow of blood checked, a compress moistened with Dakin's fluid [see The Journal, editorial, Sept. 4, 1915, p. 880; Correspondence, Sept. 18, 1915, p. 1048; Queries and Minor Notes, Sept. 25, 1915, p. 1130.—Ed.] placed on the wound, the whole covered with a layer of absorbent cotton held in place by a nonconstricting bandage, and the limb immobilized in a splint. As an antiseptic, Tuffier prefers sodium hypochlorite.

NECESSITY OF REPEATED INJECTIONS OF ANTITETANIC SERUM

At a recent session of the Société de médecine de Paris, Dr. Maurice reported five cases of delayed tetanus, one of which was fatal, which occurred in spite of one injection of antitetanic serum, or even two given eight days apart. Maurice emphasizes the necessity of making systematically a second injection of 10 c.c., eight days after the first, and a third eight days after the second, as Dr. Roux has always recommended, if the wound has not yet cicatrized. No report of any case appears to have been published in which three successive injections of serum were given at eight-day intervals. The production of antitetanic serum is at present sufficient to make it possible to apply rigorously this method of repeated injections. The demands for serum for hospital services should therefore receive more liberal response, and it should not be forbidden to give injections to patients who are reported, very often without any indication of the dose employed, as having already received a preventive injection in the first-line treatment.

Dr. Péraire thinks that it is the fear of anaphylaxis which has prevented the employment of repeated injections of antitetanic serum. To avoid such complications, the employment of very small doses should be recommended, for example, 10 c.c. injected repeatedly every two or three days.

THE GAIT OF PATIENTS WHO HAVE LOST LIMBS

A patient provided with an artificial leg has a peculiar gait which should be well studied for the sake of remedying as far as possible the defects in such apparatus. Dr. Ducroquet, licencié ès sciences, who read a paper on this subject before the Académie de médecine, thinks that the cinematograph gives the best conditions for such study. He has drawn from such a study technical conclusions of great interest with regard to the rôle played by the length of the stump, the more or less perfect adaptation of the apparatus, etc. He was also enabled thus to compare the two types of artificial legs, the French and the American. The American apparatus permits free flexion of the knee. The gait with such an apparatus is better but more fatiguing; it should be used on comparatively level ground, and it requires constant attention. This apparatus should be reserved for city dwellers. In cases of amputation of the lower leg, whether the apparatus be French or American, the gait, though different in the two cases, is often so perfect that the amputation is not suspected. The patient furnished with French apparatus utilizes the movements of articulation of the foot; furnished with American apparatus, he utilizes only a portion of these movements, and bears his weight chiefly on the fore part of the foot.

COMPULSORY REVACCINATION

A law has just been promulgated which in case of war, public calamity, epidemic or threatened epidemic makes vaccination or revaccination against smallpox compulsory for all persons, no matter what their age, who cannot prove a successful vaccination within less than five years.

ANOTHER EXCHANGE OF SERIOUSLY WOUNDED FRENCH AND GERMAN PRISONERS

I mentioned in a previous letter (The Journal, Aug. 7, 1915, p. 545) the first exchange of seriously wounded French and German prisoners of war. Another exchange of the same kind is at present in process. Two convoys of seriously wounded prisoners, returning from Germany by way of Switzerland, have already been received at Lyons.

CIDER FOR THE ARMIES

The senatorial army commission has recently adopted the conclusions of an interesting report by M. André Lebert on the utilization of cider by the armies in the field. According to the statistics of the agricultural department, forty-seven out of the eighty-six departments produce cider. Cider, like wine, may be called a national drink, and it will be favorably received by our armies, no matter from what part of the country they come. Moreover, cider supplies enough energy so that it may without danger replace the wine ration. Half a liter (about a pint) of wine furnishes 300 calories (this is the soldier's ration, which has been reduced for some time); a liter (about a quart) of pure cider will furnish the same number of calories. In order to supply the same amount of energy in the liquid nourishment given to our soldiers, a ration of double volume must be supplied. It should be added that the harvest of cider fruit has been exceptional in 1915, and that from 32,000,000 to 35,000,000 hectoliters of cider will be manufactured in France, while the average production of the last ten years is only 18,000,000. On the other hand, our vineyards have this year yielded a very scanty harvest. One consideration which guided the senatorial commission is the fact that a hectoliter (about 26 gallons) of cider costs from 10 to 12 francs (from about $2 to $2.40); a hectoliter of wine at present costs 40 francs (about $8), and the price will probably rise.

TRAINING OF DOGS FOR THE MEDICAL SERVICE

The Société nationale du chien sanitaire has just made some interesting experiments on the immense grounds of the chateau of Maisons-Laffitte in the outskirts of Paris. Ten dogs, held in leash by their trainers, were loosed in turn to seek for soldiers, hidden in the shrubbery, representing wounded patients. Thanks to their marvelously developed sense of smell, very skilfully trained, the animals discovered the soldiers without difficulty, then returned to seek their masters in order to lead them to the place where the wounded had fallen.

One of the founders and first trainers of the society, M. Leroy, read an interesting report on the present employment of dogs in the armies. It was in 1895 that Captain Tolat first undertook to train dogs. In 1908, M. Lepel-Cointet founded the society, which in August, 1914, at the declaration of war, had as yet only 140 dogs. The members of the society made a great effort, and today more than 700 dogs are at the front. About 100 are being trained in the kennels, previous to being sent to the front.

THE HOSPITAL OF FRENCH CITIES AT MILAN

At the congress held at Cernobbio by the France-Italie and Italia-Francia committees, the French committee took measures to hasten the installation of the hospital of the French cities offered to the Italian Red Cross, section of Milan, with the proceeds of the subscription of the French municipalities. As I mentioned about two weeks ago, the municipal council of Paris recently voted 20,000 francs (about $4,000) for the purpose; many other cities have made similar subscriptions. The hospital will be established in the buildings of the Ricordi workshops, an immense establishment which will permit a model organization. The formal opening of the hospital will be held during November.

MENTION OF A CIVILIAN PHYSICIAN FOR GALLANT CONDUCT

Dr. Sarrazin, mayor of la Couture, department of Pas-de-Calais, has been mentioned for gallant conduct, "never having ceased, under continual bombardment, to traverse the country in order to visit the sick; during the German occupation, the firmness and dignity of his attitude contributed to safeguard the interest of the commune, giving to his fellow citizens a fine example of civic coolness and courage."

Death of Prof. Marcel Oui

Dr. Marcel Oui, professor of the obstetrical clinic at the Faculté de médecine de Lille, has just died in his forty-eighth year at Bordeaux, where he was fulfilling his military duties as head of the first surgical sector of the eighteenth region. He had been a corresponding member of the Académie de médecine since 1910.

LONDON LETTER

LONDON, Oct. 1, 1915.

The War

THE SUPPLY OF ARMY SURGEONS

The problem of supplying the new armies with a sufficient number of surgeons still remains a difficulty, although every means is being taken both by the profession and by the military authorities to deal with it. The country is divided into districts in each of which has been constituted a war emergency committee. From the central committee the local organizations are informed of the numbers which each district is estimated to produce, and the answer to this intimation is given by the physicians in the district concerned. Local meetings of the profession have been called, and some of these have been addressed by representatives of the War Office or by prominent members of the profession. Thus all the physicians of the country are impressed by the urgency of the emergency. So far the results are encouraging, but whether they are sufficient remains to be seen. The depletion of hospital staffs for military purposes is causing serious trouble and anxiety, which is well illustrated by the statement of a deputation from Manchester to the executive subcommittee of the war emergency committee. The committee recently issued a circular urging physicians of military age to place their services at the disposal of the War Office. It was pointed out by the chairman of the board of management of the Manchester Royal Infirmary (one of the greatest of the provincial hospitals of England) that in normal times they had 530 beds, 240 had now been added for military purposes, a central branch contained 60 more, and 135 extra beds had also been provided at the relief hospital, making a total of nearly 1,000 beds, over 300 of which were at the disposal of the army. The range of the work is indicated by the following figures: In 1914, 28,000 outpatients and 13,000 inpatients were treated. In a normal year over 20,000 cases of accident come to this hospital and about 7,000 operations are performed. The work is carried on by an honorary staff of 33 and a resident staff of 23 at the infirmary, 2 at the relief hospital. Of the honorary staff, 27 are engaged in the central branch, and 2 at the relief hospital. Of the honorary staff, 27 are engaged in military work, some being wholly absent on such duty, while others doing part work are able to give only partial attention to hospital patients. The resident staff is now reduced to 8 at the infirmary and 1 at each of the auxiliary branches. The work is being done by senior students, but the number of these is limited. The work of the hospital in these circumstances is largely supervised by the resident medical officer, the resident surgical officer, and the accident house surgeon, to whom also much of the clinical education of the students falls. These posts are held by highly tried and competent men; their tenure is often three years, and the occupants are next in succession to vacancies on the permanent honorary staff. If the circular of the war emergency committee deprived the Manchester Royal Infirmary of their services at this juncture the difficulties of carrying on the work would be insuperable. The deputation asked that these men might receive an intimation that their services in their present positions are so valuable that they would not be called on; at any rate that they should receive a notice of one or two months so that the hospital could make some arrangement. The committee replied to the deputation by saying that the difficulty with regard to residents would have to be met in some places by the honorary staff becoming resident, in some by the employment of outside physicians as half timers, and in some by the principle of employing in succession recently qualified physicians who had already taken commissions in the army, though this could obtain only at hospitals to which a teaching school was attached.

WOMEN PHYSICIANS AND THE WAR

The shortage of physicians has given a great impetus to the employment of women physicians, who are now sought for posts which were not previously open to them. At the beginning of the war they organized and ran entirely Red Cross hospitals in Belgium, France and Serbia. One of their units on the way to Serbia was stopped at Malta to attend to the British wounded. When one of their earliest hospitals under the French Red Cross, stationed first in Paris and later at Wimereux, was no longer needed it was taken over by our own War Office and is now doing excellent work. But it is in civil life that the greatest demand for women physicians has arisen—to take the place of men in all sorts of capacities, public and private. The medical journals are full of advertisements offering posts to women, who before the war were practically never mentioned, and though not formally were tacitly excluded from the posts advertised. Now the position has become so acute that a large hospital sent an application to the secretary of the Women's Medical School, "Send us *any* women at *any* salary." However, it must be borne in mind that the large proportion of the posts now offered are for newly qualified and junior physicians. Practically none are offered to older and more experienced women. Many of the women at home on furlough from India and other parts are filling the posts of men who have undertaken military service. Even women who have never practiced before, or who have retired, are giving their services. An impetus has been given to the enlargement of the largest medical school for women in the country, the London School of Medicine for Women, to train more students, and a fund of $150,000 is being raised for the purpose of enlarging the school.

MAIMED SAILORS AND SOLDIERS

One of the ghastly results of the war, the sailor or soldier who has lost a limb, is everywhere in evidence. Needless to say, everything possible has been done to show the gratitude of the country to these valiant men. A special hospital has been erected at Roehampton where they are provided at the expense of the state with artificial limbs and taught how to use them. Their numbers are so great that 800 are at the present moment awaiting admission, although the hospital has been considerably enlarged. With a view to their future employment and also to provide useful occupation for the men while in hospital, workshops fitted with model motor chassis, electrical appliances, lathes, etc., are being organized with competent instructors. A man who has lost his right hand is taught to write with the left, and classes for other industries will be arranged. An employment bureau working in conjunction with existing societies and employers of labor has also been established, and already a number of men have been placed in good situations.

BERLIN LETTER

Berlin, Sept. 21, 1915.

Death of Professor Ewald

Prof. C. A. Ewald died in Berlin yesterday. Had he lived until October 30, he would have been 70 years of age. Two months ago he developed a fever, which, although of an indefinite nature, later was assumed to be a symptom of leukemia. This diagnosis was not confirmed by a necropsy, and it is probable that another diagnosis might have been made on the basis of the postmortem report, because leukemia occurs but rarely at so advanced an age as 70. Next to Kussmaul and Leube, Ewald was most responsible for the founding of the clinic for stomach diseases. Although an associate of the men mentioned, he always worked independently, contributing many original observations of the diseases of the gastro-intestinal tract. Ewald was born in Berlin, and his medical studies were made here as well as in Heidelberg and in Bonn. His doctorate thesis, published in 1870, was entitled "The Histology of the Salivary Glands," showing that his interest in the gastro-intestinal tract was already developed at the time of his graduation. In 1871 he was appointed an assistant by Frerichs in the first medical clinic. He began to lecture in 1874; in 1882 he was made extraordinary professor, and a few years ago was advanced to a regular professorship. In 1876 he was appointed director of the city gynecologic institute, and in 1886 he was appointed Senator's successor in the direction of the medical division of the Augusta Hospital.

Well worthy of mention is his long term of service as editor of the *Berliner klinische Wochenschrift*, in which position he succeeded Professor Waldenburg in 1881. He was sole editor until 1907, when he associated Professor Posner (son of the founder of the *Wochenschrift*) with himself. Until a few years ago he remained in active service as editor. The most notable of his many contributions to medical literature are his lectures on digestion and his book on diseases of the stomach. Among his other literary efforts are a handbook of therapeutics; the articles on diseases of the thyroid, myxedema and cretinism in Nothnagel's "Special Pathology and Therapeutics," and a book on diseases of the liver. He contributed to many compilations and sets of books. Of these should be mentioned Eulenburg's Real-Encyclopedia. An enormous number of clinical articles were contributed by him to the literature, covering all phases of internal medicine, and all of his illustrations were drawn by himself, both black and colored. His mentality was unclouded until the end. He occupied himself continuously with literary work, and even in his last days attempted to complete his share of the manuscript for a collaborated work.

Ewald's influence on the development of his specialty is well shown in the work done by his pupils. Nearly all the prominent younger men who are devoting their time to the study of the diseases of the gastro-intestinal tract have been pupils of Ewald, especially Boas, Rosenheim, Strauss and L. Kuttner. In spite of his activities in the field of medicine, Ewald found time to devote himself to other things, such as the building and maintenance of hospitals for children on the seacoast. For more than thirty years he was secretary of the society for "Seehospize" (seaside sanatoriums). For twenty-five years he was librarian of the Berlin Medical Society, rendering splendid and worthy service. He felt deeply the action taken by this society not long ago when it failed to reelect him to his position because of a misunderstanding of the attitude taken by him in the matter of the Russian consultations scandal, as I mentioned at the time. He never forgot this action while he lived. Science and literature in general also commanded his lively interest. As a relative of Du Bois-Reymond he soon became a valuable member of the more cultured Berlin society and, together with his popular wife, he succeeded in making his home the gathering place for the devotees of art and science. He also had many international relationships, especially with England. Personally, he was a little hard, and his rather extraordinary lack of feeling for his associates and colleagues often aroused ill feeling against him, and probably had much to do with the action taken by the Berlin Medical Society, mentioned above. His death certainly will leave a great void in the medical circles of Berlin as well as in those of the world in general.

American Red Cross for Russia

By an agreement between Germany and Austria-Hungary on the one hand, and Russia on the other, brought about through the agency of the American ambassador at Berlin, physicians and nurses of the American Red Cross will be sent to the prison camps and hospitals in Russia and Siberia to render professional service. The members of this group have been in Germany and Austria-Hungary for the past year giving service in Gleiwitz, Kosel, Vienna and Budapest. The physicians and nurses of the American Red Cross in Serbia have offered their services in the work. About twenty-five American physicians and fifty nurses will be engaged in this work, the expenses being paid by Germany and Austria-Hungary. The American Red Cross will contribute the medicines and bandages.

Injuries in Aviation Accidents

The surgeon of an aviation corps, Dr. Schöppler, has noticed that the injuries sustained by falling from a great height present a typical picture if the motor of the aeroplane does not fall on the aviator's body. As a rule there are found fractures of the base of the skull, tearing of the lung tissues, and typical fractures of the upper and lower extremities, no matter how far the body has fallen. Fracture of the sternal end of the clavicle, of the forearm, of the lower leg above the epiphyseal line, and in the middle of the femur in the upper third, and complete comminution of the tarsus are present in nearly every case. Injuries of the spinal column are seen but rarely, whereas the viscera frequently burst or are torn to pieces; especially is this true of the heart, liver, lungs and the large blood vessels.

Personal

September 21, Professor Eberth, formerly professor of pathologic anatomy in Halle, celebrated his eightieth birthday. His claim to fame is the discovery of the typhoid bacillus. Since 1911 he has been living in a suburb of Berlin.

Marriages

Horace Hutchins Le Seur, M.D., Niagara Falls, N. Y., to Miss Helen Minerva Crossett of Cortland, Ill., at Batavia, N. Y., September 29.

Clarence Flack Graham, M.D., Albany, N. Y., to Miss Mary Jarvis Fish of Brookline, Mass., at Rye Beach, N. H., October 6.

Charles Percy Noble, M.D., Boise, Idaho, to Miss Elizabeth M. Scanlan of St. David's, Pa., at Towson, Md., October 7.

Henry C. Walbeck, Jr., M.D., Stroud, Okla., to Miss Amelia Bedwell of Louisville, Ky., in Sapulpa, Okla., recently.

Eugene Bascom Wright, M.D., Richmond, W. Va., to Miss Elsie E. Daub of Baltimore, in Philadelphia, September 11.

Clara Amelia Hale, M.D., to George Groot Gregory, both of Syracuse, N. Y., at Fayetteville, N. Y., September 15.

Harry Edwin Kleinschmidt, M.D., St. Louis, to Miss Anna Josephine McNabney of Sparta, Ill., October 7.

Edward Joseph O'Brien, Jr., M.D., Brighton, Boston, to Miss Isabel Roche of Medford, Mass., September 29.

Alexander Hamilton Rice, M.D., Boston, to Mrs. Eleanor Elkins Widener of Philadelphia, in Boston, October 6.

Thomas N. Fleming, M.D., Cold Spring, Minn., to Miss Rose Bingenheim of Creighton, Neb., September 17.

Matthew Lincoln Turner, M.D. Griswold, Iowa, to Miss Loretta E. Brown of Des Moines, Iowa, October 2.

Martin Heydemann, M.D., Boston, to Miss Lillian Adelaide Pelonsky of Roxbury, Boston, October 6.

Edward Lingan Bowlus, M.D., Middletown, Md., to Miss Georgia Martin Potter, in Baltimore, October 6.

Willis Guy Mudd, M.D., to Miss Ruth Faustina Acorn, both of Denver, in San Francisco, August 4.

James Bray Bradley, M.D., Eaton Rapids, Mich., to Miss Pearl Parsall of Howell, Mich., October 12.

James P. H. Ruddy, M.D., Scranton, Pa., to Miss Mary Kilpatrick of Carbondale, Pa., October 12.

Virgil E. Robbins, M.D., to Miss Ruby Lee Thomas, both of Quitman, Texas, in Dallas, June 20.

Hugh M. Mulliken, M.D., Terre Haute, Ind., to Miss Laura Fisher of Philadelphia, recently.

Vernon C. David, M.D., Chicago, to Miss Marguerite Record of Minneapolis, October 16.

Deaths

Alice Bellvadore Sams-Turner, M.D. College of Physicians and Surgeons, Keokuk, Iowa, 1884; aged 56; an honorary member of the Jasper County (Iowa) Medical Society and of the State Society of Iowa Medical Women; health officer of Colfax, Iowa, during 1886 and 1887; one of the founders, a trustee and for twelve years president of the Colfax Free Public Library; died at her home in that city, July 10, from carcinoma of the breast.

William Merrill McCoy, M.D. College of Physicians and Surgeons, Chicago, 1901; aged 39; a Fellow of the American Medical Association and a well-known surgeon of north central Washington; formerly of Clinton, Iowa, but for the last ten years a practitioner of Wenatchee, Wash.; died in the Deaconess Hospital in that city, October 1, from intestinal obstruction following an operation for appendicitis, eleven days before.

Robert Benjamin Barron, M.D. Bellevue Hospital Medical School, 1883; aged 55; a member of the Medical Association of Georgia; formerly chairman of the Board of Health of Macon; and a member of the board of medical directors of and visiting physician to the Macon Hospital; for twenty years a resident of Macon; died at his home in Gray, Jones County, Ga., October 2, from heart disease.

James Water McLean, M.D. Rush Medical College, 1869; aged 72; a Fellow of the American Medical Association and Chicago, Milwaukee and St. Paul Railway Surgeons' Association; local surgeon of that road at Fayette, Iowa; died at his home in that city, October 4, from bronchopneumonia.

Walker W. McConnell, M.D. Western Reserve University, Cleveland, 1888; Jefferson Medical College, Philadelphia, 1898; a member of the Medical Society of the State of Pennsylvania; director of the First National Bank of Harrisville; died at his home in that city, July 2, from nephritis.

Stephen Garland Sharp, Jr., M.D. Medical College of Ohio, Cincinnati, 1905; aged 32; surgeon for the Braden Copper Company and in charge of the company's hospital at Rancagua, Chile, South America; died in Valparaiso, Chile, about September 28, from spinal meningitis.

Cameron Chamberlin, M.D. Medical College of Indiana, Indianapolis, 1902; aged 36; a Fellow of the American Medical Association; a well-known practitioner of Indianapolis; died in the Presbyterian Hospital, Chicago, October 4, from spinal meningitis.

James C. Word, M.D. Jefferson Medical College, 1860; aged 81; surgeon in the Confederate service throughout the Civil War and since that time a practitioner of Monroe County, Miss.; died at the home of his daughter in Aberdeen, Miss., October 3.

Theodore St. John, M.D. New York Homeopathic Medical College, New York City, 1881; aged 83; a pioneer of Nevada, but since 1878 a resident of Connecticut; died at his home in Thomaston, Conn., September 11, from cerebral hemorrhage.

Charles Hamilton Browning, M.D. Western Reserve University, Cleveland, 1897; aged 44; a Fellow of the American Medical Association, and a prominent practitioner of Oberlin, Ohio; died at his home, September 28, from cerebral hemorrhage.

Edward Osband Sutton, M.D. University of Michigan, Ann Arbor, 1903; aged 40; of Tacoma, Wash.; a Fellow of the American Medical Association; died in the Seattle General Hospital; October 1, a week after a surgical operation.

John Prentiss Walker, M.D. Washington University, St. Louis, 1875; aged 68; of Lamonte, Mo.; a Confederate veteran; died in the University Hospital, Kansas City, October 5, a week after a surgical operation for carcinoma.

Leonidas Mason, M.D. Medical College of Ohio, Cincinnati, 1872; aged 78; a veteran of the Civil War; formerly a member of the Indiana State Medical Association; died at his home in Bluffton, Ind., October 5, from pneumonia.

Frank Lewis Peiro, M.D. University of Vermont, Burlington, 1866; aged 76; for more than forty years a practitioner of Chicago; a veteran of the Civil War; died at the home of his daughter in Evanston, Ill., October 12.

Jacob A. Grove, M.D. Eclectic Medical Institute, Cincinnati, 1869; aged 82; a veteran of the Civil War; died at his home in Kenton, Ohio, October 4.

Samuel Stein, M.D. University of the South, Sewanee, Tenn., 1908; aged 32; a member of the Mississippi State Medical Association; of Greenville, Miss.; died in the King's Daughters' Hospital in that place, October 3.

Date Kimball Thyng, M.D. University of Minnesota, Minneapolis, 1896; aged 41; of Tacoma, Wash.; a member of the Washington State Medical Association; died in Rochester, Minn., October 2, from leukemia.

Edmund R. Bolding, M.D. College of Physicians and Surgeons, Kansas City, Kan., 1898; aged 44; of Eldurg, Kan.; was found dead in his room in the Savoy Hotel, Kansas City, Mo., October 9, from disease of the kidney.

Hiram Garrett Miller, M.D. Eclectic Medical Institute, Cincinnati, 1869; aged 90; for many years a practitioner of La Crosse, Wis., and a Forty-Niner; died at his home in Charlottesville, W. Va., October 6.

Robert J. Roach (license, Wisconsin, 1899), a practitioner for twenty-two years; died at his home in Cobb, Wis., September 28, from the effects of carbolic acid, self-administered, it is believed, with suicidal intent.

James D. Brooks, M.D. Jenner Medical College, Chicago, 1899; aged 43; a member of the State Medical Association of Texas; died at his home in San Angelo, Texas, July 2, from gangrene of the lungs.

Stephen Marcus Cook, M.D. College of Physicians and Surgeons, Keokuk, Ia., 1878; aged 82; for nearly fifty years a practitioner of Belle Plaine, Iowa; died at his home in that city, September 30.

George W. Combs, M.D. Cincinnati College of Medicine and Surgery, 1879; aged 77; a member of the Illinois State Medical Society; died at his home in Ridgway, Ill., July 2, from endocarditis.

Absalom S. Walsh, M.D. Missouri Medical College, St. Louis, 1876; formerly of St. Louis; for many years a surgical instrument dealer of London, England; died recently in that city.

Henry W. Rihl, M.D. Jefferson Medical College, 1849; aged 92; for nearly sixty years a practitioner of Germantown, Philadelphia; died at his home in that place, October 11.

Harry Oliver Lightner, M.D. Baltimore Medical College, 1896; aged 43; also a druggist; died at his home in Marysville, Pa., October 5, as the result of a nervous breakdown.

Edwin S. Kellogg, M.D. Hahnemann Medical College, Philadelphia, 1878; aged 64; died at his sanatorium in Helena, Mont., October 9, from valvular heart disease.

Floyd M. Young, M.D. Georgia College of Eclectic Medicine and Surgery, Atlanta, 1887; aged 50; died suddenly in his office in Atlanta, October 6, from acute gastritis.

Abraham H. Parker, M.D. Pulte Medical College, Cincinnati, 1889; aged 75; of Macon, Ga.; died in the Macon City Hospital, September 22, from chronic nephritis.

Charles Wallace Stiles, M.D. Boston University School of Medicine, 1878; aged 65; died at his home in Somerville, Mass., September 9, from nervous breakdown.

Thomas M. Bulick, M.D. Hahnemann Medical College, Philadelphia, 1882; aged 75; died at his home in Harrisburg, Pa., August 9, from acute nephritis.

John H. Cameron, M.D. Medical College of Virginia, Richmond, 1860; aged 79; died at his home in Goshen, Va., July 16, from heart disease.

James D. Bragg, M.D. Albany (N. Y.) Medical College, 1867; aged 69; died at his home in Bridgeport, Conn., July 23, from acute gastritis.

George W. Prugh, M.D. Medical College of Ohio, Cincinnati, 1875; aged 65; died at his home in Cincinnati, October 12.

E. B. Willan, M.D. Medical College of Indiana, Indianapolis, 1881; aged 82; died at his home in Trafalgar, Ind., October 5.

James W. Mitchell, M.D. Southern Medical College, Atlanta, Ga., 1880; aged 54; died at his home in Atlanta, October 1.

Madison Bayard Morris, M.D. Hahnemann Medical College, Philadelphia, 1871; aged 88; died in Edina, Mo., October 2.

Edward P. Harrison (license, Indiana, 1897), aged 70; died at his home in Rockport, Ind., July 31, from enterocolitis.

The Propaganda for Reform

IN THIS DEPARTMENT APPEAR REPORTS OF THE COUNCIL ON PHARMACY AND CHEMISTRY AND OF THE ASSOCIATION LABORATORY, TOGETHER WITH OTHER MATTER TENDING TO AID INTELLIGENT PRESCRIBING AND TO OPPOSE MEDICAL FRAUD ON THE PUBLIC AND ON THE PROFESSION

LACTOPEPTINE AND ELIXIR LACTOPEPTINE

Report of the Council on Pharmacy and Chemistry

Mixtures of pepsin and pancreatin are therapeutically irrational; the two substances are not indicated in the same conditions, nor can they act together. Under physiologic conditions, such mixtures are chemically impossible: in a liquid medium the ingredients destroy each other.

Lactopeptine is manufactured by the New York Pharmacal Association, Yonkers, N. Y. It is sold under the claim that it contains pepsin, diastase, pancreatin, lactic acid and hydrochloric acid. This product was among the first proprietary preparations examined by the Council on Pharmacy and Chemistry. The report of the investigation was published in THE JOURNAL, March 16, 1907, p. 959. The preparation was found to be practically inert—"essentially a weak saccharated pepsin," devoid of tryptic activity.

Six years later it was still widely advertised with the same irrational claims. A referee (A) therefore examined Lactopeptine (powdered) for the Council in 1913, and confirmed the previous findings. The referee's report was published in THE JOURNAL, Aug. 2, 1913, p. 358.

Nearly four months after this publication, the manufacturers protested against the report, maintaining, contrary to the findings of the Council, that Lactopeptine possesses pancreatic activity and contains "loosely combined" hydrochloric acid. Referee A therefore repeated his examination, and a second referee (B), independently, examined specimens of Lactopeptine (powder) purchased on the open market for the purpose shortly before.

A few specimens examined by these two referees showed a slight tryptic activity; most of them showed none. The amount of hydrochloric acid present was insignificant.

The reports of the two referees were referred to the manufacturers, who again protested vehemently against these findings, this time on the ground that the specimens were old. The manufacturers also cited the work of three chemists to disprove the findings of the referees, and demanded that the Council reexamine Lactopeptine, making use of fresh specimens. The Council refused for the following reasons:

1. So long as the packages of Lactopeptine are not dated, the activity of specimens known to be fresh is of no practical importance. The activity of the actual market supply is the only question of interest to the profession. The only fair test is that made on specimens representative of the product sold to the ultimate consumer.

2. The evidence presented by the manufacturers did not warrant a reexamination, since the work of two of the chemists cited substantially corroborates the results obtained by the Council's referees from the fresher specimens. The figures for tryptic activity obtained by the third chemist cited by the manufacturers could not be accepted by the Council, since it was at variance with all other known results of investigations of Lactopeptine.

3. As stated at the outset, whatever the tryptic activity of the mixture, it is therapeutically useless. A demonstration of tryptic activity in a mixture containing both pepsin and pancreatin is of merely theoretical interest.

Such activity, of course, cannot be expected, even on theoretical grounds, in liquid mixtures like Elixir Lactopeptine.

The Council therefore again declared Lactopeptine (powder and tablets) and Elixir Lactopeptine ineligible for New and Nonofficial Remedies and authorized publication of the following statement.

W. A. PUCKNER, Secretary.

THE COUNCIL'S REPORT*

Lactopeptine powder (New York Pharmacal Association, Yonkers, N. Y.) was examined by the Council in 1907. At that time it was claimed to contain

> ". . . the five active agents of digestion—pepsin, diastase (veg. ptyalin), pancreatin, lactic acid and hydrochloric acid—combined in the proper proportion to insure the best results."

The examination showed that the preparation was essentially "a weak saccharated pepsin," containing but small amounts of pepsin, no hydrochloric acid, or mere traces only, and no diastase or pancreatin (THE JOURNAL, March 16, 1907).

In 1913, the product was reexamined, because the claims, as to both composition and therapeutic value, were still being made. Samples were tested both of the American product, and of a British product from John Morgan Richards and Sons, London. The original findings were confirmed and the results were published in THE JOURNAL, Aug. 2, 1913, p. 358. Nearly four months later (November 24) the New York Pharmacal Association wrote to the Council, objecting to the findings and maintaining that Lactopeptine possesses pancreatic activity and contains ("in loose chemical combination") hydrochloric acid. In accordance with the custom of the Council, the work was sent back for review to the referee (A), whose conclusions were then tested by a second referee (B), a physiologic chemist, not a member of the Council, selected because of his special knowledge of the subject.

In December, 1913, Referee A made a large number of new tests to determine proteolytic and amylolytic power. His results show that the ferment activity of the preparation is so low as to merit no recognition in practical use. The tests also show that the amount of lactic acid or "loosely combined HCl" (or both) present is too small to have any appreciable physiologic activity and therefore to be of any therapeutic value.

Nine samples of Lactopeptine purchased in the open market in December, 1913, and January, 1914, were examined be Referee B early in 1914. His studies show absence of amylase in all samples; presence of pepsin, giving weak reactions even when compared with those of old pepsin preparations; complete absence of trypsin in seven out of nine samples, tryptic reaction being obtained in two samples, in one of which the reaction, "slight at best and of no practical import," was obtained only after treatment for twelve hours or more.

The presence of tryptic activity in two out of the nine samples may be due to the fresher condition of these specimens, as indicated by the serial numbers. The evidence shows that it is a commercial impossibility to market mixtures of pepsin, pancreatin and lactic acid so that they can display any material tryptic activity.

It should be reaffirmed that mixtures combining peptic and pancreatic activities are not feasible, because pepsin cannot act except in the presence of acid, and pancreatin is destroyed by acid and by peptic activity. Furthermore, in conditions in which pancreatin is called for, pepsin is not, and vice versa; therefore the administration of mixtures of pepsin and pancreatin would be unjustified, even if both constituents could be expected to exert activity.

The foregoing observations apply to Lactopeptine in powder and tablet form.

While mixtures of pepsin and pancreatin are unscientific and unjustified, theoretically the two substances *may* coexist in a solid preparation, and the activity of such a preparation is consequently a proper subject of investigation. Theoretically as well as practically, however, pepsin and pancreatin cannot exist together in solution. The claims made for Elixir Lactopeptine and all other liquid preparations sold as mixtures of pepsin and pancreatin are therefore impossible. The Council has previously taken action (The Journal, Feb. 2, 1907, p. 434) refusing to approve for inclusion with New and Nonofficial Remedies such preparations, calling the attention of the medical profession and of manufacturers to their worthlessness, and requesting the American Pharmaceutical Association to instruct its committee on the National Formulary to omit from the next edition of that work a liquid preparation of pepsin and pancreatin recognized under the title of "elixir digestivum compositum."

---

* Owing to lack of space, the referee's reports are here omitted. They will be given in full in the Annual Reports of the Council.

It is recommended that the Council reaffirm this previous action, and that Lactopeptine and Elixir Lactopeptine be declared ineligible for New and Nonofficial Remedies because of conflict with Rule 10 ("No article will be admitted which, because of its unscientific composition, is useless or inimical to the best interests of the public or of the medical profession").

Manufacturers' Protest and Council's Answer

The foregoing was submitted, together with the findings of the two referees, to the manufacturers. They protested again, alleging that:

AGE OF SPECIMENS

First.—The specimens of Lactopeptine examined by the second referee were old. The dates of manufacture corresponding to the several batch numbers are supplied by the manufacturers as follows:

2275 (Powder)	September, 1908
2301 (Powder)	June, 1909
2312 (Powder)	December, 1909
2348 (Powder)	October, 1911
2352 (Powder)	December, 1911
2364 (Powder)	July, 1912
2374 (Powder)	March, 1913
2383 (Powder)	October, 1913
1638 (Tablets)	October, 1911

The manufacturers assert that they do not understand how specimens of these ages could have been purchased on the open market in 1913 and 1914, inasmuch as their agents are and long have been instructed to take up from the druggist all lots of Lactopeptine which, as indicated by the batch numbers, have attained "any appreciable age." The age of the specimens, the manufacturers declare, deprives the table in the second referee's report of "all significance or interest."

As previously stated, however, the specimens of Lactopeptine examined were purchased on the open market in various localities in unbroken packages, in December, 1913, and January, 1914. They thus represent stock used in filling physicians' prescriptions or sold to the public. Neither the referees nor any one connected with the Council had any means of knowing the age of the specimens until the dates of manufacture were furnished by the New York Pharmacal Association. The first tests of the second referee were made in February, 1914, on Specimens 2374 and 2383, which were then, it would appear, about one year old and four months old, respectively. The Council has repeatedly urged that pharmaceutical substances which are subject to deterioration should be dated by the manufacturer, and a similar suggestion has been made by the Bureau of Chemistry of the U. S. Department of Agriculture concerning mixtures containing enzymes. Nothwithstanding the instructions which the New York Pharmacal Association claims to have given its agents, the market supply of Lactopeptine in December, 1913, and January, 1914, was not composed of new stock, and until the manufacturers adopt the practice of dating packages, there can be no assurance that it will be fresh. In this connection it is of interest to note that the Bureau of Chemistry of the U. S. Department of Agriculaure has issued a warning that it will judge such products by the degree of their activity when they reach the consumer, i. e., as they are found on the market.

REPORTS OF OTHER CHEMISTS

Second.—The New York Pharmacal Association cites the work of several chemists, who have examined Lactopeptine and report the presence of tryptic activity. Dr. S. R. Benedict in December, 1913, reported to the Council "distinct" tryptic activity (digestion in twelve hours by Lactopeptine of 4.2 times its weight of fibrin containing 50 per cent. moisture) in specimens examined by him. These specimens were numbered 2382, and were therefore probably manufactured in October, 1913; compare the dates furnished by the manufacturer for the specimens used by the second referee. No tests against other preparations possessing tryptic activity are reported, and Dr. Benedict expressly disclaims any opinion as to the therapeutic value of the preparation.[1] Dr. P. B. Hawk, whose report was submitted by the manufacturers, found in Lactopeptine by Fermi's method one-fifth the tryptic activity of that of Merck's pancreatin, and by Grützner's method an activity of 18 per cent. of the pancreatin. A test for the production of tryptophan was reported positive. The New York Pharmacal Association also submitted a report from Dr. A. W. Balch, who found pepsin, rennin, trypsin, steapsin, amylopsin and lactic acid present in Lactopeptine; also an amount of combined hydrochloric acid in 1 gm. the equivalent of 1.05 c.c. tenth normal solution or 0.00383 gm. hydrochloric acid. (He reports digestion in twenty-four hours by Lactopeptine of 25 times its own weight of fibrin. "An active extract of pancreas reacted exactly like the Lactopeptine solution.") The serial numbers of the specimens tested by Hawk and Balch are not given, but no doubt they were fresh.

CONCLUSIONS

The New York Pharmacal Association demanded that the referee reexamine Lactopeptine, making use of fresh specimens. The Council held that this was unnecessary, for the following reasons:

1. The previous finding of the Council, that specimens of Lactopeptine found on the open market are essentially weak saccharated pepsins, is not to be refuted by examination of fresh specimens. Even if it be assumed that all old specimens of Lactopeptine have been withdrawn from the market since the last purchase of specimens for the use of the Council's referee, there can be no assurance that the stock will be constantly kept fresh. Unless the manufacturers date their product, physicians cannot know that their pre-

---

[1] Dr. Benedict's personal communication to a member of the Council is as follows:

"In the report of the Council upon Lactopeptine which you sent to me, I find the following statement: 'Careful examination failed to show the presence of either diastase or pancreatin.' In this connection I will cite to you the following experiment, carried out by myself: A package containing a 1-ounce bottle of Lactopeptine (powder) with seal unbroken was purchased in the open market and opened in this laboratory. The label bore the special Number 6 2382. Two hundred milligrams of this product was dissolved in 50 c.c. of a 0.25 per cent. solution of sodium carbonate in water. This solution was divided into two portions of 25 c.c. each. One of these portions was boiled at once, and after cooling was added to 1 gm. of moist fibrin contained in a flask. The other portion (unboiled) was also added to 1 gm. of moist fibrin contained in a flask. Both flasks (after addition of 5 c.c. of toluene to each) were stoppered and placed in an incubator at 37 degrees, and left there for twelve hours. Examination of the two flasks at the end of this period showed that the one to which the unboiled solution of Lactopeptine [powder] had been added contained much less solid protein than did the other. Although this fact was obvious to the naked eye, the exact extent of digestion in the two flasks was determined by heating both to boiling, acidifying with acetic acid, diluting to definite volume, filtering and determining the nitrogen in the filtrate by Kjeldahl's method. Subtracting the trace of nitrogen contained in the filtrate of the control flask, the results showed that 42 per cent. of the original fibrin present had been dissolved by the unboiled Lactopeptine solution. This can be ascribed only to tryptic activity under the conditions of this experiment. Furthermore, this is not simply a 'trace' of activity, but is at least sufficiently marked to warrant a statement that this sample showed a distinct tryptic activity. Inasmuch as I have obtained exactly similar results with two other samples of Lactopeptine (powder) (these being the only ones I have examined), I am inclined to question the correctness of the Council's statement regarding the absence of trypsin from this preparation. [As noted above, a fresh preparation was used.—Ed.]

"May I again add that I am making no statement regarding therapeutic value of preparation, and that I have no opinion upon that matter one way or the other. My work was undertaken solely out of interest to see whether trypsin could exist in the powder (which gives a markedly acid solution when dissolved in water). The Elixir Lactopeptine could theoretically show no tryptic activity, nor have I found any trace of such activity in one sample of the Elixir examined.

"In making use of any of the contents of my letters kindly include the statement that my work upon Lactopeptine was done without remuneration of any kind, and was done only for the scientific interest attached to the question."

scriptions are filled with fresh material. Nor is it reasonable to ask that the Council examine the market supply of any given proprietary at a time selected by the manufacturers.

2. Without entering into all questions of detail in the analyses, the Council is willing to accept the reports of Drs. Benedict and Hawk as representative of fresh Lactopeptine powder. It is therefore unnecessary for the Council to make further experiments along this line. The results of these two chemists in no wise contradict the conclusions of the Council's referees, being comparable with those obtained by the referee on the fresher specimens used by them. The experiments of Drs. Hawk and Benedict show a degree of tryptic activity which, though chemically not negligible, is quite without significance practically, even if it could be assumed that the trypsin in the fresh Lactopeptine escaped destruction in the stomach. The figures for tryptic activity given by Dr. Benedict do not differ materially from those of the first referee. Those of Professor Hawk show a tryptic activity of from 18 to 20 per cent. of that of commercial pancreatin—and commercial pancreatins ordinarily are of low tryptic activity, if not inert (see Long and Muhleman: *Arch. Int. Med.*, February, 1914, p. 314.) The reports of these chemists present no reason for changing the conclusion that "it is a commercial impossibility to market mixtures of pepsin, pancreatin and lactic acid so that they can display any material tryptic activity."

The results which Dr. Balch obtained in a test for tryptic activity show a marked discrepancy with those obtained by Drs. Hawk and Benedict, not to mention the Council's referees, and also with the fact that only about 11 per cent. of "pancreatin" is claimed in the published formula of Lactopeptine. The Council is unable to accept Dr. Balch's results for trypsin or rennin as reliable. His other results are without significance and call for no special comment.

3. Even if tryptic activity were conceded to Lactopeptine, the preparation, like all preparations containing pepsin and pancreatin, would still be, as previously stated, therapeutically irrational.

The Council approved the report.

Correspondence

The So-Called "New" Anthrax Serum

To the Editor:—A recent case of anthrax in man in a New York hospital was given unusual publicity by the daily press. This was primarily due to the great respect which the patient enjoyed in his community, and also to the extraordinary courage he manifested during the course of his horrible affliction.

My stenographer happened to be in New York at the time, and reading of the case, he lost no time in communicating with the attending physicians, calling to their attention an anthrax serum which has been prepared by me and which has been extensively tested, both for its prophylactic and its curative value.

The stenographer had this information from taking dictation from me while I was preparing a paper on the subject for the American Veterinary Medical Association's meeting at Oakland, and also from notes which he transcribed for me in connection with the work during the progress of the experiments.

On telegraphic request the serum was forwarded to New York, and was repeatedly administered to the patient with apparently good results. From the reports of the attending physicians the infection had subsided, but as a result of extreme heart weakness he succumbed quite suddenly, his recovery from anthrax being announced in the bulletins sent out by the physicians.

In the meanwhile the daily press heralded the serum as a wonderful discovery, and made many misstatements as to its preparation, application, origin, etc. It is needless for me to explain the difficulty of having scientific matters correctly quoted in the daily press. It was a useless task to have correct data published as to the serum and its preparation. I was placed as a central light in many newspaper dispatches, which was rather an embarrassing position, realizing the undeserved credit given to me.

I have undertaken the experimental work in immunization against anthrax with a view of establishing a more satisfactory method of immunization than those which are now employed in this country. The simultaneous method—consisting of an injection of a potent anthrax serum and a carefully standardized spore vaccine—proved very promising and to my mind superior to the Pasteur method. The results of these experiments were embodied in my paper read before the American Veterinary Medical Association, in which have also been included the results of field experiments.

During the progress of the work we had occasion to treat a considerable number of affected animals with our serum, and obtained remarkable recoveries in a very high percentage of cases, including some of the most severe types. The stenographer, knowing of these results, praised the curative qualities of the serum somewhat beyond its known value, which naturally was interpreted by the newspapers as something wonderful.

It is needless for me to state that anthrax serum has been prepared in Europe by many institutions, and that this phase of immunization has been practiced for several years. We have, however, succeeded in concentrating the serum by a method of precipitation and are now endeavoring to prepare the specific proteins of the immune serum in a dry form to insure its keeping qualities and to prevent contamination. Furthermore, the vaccine which is being used in connection with the serum is an accurately standardized spore vaccine, by which it is possible to establish accurately the number of spores given to an animal.

Although I am satisfied that members of the medical and veterinary professions are familiar with the work which has been carried on in the immunization against anthrax, nevertheless I deem it advisable to state my position in the case in order that I may not be misjudged as attempting to claim priority for something which should and is known by all professional men to belong to others.

It might be of interest, however, to state that in the course of the experiments it was necessary for us to obtain anthrax serum for comparative tests, and to our surprise we found that it was not obtainable in this country. We therefore imported a quantity of such serum, and to our further surprise the comparative test revealed our serum to be at least twice as potent as the one of foreign make, and this may explain the splendid curative value of our anthrax serum.

A. Eichhorn, Washington, D. C.
Chief, Pathological Division, Bureau of Animal Industry,
U. S. Department of Agriculture.

Statistics Regarding Motor Accidents

To the Editor:—Your editorial on the safe and sane Fourth (The Journal, Aug. 28, 1915, p. 803), is of especial interest to me, for I have followed closely the campaign begun by you in 1903. Your success has suggested that I urge you to begin another campaign which, prosecuted with the same zeal as the other, will result in saving many lives, physical suffering and property each year. I refer to automobile accidents. If you will follow the same plan, you will not be compelled to go far in gathering statistics to get appalling figures—figures that will surely arouse the public press to assist you.

W. S. Clark, M.D., Los Angeles.

Rightly Objects to "Guards"

To the Editor:—When I saw in a daily paper the statement that the "guards" at the Springfield State Hospital, Sykesville, Md., had asked an opportunity to form an organization for military drill, I was inclined to make another attempt to dissuade newspaper writers from using the phraseology of medieval times in the care of the insane. But the constant use of the terms "keepers," "guard," "cell," "maniac" and the like, in reference to hospitals for the insane has discouraged me. When, however, a medical journal prints information from Maryland, presumably furnished by a medical man, in which the word "guard" is used, a term alike offensive to patients and friends of patients in hospitals, and to those who have labored for real hospital methods in our institutions for the insane, a feeling of discouragement if not something worse results.

Edward N. Brush, M.D., Towson, Md.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

S. WEIR MITCHELL — RELATIONS BETWEEN ANESTHETIST AND SURGEON

To the Editor:—Please give me: 1. (*a*) The first name of S. Weir Mitchell. (*b*) The year of his birth and death.

2. Has the operator any legal right to dictate to the anesthetist as to what anesthetic shall or shall not be given?

3. Has the anesthetist the legal right to stop the operation at any point if he considers the patient at the time too weak to sustain further manipulation?

A. S. McCormick, M.D., Akron, Ohio.

Answer.—1. (*a*) Silas. (*b*) Born Feb. 15, 1829; died Jan. 4, 1914. The death notice of Dr. Mitchell appeared in The Journal, Jan. 10, 1914.

2. The anesthetist is usually selected by the surgeon. It is customary, as a matter of professional courtesy, for the anesthetist to be governed by the wishes of the surgeon in charge of the case. There is no question of "legal right" involved as there are no laws on this subject. If the anesthetist and the surgeon are unable to agree as to the anesthetic to be used, the anesthetist should withdraw and permit the surgeon to select an anesthetist whose views are in harmony with his own. The responsibility for the result of the operation rests on the surgeon.

3. Here again no "legal right" is involved. It is customary for the anesthetist to call the attention of the surgeon to the patient's condition should dangerous symptoms appear, but it is entirely at the discretion of the surgeon whether or not the operative manipulations should be continued. A few court decisions in malpractice cases touch on the question indirectly, the general principle upheld being that where two or more physicians are jointly in attendance on a patient, each is responsible for the result of his own acts, but not for the results of the acts of the others.

ANAPHYLAXIS FROM DIPHTHERIA ANTITOXIN IN PERSONS PREVIOUSLY INJECTED

To the Editor:—Is it contraindicated to give diphtheria antitoxin to a patient having diphtheria if the patient had diphtheria antitoxin injected either for immunizing or curative purposes at some time previous, say from six months to several years?

In what percentage of cases do we get anaphylactic reactions? Are these very dangerous conditions?

Four days ago I gave a child aged 3 years 5,000 units; one and one half years ago I gave the same child 5,000 units. So far I have had none but gratifying results.

P. N. Wentz, M.D., York, Pa.

Answer.—The possibility of an anaphylactic reaction should not prevent the use of antitoxin in a patient with diphtheria, even though he has previously received antitoxin for immunologic or curative purposes. In such persons it is advised to give a small amount (from 0.1 to 1 c.c.) subcutaneously; if no severe symptoms appear after one or two hours, the full dose may be given.

Several considerations make it difficult to state the probability of appearance of anaphylactic phenomena in any given case. In addition to individual peculiarities which no doubt play a part, the volume of serum injected and the method of preparation of the serum are important factors. Weaver (*Arch. Int. Med.*, June, 1909, p. 485) found that when the volume of serum was small (from 1 to 9 c.c.), serum disease (urticaria, erythema, arthritis, etc.) appeared in 10.9 per cent.; with increasing volumes of serum, the percentage of reactions progressively increased so that in those cases receiving from 80 to 200 c.c., serum disease was noted in 61 per cent. The more recently developed methods of concentrating and refining antitoxin yield serums of high potency, so that the necessary amount of antitoxin units is available in small volume of serum, and the probability of serum disease is accordingly decreased. The removal by the refining process of certain albumin fractions of the serum decreases the incidence of serum disease. The older statistics, therefore, probably show a higher incidence of reactions than are being obtained at present with concentrated serum.

In persons receiving serum for the first time, serum disease appears in the majority of cases from the seventh to the tenth day, but sometimes earlier or much later, and rarely need cause alarm. Of 200,000 persons injected with serum, there was but one death from anaphylactic shock (Kolle).

The reactions which follow reinjections of serum (that is, in persons previously injected) may be immediate, and in any case are likely to occur earlier than those after first injections (accelerated reactions). The immediate reactions usually present, in addition to urticaria and other symptoms of serum disease, are symptoms of respiratory disturbance, cyanosis, rapid pulse, etc., and correspond to the anaphylactic shock seen after reinjection of experimentally sensitized animals. Epinephrin and atropin have been used with benefit. Even these severe reactions are very rarely fatal. About 50 per cent. of fatal instances of anaphylaxis have occurred in asthmatics, and in some of the latter the fatality followed the first injection of serum. When the reinjection is made within six days after the first injection in man there is practically no danger of anaphylaxis; reinjection in from three to eight weeks after the first injection is followed by some degree of anaphylaxis in about 90 per cent. of cases; reinjection after six to nine months is followed by reaction in about 50 per cent. of cases (Seidel: *München. med. Wchnschr.*, 1915, lxii, 1210). With the lapse of years the percentage of reaction on reinjection is further decreased, and usually appears as an accelerated reaction.

The danger of serum reactions even in previously injected persons is so much more remote than the danger from diphtheria that the physician should not hesitate to avail himself of so potent a remedy as antidiphtheric serum.

ARTICLES ON ARNETH FORMULA

To the Editor:—Please furnish me a reference to the original article and subsequent literature on the Arneth formula.

P. L. Querens, M.D., New Orleans.

Answer.—The following is a list of references on this subject:

CZAPLEWSKI'S CARBOLFUCHSIN STAIN

To the Editor:—1. Please give the formula for Czaplewski's carbolfuchsin stain, and state where it can be obtained.

2. Will Ziehl's carbolfuchsin stain the *Endameba buccalis* properly?

C. A. Sellers, M.D., Hartford City, Ind.

Answer.—1. Czaplewski's stain is prepared as follows: One gm. of fuchsin in 5 c.c. of phenol are placed in a dish; 50 c.c. of glycerin are added, with constant stirring, and then diluted with 100 c.c. of water. The constituents of the stain can be purchased from any medical supply house. We do not know where the stain may be purchased already mixed.

2. The following directions are given by Bass and Johns for staining *Endameba buccalis* properly: Spread pus on slide; fix with heat; pour on carbolfuchsin; wash off at once; stain with Loeffler's methylene blue from one-fourth to one-half minute; wash, dry and examine with oil-immersion lens.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

Arkansas: Regular, Little Rock, November 9-10. Sec., Dr. T. J. Stout, Brinkley. Homeopathic, Little Rock, November 11. Sec., Dr. Scott C. Runnels, 900 Scott St., Little Rock.

Connecticut: Regular, New Haven, November 9-10. Sec., Dr. Charles A. Tuttle, 196 York St., New Haven. Homeopathic, New Haven, November 9. Sec., Dr. Edwin C. M. Hall, 82 Grand Ave., New Haven. Eclectic, November 9. Sec., Dr. T. S. Hodge, 19 Main St., Torrington.

Louisiana: New Orleans, December 2-4. Sec., Dr. E. L. Leckert, 716 Macheca Bldg., New Orleans.

Maine: Portland, November 9-10. Sec., Dr. Frank W. Searle, 776 Congress St., Portland.

Mississippi: Jackson, October 26-27. Sec., Dr. E. H. Galloway, Jackson.

Nebraska: Lincoln, November 10-11. Sec., Dr. H. B. Cummins, Seward.

Nevada: Carson City, November 1. Sec., Dr. Simeon L. Lee, Carson City.

South Carolina: Columbia, November 9. Sec., Dr. A. Earle Boozer, 1806 Hampton St., Columbia.

Texas: Dallas, November 9-11. Sec., Dr. M. P. McElhannon, Belton.

West Virginia: Elkins, November 9. Sec., Dr. S. L. Jepson, Charleston.

Higher Preliminary Standard

An official communication from the secretary of the Virginia State Board of Medical Examiners states that the requirements of preliminary education by that board, according to the provisions of the medical practice act, will be automatically changed as the requirements of the University of Virginia, department of medicine, are increased. The latter has adopted, in addition to a four-year high school education, the requirement of two years of collegiate work, to become effective for all students entering in the session of 1917-1918 and thereafter. The licensing board of Virginia, therefore, will hold a similar standard as the minimum requirement of preliminary education for all graduates of 1921 and thereafter who seek licenses to practice medicine in that state.

Rules Governing Reciprocity in New Hampshire

All applicants for registration by reciprocity must appear in person before the board at Concord, N. H., and bring with them a certificate as to moral character, also documentary proofs that their preliminary education is up to the standard required by the laws of this state, and that they graduated from a Class A medical school according to the classification of the Council on Medical Education of the American Medical Association. They must also present documentary evidence that they have passed some state board examination. If the applicant's qualifications are satisfactory, on payment of the fee of $20, he will be granted a license to practice medicine in New Hampshire.

All graduates of medicine prior to the year 1907 must bring proofs of their education, both preliminary and professional, and proof that they hold a state license. Each case will be considered on its merits and, if satisfactory to the board, a license will be granted.

No person who has failed to pass the New Hampshire state examination will be considered as a candidate.

Wyoming March Report

Dr. H. E. McCollum, secretary of the Wyoming State Board of Medical Examiners, reports the written examination held at Laramie, March 10-12, 1915. The total number of subjects examined in was 10; total number of questions asked, 100; percentage required to pass, 75. The total number of candidates examined was 6, of whom 5 passed; 1 osteopath did not complete the examination. The following colleges were represented:

PASSED

College	Year Grad.	Per Cent.
Georgetown University	(1904)	83.2
University of Louisville	(1911)	*
College of Physicians and Surgeons, Boston	(1912)	76
College of Physicians and Surgeons, Dallas	(1905)	80.4†
Medical School of Osaka	(1899)	80.4

* No grade given.
† Graduation of this applicant not confirmed by official information.

Wyoming June Report

Dr. H. E. McCollum, secretary of the Wyoming State Board of Medical Examiners, reports the written examination held at Laramie, June 28-30, 1915. The total number of subjects examined in was 10; total number of questions asked, 100; percentage required to pass, 75. The total number of candidates examined was 3, all of whom passed. The following colleges were represented:

PASSED

College	Year Grad.	Per Cent.
University of Colorado	(1911)	79.1
Missouri Medical College	(1899)	76.4
Syracuse University	(1903)	84.5

Book Notices

The American Encyclopedia and Dictionary of Ophthalmology. Edited by Casey A. Wood, M.D., C.M., D.C.L., Professor of Ophthalmology, College of Medicine, University of Illinois. Volumes IV-VII. Cloth. Price, $6 per volume. Chicago: Cleveland Press, 1915.

Volumes IV, V, VI and VII of this monumental work have come from the press in rapid succession. They uphold the high standard of the early volumes both in manner of treatment of the subjects covered and in material characters. Many of the articles are by the same authors as articles found in the first three volumes. The book has now reached the end of the letter G, and of course has covered many important subjects in ophthalmology. In Volume IV, among the extended and leading articles are those on color blindness, comparative ophthalmology and congenital anomalies of the eye. Volume V contains a complete review of the subject of conservation of vision, an extremely interesting article on Jacques Daviel and the extraction of cataract, and a practical study of the cornea and its diseases. Volume VI includes articles on electricity in ophthalmology, electric magnets, exophthalmic goiter with especial relation to its ocular aspects, and a complete and helpful article on examination of the eye. Volume VII, the last of the series here considered, discusses eye glasses, the eyes of soldiers and sailors, and the use of color signals on railroads, in harbors, at sea, etc. It makes a most interesting and practical discussion of the subject. Glaucoma is given much space in the volume, and the scientific information developed to date concerning it is well and completely set forth. Much biography is scattered throughout the volumes, with portraits, in many instances, of the past masters in ancient and modern ophthalmology. Good illustrations abound throughout.

The reader is continually impressed with the fact that a vast amount of time and energy and an excellent sense of discrimination and selection have accompanied the preparation of this monumental work. It is time and energy well spent, for the value of such a series is not for a day or a year, but for generations to come.

Cancer. Its Study and Prevention. By Howard Canning Taylor, M.D., Gynecologist to the Roosevelt Hospital, New York. Cloth. Price, $2.50 net. Pp. 330. Philadelphia: Lea and Febiger, 1915.

This is a concise yet complete presentation of our knowledge of the various forms of cancer (and sarcoma). The subject is treated from historical and statistical points of view and as to etiology, clinical pathology, diagnosis and treatment. The study and prevention of cancer constitute one of the most important and at present most discussed problems confronting either laity or profession. The value of the book is enhanced by its reiteration of the necessity for early treatment. This can be brought about only through recognition of the earliest symptoms of cancer, and these the author constantly emphasizes throughout.

Medicolegal

Risk Assumed by Those Undertaking Work they Know they are Not Physically Fitted for

(Tennessee Coal, Iron & Railroad Co. vs. Moody (Ala.), 68 So. R. 274)

The Supreme Court of Alabama reverses a judgment obtained against the complainant by plaintiff Moody, an epileptic, who sued for damages for personal injuries sustained by him by falling into a pit and being burned, while in the company's employ. It appeared that he had been employed by the company at its furnaces for about nineteen years, when he began to have epileptic fits, and was laid off from work for two or three months. He was then employed to break the runway of molten cinders, or "to work the cinder fall," as he stated it. This he was accustomed to do, with or without direct orders, and was doing when he fell into the pit. He had been ordered by the superintendent thirty to forty-five minutes before, but there was no evidence of any indication then that he was going to have a seizure, although it was said that his spells gave visible indications in conduct or appearance from fifteen to forty minutes before an actual seizure. The plaintiff knew and understood his infirmity, but it did not appear that the superintendent had any knowledge of it, unless it was inferable from notoriety about the plant. The court holds that the order in question was not negligent under the circumstances, and that the plaintiff assumed the risk of injury when he undertook to do the work in which he was engaged.

The court says that the reported cases present only a few instances in which a servant has sought to recover from a master for injuries which resulted primarily from the physical unfitness of the servant for the work which he had undertaken to do. In this case it might perhaps be justly affirmed, on the plaintiff's own showing, that, with or without the order complained of, he would equally have undertaken his regular work on this occasion, with the same result, and hence that the order was not the proximate cause of his injury. But conceding that it was, the company could not be held responsible for that result.

So far as their own safety is concerned, persons not under contractual disability should be, and are allowed to determine for themselves, whether their physical infirmities, known to themselves, shall debar them from any particular employment. According to the nature and degree of their infirmities, they must be more or less exposed to dangers, naturally resulting from their attempt to serve, in almost any of the modern industries. It is no doubt a hard choice, but such persons must estimate for themselves the chances of injury, and it would be unjust as well as illogical to visit the consequences of their choice on their employers. It may be a matter of delicacy as well as difficulty for the employer to undertake in each case to determine the nature and extent of the malady or infirmity of one who offers to work, or the likelihood of injury resulting thereform; and the court thinks the employer may, without liability, legal or moral, accept the judgment of a would-be servant who knows his own condition.

Nor would the imposition of liability on the master in such cases be either politic or humane, even from the servant's point of view, since it would inevitably result in depriving of a livelihood many afflicted persons who have no choice but to labor, and who are impelled by experience or necessity to choose the more lucrative, if more dangerous, employment.

Cleanliness Now Cheaper Than Chemicals.—The European war sent the prices of benzoates from about 18 cents per pound to $2.00 per pound and then food manufacturers who claim we could not get along without benzoates, at once seem to have made a new discovery that after all benzoates are not necessary—sterilization is a cheaper food preservative than benzoate at $2.00 per pound.—*N. Dak. Agric. Experiment Station Bull.*, September, 1915.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA

Sixty-Fifth Annual Meeting, held in Philadelphia, Sept. 20-25, 1915

(Continued from page 1401)

Treatment of Empyema

Dr. Edward Martin, Philadelphia: In order to avoid infection from the skin, a puncture is made through the skin, deep fascia and into the muscle by means of a cataract knife. The trocar is pushed into the pleural cavity, and stopped when the resistance of the chest wall is no longer felt. The location of the pus thus having been determined, an incision 1½ inches long is made through the skin and a large trocar thrust into the pus cavity. The stylet is removed and a silver tube is passed through the cannula. The cannula is then withdrawn and the flanges of a tube are stitched to the skin by means of silver wire. The silver is not irritating to the tissues, and provides against compression or kinking, as is the case with a rubber tube. If necessary, a cupping glass or suction apparatus can be applied intermittently to produce negative pressure. Pulmonary exercises are to be instituted early. A dressing dampened with mild antiseptic solution is applied over the tube. If there is much adhesion between the pleural layers, these should be freed through a large incision in the intercostal space.

DISCUSSION

Dr. John H. Jopson, Philadelphia: My own practice has been in favor of the ordinary methods of drainage and the following of Richardson's advice to make large holes. We can do this operation early and painlessly on a child if we will carefully and systematically anesthetize everything down to the pleura. I believe we should do this under general anesthesia, local anesthesia being used only if the patient is in bad condition. I like to get a look in the chest and free light adhesions in the lungs in the early stage and remove large loose masses of lymph which will clog any tube and will probably break down and disintegrate. If one can do that and introduce the tube Dr. Martin advises, we are making a great advance.

Dr. John D. Singley, Pittsburgh: As regards breathing exercises in these cases of empyema, it has been my custom for years to have the patients use an ordinary football to blow into. The amount of pressure is limited only by the will of the patient, and it can be carried outdoors, where we like to keep these patients most of the time.

Treatment of Puerperal Infection and Septic Abortion

Dr. John M. Fisher, Philadelphia: In cases of puerperal sepsis, the severity of the infection with the same microorganism, even, varies in type from the most malignant, fatal in a few hours, to a type with symptoms so mild that in the absence of extraordinary precautions it may escape detection. I still believe alcohol to be of service in the treatment of profound toxemia characterized by feebleness of heart action, depression of the nervous centers, and the so-called typhoid states with either high or low temperature. The importance of eliminating toxic products through the excretory canals cannot be too strongly emphasized. The influence that the ingestion of water exercises on the skin and kidney is well understood. By whatever method administered it adds to the volume of the circulation, raises blood pressure, improves the quality of the heart's action, promotes nutritive changes incident to constructive and destructive metamorphosis, dilutes toxic products and promotes their elimination by its stimulating action on the kidney structure. The profession has been slow in estimating the value of outdoor life in tents or porches in the care of patients suffering from puerperal and other forms of sepsis. By the open-air treatment is meant the actual outdoor exposure of the patient and not merely her removal to a sun parlor or veranda with closed sides.

Treatment of Cancer by the Use of Radium in Conjunction with Surgery

Dr. Guy C. Boughton, Erie: Most of the cases of cancer in which radium treatment has been used have been inoperable cases; many of the patients have been almost moribund, and in this type of cases radium treatment has achieved what no other treatment could do. We would not replace surgery by radium therapy, but rather, by combination with radium therapy, make surgery more effective. The surgeon can remove the greater part of the malignant tissue, but the radium rays in suitable cases can go in and destroy all of the remaining malignant cells. In the treatment of even inoperable superficial cancers, carcinoma of the uterus, the prostate, the rectum and the breast, and in spindle-cell round-cell sarcoma, lymphosarcoma and rodent ulcers, radium has been shown to be of definite value.

Surgical Treatment for Absent Vagina

Dr. E. E. Montgomery, Philadelphia: I advise such patients not to have the operation but to accept the situation and give up the idea of marriage. Where conditions seem to make it desirable that a vagina should be constructed, it is important that it should have a lining of mucous membrane. The best plan is to line the constructed canal with a section of the intestine, utilizing a portion of either the ileum or the rectum. I prefer the latter. The lower end of the rectum above the sphincter is utilized for the vagina, and the rectal canal is reconstructed by loosening the rectum and bringing it down and making an anastomosis at the anus.

Treatment of Undescended Testes

Dr. John H. Gibbon, Philadelphia: In the early months and years of life, the mother or nurse should be instructed to draw down gently and push the testicle toward the bottom of the scrotum. If this fails by the third or fourth year, the Bevan operation should be performed. I have done this operation twenty-two times and have been surprised at the facility with which the organ can be carried into the scrotum. Eight of my patients were over 18 years of age.

DISCUSSION

Dr. R. G. Le Conte, Philadelphia: I am entirely in accord with the views expressed by Dr. Gibbon, but the manipulations for relief of the condition in infancy should be carried out very gently, or more harm than good may be done.

Free Transplantation of Fascia Lata in the Treatment of Inguinal Hernia

Dr. Francis T. Stewart, Philadelphia: The free transplantation of fascia has proved to be almost uniformly successful, and for the very reasons that were thought to render fascia unsuitable for transplantation: its poor nourishment and its lowly situation in the scale of organized tissues. This method is especially called for when the hernia is large, recurrent, sliding or direct. The best place from which to obtain the fascia is from the region just below the outer portion of Poupart's ligament. After undermining the lower edge of the skin incision for exposing the inguinal canal, the transplant is immediately sutured with catgut to the under surface of the everted margins of the transversalis fascia. The edges of this fascia are then united over the transplant.

DISCUSSION

Dr. J. S. Rodman, Philadelphia: The recurrent cases of inguinal hernia are the most troublesome, and it is here especially that the use of some material to strengthen the abdominal wall would seem to be called for. I believe that Dr. Stewart has chosen the best material of all to transplant. In operating for recurrence, the most difficult problem is to restore the anatomy to something approximating the normal. This can usually be done with the Bassini technic, and, if transplantation is added to this, it will suffice to cure the majority of such patients.

Preliminary Report of a New Method of Treating Gonococcic Virulent Conjunctivitis by Iced Normal Salt Solution

Dr. Edward B. Heckel, Pittsburgh: Ice pads have long been used in treating this malady on the theory that cold would inhibit the bacterial growth. In view of this and the assumption that gonococci are found only in superficial tissues, I have used iced normal salt solution in a few cases, and firmly believe that we have in it a specific in the treatment of gonococcal conjunctivitis. It is a harmless, effective germicide, easily applied, and well borne by the patients.

Pregnancy and Tuberculosis

Dr. Charles C. Norris, Philadelphia: Two years ago Dr. C. S. Bacon of Chicago estimated that there were in the United States alone 32,000 tuberculous women who became pregnant annually. Whether or not the normal pregnant woman is more susceptible to infection by the tubercle bacilli than her nonpregnant sister is still an undetermined point. The combined statistics of Fishberg, Funk, Jacob, Panwitz and a number of other observers in more than 1,100 cases give the proportion of women believing their infections to have originated during pregnancy or the puerperium as 39 per cent. While it is admitted that pregnancy exerts an unfavorable influence on tuberculosis, no hard and fast rule can be made, but each case must be individualized. Marriage should be advised against in the presence of an active lesion. A hard and fast rule that a tuberculous woman should not marry is too sweeping, although as a general principle this advice is correct. In cases in which conception has been countenanced, especial hygienic surroundings must be enforced, and frequent examinations should be made by an internist. In the cases of pregnancy in the presence of an extensive tuberculous lesion, even in the quiescent stage or small active lesion prior to the fifth month, the uterus should be emptied at once. This applies also when laryngeal or other secondary lesions are present. During the first six or seven weeks of pregnancy, dilatation and curettage is the operation of choice; beyond this period, vaginal hysterotomy. Practically all authorities agree that nothing is to be gained by operative intervention during the last four or five months of pregnancy. The indications, which are for treatment along general lines, should in cases of advanced tuberculosis be directed especially to obtaining a living child. A much more difficult problem is presented by the woman with a quiescent lesion of moderate extent. While it is accepted that continuance of the pregnancy is an added risk, abortion is not justifiable in every case. The patient should be studied closely and a guarded prognosis given.

DISCUSSION

Dr. H. R. M. Landis, Philadelphia: While a very considerable number of tuberculous women state that the first manifestation of the disease has occurred during pregnancy, I doubt whether any such instance is one of primary infection, but one rather of quiescent tuberculosis in which the added stress of pregnancy has lighted up the process. I have known of instances in which women after six or seven years of sterility have become pregnant, after recovery from an attack of incipient tuberculosis, without recurrence of the disease. I am opposed to the legislation advised by eugenists against the marriage of all infected persons.

Dr. Alexander Armstrong, White Haven: It is my custom to advise against the tuberculous woman bearing children until after at least five years of health. This opinion applies also to the question of marriage.

Dr. Elmer H. Funk, Philadelphia: In a series of 100 tuberculous women studied at the Jefferson Hospital, forty-three showed definite lesions dating from the beginning of pregnancy and during the puerperium. Termination of pregnancy in the earlier months gave better results than when gestation was allowed to proceed.

An Unappreciated Form of Pneumothorax

Dr. Charles Rea, York: By the "unappreciated form of pneumothorax" is meant that form coming on suddenly without obvious evidence of illness. The condition is regarded as due to rupture of air vesicles from a tearing of the pleura, probably always due to a previous pleurisy resulting in an adherence of the two surfaces. Its frequency is greater than is generally supposed. Differential diagnosis is of interest so far as extreme emphysema is concerned. General care is practically all the treatment required. Unnecessary muscular effort should be avoided until absorption of the air and obliteration of the rent have taken place. While in the majority of cases prognosis is excellent, cases have been reported in which absorption of the air had not taken place for many years. Pulmonary tuberculosis has occurred in several instances.

Therapeutic Pneumothorax in Pulmonary Tuberculosis

Dr. Alexander Armstrong, White Haven: This method of treatment has been used at White Haven for three years. The procedure consists in the introduction of gas, preferably nitrogen, into the pleural sac, compressing and eventually collapsing the affected lobe or lung. Strict asepsis is to be enjoined throughout the operation. While the lung is usually kept under compression for six months, in some cases a much longer time is essential. The rationale of the measure is to lessen expansion of the alveolar tissue and to encourage drainage of septic matter. Three indications for the treatment are: (1) progressive softening in one or more lobes of one lung, the other lung being normal; (2) relief of hemorrhage; (3) pleurisy, either dry or with effusion. A careful selection of cases is advisable, but it is not essential that treatment be restricted to those in which the disease is unilateral. In view of our results, we believe that therapeutic pneumothorax has a fixed place in the treatment of pulmonary tuberculosis.

DISCUSSION

Dr. Charles M. Montgomery, Philadelphia: I believe the cases referred to by Dr. Rea as "unappreciated pneumothorax" are not recognized as promptly as they should be, although the physical signs are sufficiently plain to be known. A number of cases have been recognized only by the Roentgen ray. Regarding pneumothorax, I know of no more encouraging report in literature. My only fear is that the impression may be received that the procedure is a simple one. It should be emphasized that its employment should be limited to experts in the work.

Dr. Isadore Kaufman, Philadelphia: A very large percentage of the cases mentioned by Dr. Rea develop in only phthisical subjects. As to therapeutic pneumothorax, I would emphasize the employment of the procedure in the earlier cases.

Case of Cholesteatoma of the Spinal Cord

Dr. William Egbert Robertson and Dr. Samuel D. Ingham, Philadelphia: A girl was taken from school when 15 years of age because of increasing languor and anemia. She was first seen, Dec. 28, 1914. There were progressive loss of flesh, intermittent insomnia, motor and sensory disturbance of the left leg, later of the right, variable in character, obstinate constipation and involvement of the bladder, with marked cystitis and a mixed spastic and steppage gait. At operation, a tumor 5½ inches long was removed, which on microscopic examination, proved to be a cholesteatoma. The patient has gained 25 pounds in weight. There is still moderate foot drop in the left leg with a little anesthesia and loss of muscle sense. There is, however, considerable gain in power, with increased size of the left leg, and the gait is almost normal.

Value of the Psychopathic Hospital

Dr. Daniel J. McCarthy, Philadelphia: Within recent years the psychiatrist and neurologist have felt the necessity of a fuller and better equipment for the care, study and prevention of mental diseases. There probably has been no greater blot on the art of medicine than the care and treatment of the insane during a period when in every other direction medicine was advancing. Effort has been directed largely to administration and custodial care of the patient rather than to the scientific study of the cause of mental diseases. Two problems facing the state are the immediate care of large numbers of insane, and the ever-increasing number of those requiring such provision. Insanity is a problem not only of the brain tissues but also of the entire economy. The psychopathic hospital should not, therefore, differ from the most advanced hospital connected with medical schools, and should be divided into the clearing house type for (1) the reception and distribution of cases; (2) the investigation of cases, and (3) the cure of borderline cases. There should be facilities in every general hospital for the temporary care of all mental cases. We should have institutions receiving not only wards of the state but also patients able to pay partial or full fees.

DISCUSSION

Dr. James Hendrie Lloyd, Philadelphia: The term "psychopathic hospital" has come to be a favorite one at the present time and one much used by persons of an optimistic turn of mind. It is meant to note progress, and is used to signify an institution different and theoretically better than that which is meant by the old-fashioned term "insane asylum." So far as the term means progress it is commendable. Progress does not, however, depend on mere words. A psychopathic hospital is, after all, nothing but a hospital for the study and treatment of the insane; one should not be deceived by a name. The treatment of the insane should be practically the same in all hospitals. I believe that a large municipal hospital offers the equipment and facilities desirable for mental cases.

Dr. George E. Price, Philadelphia: I do not entirely agree with Dr. Lloyd that the psychopathic hospital should be entirely under the care of the municipality. The great difficulty in the present situation is that people of moderate means have no hospital to which they can go, but to the municipal hospital at Blockley. Every large hospital, particularly those connected with the teaching institutions, should make provision for the mentally sick, just as they would for the man with an acute pneumonia or nephritis.

Dr. Alfred Gordon, Philadelphia: There should be a place for those persons, not insane in the true sense of the word, yet not normal mentally. Such persons, though free from delusions and capable of reasoning, are in a state of mental disquietude and cause much anxiety to their friends. For these I feel very strongly that there should be a place between the general hospital and the hospital for the truly insane. In spite of the later teaching, a stigma attaches to the placing of a patient in an insane asylum.

KENTUCKY STATE MEDICAL ASSOCIATION

Sixty-Fifth Annual Meeting, held at Louisville, Sept. 21-23, 1915

(Concluded from page 1398)

Diagnosis and Treatment of Gastric and Duodenal Ulcers

Dr. J. G. McClymonds, Lexington: The decision to operate more frequently rests with the internist and with the surgeon. As a rule, there should be no disagreement. Those cases with organic pyloric stenosis, hour-glass contractions, or perforations come definitely under surgical treatment. To these we must add cases in which repeated hemorrhages occur or relapses after apparent cure persist. Again, in those cases in which improvement is slow or arrested from inability to take sufficient nourishment, surgical intervention should be considered before the patient has reached a stage of exhaustion in which surgery would be a last resort.

Digitalis: Its Indication and Manner of Use

Dr. W. W. Anderson, Newport: Next to auricular fibrillation and flutter, the occasion of highest usefulness for digitalis is in acute cardiac dilatation. This occurs whenever the heart is subjected to a too great strain without time for hypertrophy. Thus it may result from a wrestling match, a marathon race, or pumping the blood against the constriction of asthma, emphysema or pneumonia. In the last instance dilatation is favored by the toxic degeneration of the myocardium. The effect of digitalis in these cases is most satisfactory. Too many of us have been giving digitalis in every case in which a heart murmur could be detected. The drug is worse than useless in true valve disease unless compensation is broken. Digitalis in therapeutic doses has no effect on the normal heart. A heart fully compensating for an impaired valve is a normal heart for present purposes of circulation, and needs no medicine. The tincture and fluidextract are not to be compared with like preparations of other drugs for stability. If fairly fresh they represent the whole drug. The fresh infusion represents all the nastiness and most of the virtues of digitalis, but is worthless in two days. Not one of the so-called active principles, even at its best, represents the whole drug. Most of them as found in the shops are worthless. They have only the advantage of fitness for hypodermic use even when right. All active preparations of the drug tend to disturb digestion. I cannot agree with those distinguished authorities who assert that this disturbance all comes through the vomiting center, some even adding that it proves overdosing and that digitalis is not a local irritant to the stomach. If their contention were true, there would be no advantage in giving the drug by the rectum. By giving from one third to one half more by rectum, digestion is often spared and full therapeutic effect obtained. The approach of toxic symptoms may be noted in gastric irritation (hunger, pain, weight and pressure soreness) and in slow pulse. Both these effects are in part overcome by combining the drug with atropin, but this combination is liable greatly to increase blood pressure. Coupled rhythm or bigeminal pulse is the danger signal that should mean instant discontinuance of digitalis.

Gastric and Duodenal Ulcer; Surgical

Dr. Michael Casper, Louisville: The chief danger of gastric ulcers are: first, hemorrhage; second, perforation; third, cancer formation; fourth, stenosis, if in the pyloric region. Other dangers exist, such as malnutrition and chronic invalidism, which naturally predispose to other intercurrent diseases. Gastrojejunostomy is the recognized operation for gastric ulcer with excision of the ulcer. Recently Balfour's method of cautery puncture has met warm approval. All gastric ulcers should be excised or destroyed by cautery, because of cancer menace. This disputed point is about settled now, and the only question that remains is what proportion of cancers of the stomach are preceded by ulcer period. Gastrojejunostomy does most good, of course, in ulcer of the pyloric region on account of improved drainage. The causes of failure in gastrojejunostomy are: first, vicious circle; second, narrowing or closing of anastomotic opening; third, jejunal ulcer; fourth, persisting irritation of nonabsorbable inner suture; fifth, jejunal or gastrojejunal ulcer. Nearly all of these are obviated by the more improved technic of posterior, no-loop gastrojejunostomy, absorbable inner through-and-through suture being used and otherwise careful manipulation of anastomotic structures. The final results of operative procedure in gastric and duodenal ulcers compare favorably with operation on the gallbladder and appendix. The mortality is likewise reasonably low, and is being constantly lowered. We cannot too strongly emphasize the hearty cooperation of the internist and the surgeon in this class of work, not only prior to but after operation as well.

Verumontanum with Reference to Referred Symptoms

Dr. George H. Day, Louisville: The etiology of these conditions discloses some very interesting information. In our series of nearly 200 cases, only about 80 per cent. gave the history of a preceding gonorrhea; 20 per cent. were found in men with a negative venereal history. In the gonorrheal type, a large majority had a complicating infection of the prostate and seminal vesicles, some singly and some both. Again, quite a number were observed with a history of an infection years previously and absolutely clear urine, normal vesicle and prostate, with an enormous tender verumontanum, together with resulting neurotic symptoms. In the acute or subacute infectious types the verumontanum takes a many-sided picture of pathologic changes. The sinus pocularis in these cases is usually widely gaping, simulating closely the existing anatomic changes, as attends the urethral orifices in a kidney infection. The causes of these conditions are divided naturally into those giving a history of a previous infection and those with a negative venereal history. It is in the cases with a negative venereal history that the best results are noted. The open air endoscope offers a useful place in the treatment of these disorders, and, while a great many drugs have been suggested, in my hands silver nitrate in varying solutions has been the agent *par excellence.* It has been my habit after thoroughly drying the verumontanum and adjacent tissues with dry applicators to apply varying strengths of silver, either 10, 20, 30 or 50 per cent., as is tolerated by the patient. It is necessarily wise to suggest that the treatment is rather painful and the reaction from the silver at times rather severe, but with a proper selection of cases and the solutions discriminately applied, amazing results are usually obtained. It is my habit to apply them at weekly intervals over a period of more or less length of time. It is wise after the application of the silver to allow it to dry thoroughly. The excess is always to be removed, before the endoscope is withdrawn.

6 *Atropin Treatment for Exudative Diathesis in Infancy. J. S. Leopold, New York.

1. Study of Woman's Milk.—In the colostrum period woman's milk, according to the authors, has high protein and high ash with rather low fat; in the transition period the protein and ash are lower while the fat is higher; in the mature period (after one month) the composition of normal milk does not vary in any essential or constant way quite up to the end of lactation. The only striking feature of late milk is a decline in quantity, though there is noted a slight fall in all the solid constituents except the sugar. Of the different constituents of milk the least variation both in individuals and in periods is seen in the sugar. The proportion of this is somewhat higher than the generally accepted 7 per cent.; 7.5 per cent. is nearer the correct figure. The greatest individual variations are seen in the fat, though the period variations in fat are not marked. The protein is highest in the colostrum period and falls to a little over half the proportion in mature milk, during which period it is seldom over 1.25 per cent.; of this about one-third is casein, and two-thirds lactalbumin.

The high ash of the colostrum period is chiefly due to the amount of Na_2O and K_2O. Of the salts which make up the ash, the greatest individual, as well as the greatest period, variations are seen in the Na_2O; the least individual and period variations are seen in the CaO, the proportion of which is nearly constant throughout the period of lactation. The largest constituent of the ash of woman's milk is K_2O; this with the CaO together make up more than half the total ash.

Although in amount the total ash of cow's milk is about three and one-half times as great as that of woman's milk, the proportion of different salts which make up the ash is nearly the same, the only exceptions being that cow's milk has more P_2O_5 and less iron.

2. **Artificial Milk.**—By mixing varying proportions of different animal and vegetable fats Gerstenberger and his associates found that it is possible to get a fat that in its Reichert-Meissl number (small per cent. of low volatile fatty acid glycerids), saponification number, iodin number, and other characters, is nearly identical with the fat of human milk, as has previously been shown by Arnold. By replacing in an artificial milk cow's-milk-fat with the fat of the above description in an emulsified state (homogenized), a distinct step in advance toward the more complete adaptation of an artificial food to breast milk is made. It is also possible to take into consideration the "growth factors," "vitamine factors," and the like, in choosing the individual fats for an acceptable mixture. This represents a further step in the more complete adaptation of an artificial milk to human milk. The homogenizer represents the important means by which the mixing and emulsification of the fat in the artificial milk is possible. The homogenizer also changes the physical condition of the fat (smaller globules, brownian movement), which may be of advantage.

The meager clinical data suffice to show that the infants fed with Friedenthal's milk in which the cow's-milk fat has been replaced by a fat with a low volatile fatty acid glycerid content, similar to that of human milk fat, vomit less and have more normal stools than the children reported by Bahrdt, and fed with Friedenthal's milk containing unchanged cow's-milk fat. Washing butter with cold or hot water does not remove the low volatile fatty acids from butter, except in an insignificant degree. Washing butter with hot alcohol does remove the low fatty acid glycerids to a decided degree. The manufacture of a food like G-R milk can be arranged to give a very low bacteriologic count. The production of milk like G-R milk can be made at a reasonable cost.

3. **Purpura in Meningitis.**—The unusual features of the two cases cited by Morgan were: 1. The character and distribution of the eruption, which was unlike the usual purpura hemorrhagica and which though differing greatly in degree was almost identical in both patients. 2. Paucity of other meningeal signs, such as opisthotonos and other manifestations of increased muscle spasm. 3. Demonstration of the specific organism in the blood of both patients, though attempts to grow the same organism from the skin lesions were unsuccessful. 4. Refutation of the old theory that the extent and color of the eruption was of prognostic aid. In both the above cases the meningeal manifestations were no more marked than usual, and were quite amenable to treatment. 5. Both cases were sporadic as far as could be learned by investigation of the locality and by a study of the Board of Health daily bulletin.

4. **Tonsillar Spots in Measles.**—Tonsillar spots in measles were observed by Herrman in thirty-five cases (40 per cent. of the eighty-eight cases examined). In 9 patients they were present one day before the eruption appeared; in 11 patients two days, in 7 patients three days, in 5 four days, in 2 six days, in 1 nine days before the eruption appeared. In 30 of the 35 patients Koplik's spots were observed, in 14 patients one day before the eruption appeared, in 15 two days, in 1 three days before the eruption appeared. In 13 patients the tonsillar spots were seen one day before Koplik's spots; in 3 two days, in 2 three days, in 1 four days, in 1 seven days before Koplik's spots. In 5 patients the Koplik's spots were seen 1 day before the tonsillar; in 5 patients the Koplik's spots were seen on the same day as the tonsillar spots, and in 5 patients the Koplik's spots were not seen, so that the interval could not be determined. In 12 patients the spots were visible for one day; in 17 two days, in 6 for three days. At the time when the spots were first seen, the temperature was less than 100 in 6 patients, between 100 and 100.5 in 6, between 100.5 and 101 in 3, between 101 and 101.5 in 8, between 101.5 and 102 in 2, between 102 and 102.5 in 7, between 102.5 and 103 in 1, and between 103 and 103.5 in 2 patients.

6. **Exudative Diathesis.**—During the past year Leopold has administered the atropin treatment to ten infants suffering from symptoms of the exudative diathesis—severe eczema, bronchitis or asthma. Mild cases were not treated. The patients were all institutional babies ranging in age from 4 months to 2 years, and were under constant medical supervision. The results of the atropin treatment on the lesions of the exudative diathesis were excellent; and this despite the fact that no changes in diet were made, and no other drugs administered. One infant died during the period of observation. In this patient atropin had a beneficial effect on the eczema, but in no wise influenced the pulmonary condition, death following a terminal bronchopneumonia.

Atropin was used in a solution of 1 grain of atropin sulphate to 480 drops of water. Three drops of this solution were given on the first day of treatment, and if no untoward effects were observed, the dose was increased 1 drop daily until patients received about 30 drops daily (equivalent to 1/16 grain of atropin sulphate). This last dose was given daily for one or more weeks until the manifest signs of the exudative diathesis had disappeared. Smaller doses were then administered for a few more days or weeks. In only one case did untoward manifestations appear; they were very mild, and did not recur after the initial dose of the atropin solution had been reduced. In no case was there any harmful result from the atropin treatment. It was clearly evident from the beginning that infants suffering from exudative diathesis were able to take large doses of atropin sulphate without showing toxic effects.

12 Carcinoma Uteri. L. W. Strong, New York.
13 Mentally Backward Child from Standpoint of Neurologist. M. Neustaedter, New York.

9. **Operation of Uterine Fibroids.**—Frank claims that the Roentgen ray cannot be used with safety: In rapidly growing tumors; in cases of metrorrhagia in which complete preliminary curettage with microscopic examination of the curettings is not feasible; in complicated cases in which ovarian cysts or serious adnexal trouble cannot be excluded; in fibroids complicating pregnancy. The rays should not be used in cases in which expense is a factor or in cases in which time is a factor. The rays are of chief value in cases in which operation is declined, in cases in which operation is contraindicated by serious heart, renal or pulmonary lesions, or in cases in which operation is contraindicated because of extreme psychical unrest. Consequently Roentgen-ray treatment is applicable to at the most 5 to 6 per cent. of all patients having fibroids.

10. **Abdominal Cesarean Section.**—A slight modification of the Davis operation is practiced by Brown. He makes the incision in the usual manner, about 10 cm. long and entirely above the umbilicus, if possible. By pressure on the sides of the abdomen an assistant holds the uterus firmly up against the abdominal incision while the cut in the uterus is being made. When the uterus has been carefully opened, and before the child is delivered, the uterine cut is sewed to the abdominal wound either with eight or ten interrupted sutures, or possibly by a continuous suture. The uterus is then emptied of child, placenta and membranes. It is impossible for the uterine viscera to get into the peritoneal cavity or for the abdominal contents to get into the way of the operator. In closing this

incision Brown finds that it is quite easy to place the whole of the first row of uterine muscle sutures before the temporary sutures are removed. By leaving the permanent sutures in the upper and lower angles of the incision long they are convenient for holding the uterus up in view while the last stitches are being taken. Brown has used this method now in four cases.

11. **Contracted Pelvis and Difficult Labor.**—Small external measurements when they are all proportional with an external conjugate of 15 cm. or over, provided they are found in a woman whose slender build accounts for a small pelvis, Hornstein insists deserve a fair test of labor. They usually have small children and will deliver spontaneously if the fetus presents favorably. A fair test of labor in a doubtful case and especially in a primipara must include a period of four to six hours in active labor with the membranes ruptured, although as a rule, three hours will decide the outcome. Cesarean section for relative contraction in a primipara, means repeated cesarean for subsequent children, whereas extraction of the child through nature's passages, even if it should result in a stillbirth, will enable the woman to deliver her subsequent children per viam naturalem, since a good deal of resistance which is encountered in primiparae is due to the soft parts.

15 *Id. Sugar Retaining Power of Liver in Relationship to Amount of Glycogen Already Present in Organ. J. J. R. Macleod and R. G. Pearce, Cleveland.
16 *Differential Effects of Epinephrin on Splanchnic and Peripheral Arteries. F. A. Hartman, Boston.
17 Osmotic Properties of Calcium and Magnesium Phosphate in Relation to Those of Living Cells. E. B. Meigs, Philadelphia.

14. **Level of Blood Sugar in Dog.**—Macleod and Pearce point out that although the blood sugar level in an anesthetized animal does not remain unchanged from time to time, yet the changes occurring during a period of ten minutes are small when compared with those observed on blood similarly removed from animals in which the splanchnic or hepatic nerves were stimulated.

15. **Influence of Glycogen on Sugar Storage of Liver.**—Briefly summarized, the authors' experiments showed that the existing glycogen content of the liver does not demonstrably influence the rate with which this organ removes dextrose from the blood of the portal vein. The following points were noted: 1. The quicker rise in sugar concentration in the portal blood than in that of the vena cava. 2. The delay, after discontinuing the injection, in the return to the normal level of the sugar concentration of the blood of the vena cava and frequently also in that of the portal vein.

16. **Effect of Epinephrin on Splanchnic and Peripheral Arteries.**—Hartman found that dilute epinephrin slowly injected caused a fall in general blood pressure in forty-eight out of fifty-three animals tried. Three of the animals in which a fall did not occur, were in poor physical condition and one was just recovering from the effects of alcohol. Dilute epinephrin caused dilatation of the peripheral arteries even after extremely low pressures had been produced by hemorrhage. The same dose of epinephrin caused constriction of the splanchnic arteries. When the blood pressure was lowered by depressor stimulation, the same dose of epinephrin caused a fall, a rise and fall or a pure rise, depending somewhat on the height of the pressure. The average latent period for the peripheral fall in the blood pressure (from doses of 0.2 c.c. epinephrin, 1:100,000) was 15.7 seconds; the latent period for the splanchnic rise was 18.6 seconds. The duration of the splanchnic rise was 37.8 seconds, while the duration of the peripheral fall was fifty-nine seconds. The threshold for the change of a fall to a rise in the peripheral arteries, when epinephrin was injected (in three animals only) over a period of from ten to twenty seconds, was betweetn 0.1 and 0.3 c.c. of a 1:10,000 solution. Large doses of ergotoxin phosphate inhibit the splanchnic response to dilute epinephrin. The existence of sympathetic vasodilator nerves in the peripheral arteries and their absence in the splanchnic arteries would account for the opposed action of like doses of dilute epinephrin on the peripheral and splanchnic arteries.

21 Use of Calcium in Treatment of Epilepsy. J. Bryant, Boston.
22 Synchronous Inspiration and Systole in Patient Exhibiting Equal Respiratory and Pulse Rates. P. D. White, Boston.

18. **Criminal Problem.**—If the criminal problem is one of treatment of the individual for his deficiencies rather than of punishment for the crime committed, Spaulding says that the following fundamental provisions for the administration of such treatment are necessary: 1. Adequate provision by the state for the permanent custodial care of all committable cases of mental defect, whether or not they have a court record. 2. The establishment of laboratories in their courts and correctional institutions for the study and diagnosis of all offenders. The equipment of all their institutions with facilities for classification and treatment of the various types which will remain even after the removal of the most defective. Such a classification will necessitate separate buildings, at least one of which should be equipped for hydrotherapy. The adoption of an indeterminate sentence, which shall enable us to treat patients until they are able to return with safety to the community. The physician has it in his power to do much toward educating the public to the need of fundamental measures of reform and toward counteracting the tendency toward superficiality of some enthusiastic believers in universal reform. His knowledge of mental and physical defect enables one to see more than the cross section of the subject, which is represented by the population at present confined in their penal institutions, and to appreciate the social and economic waste which is the result of their past neglect of generations of inefficients in the community.

19. **Blood Pressure Determinations.**—Lee examined 662 normal young men, the average age 18, average height 5 feet 8 inches, average weight without clothes, 143 pounds. The average systolic pressure was approximately 120 mm. of mercury; the average diastolic pressure 80 mm. Eighty-five, or 12.8 per cent., of the 662 presented systolic blood pressure readings over 140. The highest reading was 180. The diastolic pressures were found to be much more uniform. There was comparatively little variation between the readings in the recumbent and standing positions. The average was 80. Only five cases had a diastolic blood pressure over 100. All these five cases presented systolic blood pressures over 140, but only one of them presented a systolic pressure over 160. Of the five who presented diastolic blood pressures over 100, no other abnormality was found in three patients.

Of this group of eighty-five cases, 9 (or 10.5 per cent.) showed albuminuria. The percentage of albuminuria in the total 662 men was 5.1 per cent. In only one case with albuminuria was the systolic pressure in either the standing or recumbent position over 160. In seven of the eighty-six cases, a definite valvular lesion of the heart was found. One of these patients also presented albuminuria. In one patient a slight goiter was present. Another case of obesity presented a persistently high blood pressure. Five patients showed sugar in the urine; in two patients the sugar immediately cleared up and has not reappeared. Blood smears were made in every case. Only five patients presented a polynuclear leukocytosis of over 75 per cent. Only four patients showed an eosinophilia of over 5 per cent.; the reasons for these were not apparent. Seventy-three patients showed a lymphocytosis of over 50 per cent., but in no instance was the lymphocytosis over 60 per cent. In 153 cases the lymphocytes were between 40 and 50 per cent. of the white cells. In other words, 231 of the 564 cases showed a lymphocyte count between 40 and 50 per cent. The red cells were essentially normal in every case.

20. **Gastric and Duodenal Ulcers.**—According to Graham 72 per cent. of duodenal cases seen at the Mayo clinic in the past nine years gave fairly regular symptoms and 71 per cent. of gastric cases gave the expected syndrome, or were so clearly gastric that little hesitancy was felt in making a diagnosis. Pain is the one constant diagnostic factor in all peptic ulcers. Less than 1 per cent. of patients are recorded free from pain. The time of pain has some distinctive diagnostic significance. In the duodenal ulcers the pain came one-half to two hours after food in 23 per cent. of cases, and two to five hours in 77 per cent. of the cases. In gastric ulcers the time limits of one-half to two hours included 50 per cent. and two to five hours an equal number. In 20 per cent. of the duodenal and in 19 per cent. of the gastric ulcers the time of pain was not recorded. Eight per cent. of the patients with duodenal ulcer and 19 per cent. with gastric ulcer had pain within one-half to one hour after eating.

Pain at night appeared to be more decidedly frequent in duodenal ulcer, while ease from posture (lying down) seemed decidedly more frequent in gastric ulcer. However, the final analysis gives 14 per cent. of the patients with duodenal ulcer and 10 per cent. of those with gastric ulcer having pain at night. Postural ease was noted in 8 per cent. of the duodenal and in 9 per cent. of the gastric cases. These figures correspond much more closely than one would suppose from impressions gained in history writing. Continuous pain from the beginning of symptoms was mentioned in 4 per cent. of the duodenal and 9.5 per cent. of the gastric cases. Tenderness to touch was recorded in 41 per cent. of the duodenal and 40 per cent. of the gastric histories. The location and radiation of pain was noted as follows: Of the duodenal ulcers 49 per cent. were well confined to the epigastrium, 52 per cent. of the gastric were similarly located. Those with radiation to the back ran 24 per cent. duodenal and 22 per cent. gastric. In the diagnosis gallstones were considered certain or were given first place in 13 per cent. of the duodenal and in 9 per cent. of the gastric cases. Radiation to the left epigastric area occurred twice as often in gastric (10 per cent.) as the duodenal cases (4 per cent.). The percentage of radiation to the abdomen and fossae was quite similar (9.5 per cent. duodenal, 9 per cent. gastric). Radiation to right epigastrium was present in 6.6 per cent. of the gastric and in 13.7 per cent. of the duodenal cases. Therefore, tenderness to touch, radiation of pain, and the patient's ability to locate his subjective pain gave little basis on which to arrive at a differentiation. Vomiting was recorded as occurring in 79 per cent. of the duodenal and in 82 per cent. of the gastric ulcers, while gas was present in 77 per cent. of the duodenal and in 94 per cent. of the gastric.

History of hemorrhages by mouth was recorded in 18.5 per cent. of duodenal and in 25 per cent. of gastric cases. Blood by the bowels was similarly recorded in 18 per cent. of duodenal and in 24 per cent. of gastric cases. Perforation ran about equal in both classes (duodenal 28.7 per cent., gastric 26 per cent.) and of those that perforated, the pancreas received the perforation in 17 per cent. of the duodenal and in 25 per cent. of the gastric cases. Pain to the back, which more or less simulated gallstones radiation, ran about equal (24 per cent. duodenal, 22 per cent. gastric) in two conditions, all cases considered.

27. **Benzene Treatment in Leukemia.**—The principle of the treatment is considered sound by Boardman. He believes that with proper precautions, there is no appreciable danger in using benzol. The improvement is a real improvement and not due to accumulation of the leukocytes in the central vessels. The improvement is only temporary, as in their other methods of treatment. The treatment is applicable in all chronic cases of leukemia. Bronchitis and anemia cannot be considered contraindications. The presence of nephritis is a more serious complication and demands more careful consideration. The treatment is more readily administered and is less costly than the Roentgen ray and may be given to those unable to obtain Roentgen ray. The percentage of improvements is about the same under benzol as under Roentgen ray.

The drug is best administered in freshly filled gelatin capsules with an equal amount of olive oil; the maximum daily dose not to exceed 5 gm. The treatment must be carefully controlled by frequent blood and urine examinations and discontinued if there is evidence of kidney irritation, or when the leukocytes reach values of 25,000 to 20,000. The best results follow the combined benzol and Roentgen-ray treatment, the benzol effect apparently being increased by a preliminary Roentgen-ray treatment. Some cases will not respond to benzol in the usual dosage and in the usual time, and other patients are unable to take the drug owing to gastro-intestinal disturbances, etc. When carefully administered and carefully controlled, benzene is apparently a valuable addition to the methods of treating chronic leukemia.

59. **Congenital Fracture of Clavicle.**—Johns' patients were brothers, aged, respectively, 24, 17, 14 and 12 years. The parents are living and in good health. There is another brother, 22 years of age, and one sister, 15 years of age, each in good health. No children of these parents are dead. The parents are farmers. These sons were reared on a farm, and now reside with their parents. One aunt, 35 years of age, is rachitic, the disease being of congenital origin and in a most severe form. With this exception, no other rachitic tendency is known among the relatives. There was an absence of a traumatic history in all four cases. None of the brothers had any knowledge of the existence of fractures. They had not experienced any inconvenience or pain from them, except the oldest brother, who suffered slight pain in his shoulder, when performing labor which exerted the shoulder muscles. Each of these cases show dystrophic conformation of other bones, more commonly of the cranium and thorax. In each the frontal bones are prominent. In one there is a flattened occiput. The ribs in two are of irregular curve, producing the barrel-shaped chest. The sternum in one shows imperfect development. There was irregular dentition in one, lordosis in one, and talipes varus in another.

112. **Gonorrhea Complement Fixation Test.**—This paper is based on a study of 155 gonorrhea complement fixation tests, in which the serums of 141 individuals were tested by each of four competent serologists. The blood was withdrawn with a dry sterile needle from a vein in the forearm, collected in four sterile test tubes of 5 c.c. capacity each, and one tube was sent to each serologist. When more than one specimen of blood from the same individual, withdrawn at the same time, was submitted, different names were used. Of the 141 patients, fifteen were normal controls who never had gonorrhea; thirty-seven suffered from other diseases, and all denied ever having had gonorrhea, and presented no clinical evidences of infection; the remaining eighty-eight have or have had gonorrhea. Of the fifteen series of tests on normal people in the present group, reported by each of the four serologists, only one laboratory, B, reported negative in each case. The percentage of positive reports by the other three serologists varied from 6.6 to 13.3 per cent. In the next group of thirty-seven patients, none of whom presented clinical evidences of gonorrhea, laboratory B again reported negative in each case, while the other three laboratories vary in their proportion of positive findings from 13.5

to 35.1 per cent. Of these thirty-seven patients positive reports were submitted by one or more of the laboratories in twenty-one cases; two laboratories reported positive reactions in eight cases and one laboratory in the remaining thirteen.

Of the eighteen patients clinically cured for over five years, all laboratories agree in a negative report in eight; one laboratory reports a positive in four cases; two laboratories a positive in five cases, and three laboratories a positive in one case. Of eleven patients with acute gonorrhea of less than four months' duration, all the laboratories agree in a negative report in three cases. Six patients had uncomplicated chronic urethritis; twelve had chronic urethritis with a history of previous epididymitis, and twelve chronic gonorrheal prostatitis. A positive report was received: In ten cases from one laboratory, in seven cases from two laboratories, and in two cases from three laboratories. In the remaining eleven, all reports show negative findings. Of the patients with acute gonorrhea with complications, three had epididymitis, three arthritis, and one iritis. In two cases, both of epididymitis, uniform negative reports were submitted. In two cases there were one positive and three negative reports; in two other cases there were three positive and one negative report, and in one case four positive reports. Of the 141 cases, excluding all anticomplementary reactions, there were 128 tests reported by each serologist; fifty-one or 39.9 per cent. agree, and seventy-seven or 60.1 per cent. disagree.

137 Case of Continued Fever of Undetermined Nature. B. F. Stahl and N. B. Gwyn, Philadelphia.

133. **Case of Spina Bifida.**—After a somewhat prolonged and difficult labor Rockwell's patient gave birth to a female child deformed as follows: The child's body was normal above the pelvis; the pelvis, however, was double with three legs, the middle and smallest leg being somewhat deformed. There was a single opening behind, anal, in the right pelvis; there were two openings in front, one in each pelvis, the one in the right pelvis being a vaginal opening with urethra communicating with the bladder, which was single; the other opening in the left pelvis, at first taken for the second vaginal opening, proved to be a second anal opening, although without sphincter muscle. There were fecal discharges from both openings, not always simultaneous, but continuing during her life. Between the middle and left leg at lower end of sacrum was a large fluctuating tumor, spina bifida, covered with integument, tense and almost transparent. The child lived and grew, though never strong, and never walking, but mentally a bright and attractive child, until nearly 10 years old when after a few days of extreme suffering due to pressure, the tumor ruptured, discharging large quantities of bloody serum; death followed in about seventy-two hours after the rupture.

2 Administrative Control of Measles. R. M. F. Picken.
3 Universal Suspension Apparatus for Arm and Leg. M. Sinclair.
4 *Obliteration of Cavity in Tibia Remaining after Sequestrotomy. W. Gemmill.
5 Treatment of Septic Wounds by Electrolytic Bath. F. Fowler.
6 Case of Hysterical Amblyopia. K. Campbell.

1. **Cholera Treated by Hypertonic Saline Solution.**—In the course of the Swatow epidemic reported on by Whyte, 212 patients were treated with intravenous saline injections; 154 recovered, that is, 72 per cent. It was on these lines that the Swatow epidemic was treated and the results varied according to the age, sex and habits of the patients. The main causes of the fifty-eight deaths were collapse, hyperpyrexia, uremia and asthenia. Collapse accounted for death in 6 per cent. of the patients treated. Hyperpyrexia accounted for death in 11.5 per cent. of the patients treated. Seven patients died from uremia; that is, 3 per cent. of those treated.

4. **Obliteration of Cavity in Tibia.**—The operation described by Gemmill is after the osteoplastic method recommended by Schulten.

12 *Pathology of Obstructive Edema of Lung, Based on Observations with Starling Heart-Lung Preparation. Y. Matsuoka.
13 Sarcoma Immunity in Mice. M. Tsurumi.

7. **Experimental Study of Metastasis.**—The studies with which Takahashi's paper deals were carried out by intravenous injection of tumor emulsions into the tail vein of mice. Fourteen different tumor strains were used; three sarcomas and eleven carcinomas. Of the three sarcoma strains studied, one failed to grow in the single short series inoculated, and the other two gave 33 and 88 per cent. of success, respectively. The eleven carcinoma strains varied between 0 per cent. and 78 per cent. success. The more differentiated carcinomas, papilliferous cystic adenocarcinomas and squamous-cell carcinoma, however, all failed to grow in the lungs. Seven alveolar carcinomas were not uniformly successful, five strains giving from 16 to 78 per cent., two strains 5 per cent. and 0 per cent., respectively. The solid alveolar tumors, therefore, appear to be more capable of intravascular growth than the more differentiated adenocarcinomas and the cancroid. As a general result it is concluded by Takahashi that the tumors of rapid growth grow better and in a higher percentage in the lung capillaries than the strains which grow slowly. Among the tumor strains used for these experiments some had produced metastasis after subcutaneous inoculation, while others had produced none through many (fifty to sixty) generations. On the other hand, the strains which did not metastasize to the lungs naturally, failed to grow on intravenous inoculation with a single exception. The percentage of successful intravenous inoculations is, however, not high in this strain. The conclusion seems justified that the absence of metastases after subcutaneous inoculation of many mouse tumors, is due to the inability of the tumor cells to survive after arrest in the lung capillaries and to establish organic union with the vessel wall.

9. **Hemorrhagic Septicemia Group of Organisms.**—McGowan and Wang show how an organism of the hemorrhagic septicemia group, by an increase of virulence through pas-

sage, has also concurrently been endowed with an increased biologic activity on artificial mediums, whereby it grows much faster on these mediums and produces acid and gas fermentation in some carbohydrate mediums in cases in which it only produced acid or no change previously. It would seem to be essential for the success of this passage that the organism be taken directly from one animal to another without intervening growth on artificial mediums. Retrogression of these newly acquired biologic activities would appear to be slow. The serum obtained by immunizing rabbits with the original and virulent strains, respectively, while agglutinating their own strains well, do not, or only slightly, cross-agglutinate. The immunity to a subsequent injection, both of the virulent and of the original strain appeared to be much greater after the preparatory injection of the virulent strain than after a similar injection of the original strain.

10. **Absorption of Iron After Hemolysis.**—Muir and Dunn found that after acute hemolytic anemia in rabbits the excess of iron which has been stored in the organs, has been nearly all absorbed by the time of complete regeneration of the blood, and has been presumably utilized for purposes of blood formation. The absorption is most complete from the liver cells; it is less complete, a certain excess still remaining, in the endothelium of the liver capillaries, in the pulp of the spleen and especially in the cortex of the kidneys.

12. **Experimental Edema of Lungs.**—Matsuoka carried out a systematic study of the experimental production of obstructive edema of the lungs in isolated heart and lungs of dogs. His investigations were made with the aid of the Starling heart-lung preparation in which the part played by the heart in the production of obstructive edema of the lungs can be well studied. He also investigated the influence of the extirpation of the pericardium and of changes in the temperature of the blood on the production of obstructive edema, and studied the gaseous metabolism and energy of the heart in this condition. Obstructive edema of the lungs takes place when certain limits of combined arterial pressure and venous inflow are exceeded. (*a*) Obstructive edema is produced with a constant moderate arterial pressure of 80 mm. of mercury, when a total output of heart of not less than 92 liters per hour is maintained for over fifteen minutes. Obstructive edema of the lung is produced with a constant high arterial pressure of 160 mm. of mercury when a total heart output of not less than 38 liters per hour is maintained for over fifteen minutes. In cases of arterial pressure between 80 and 160 mm. of mercury, the limits of the output of the heart may be taken as lying about the average of the two extreme cases. All the above-mentioned maximum and minimum volumes refer to dogs' hearts which have an average weight of 42 gm.

The above mentioned limits may be raised still higher in cases in which a high arterial pressure of abundant venous inflow continues for a shorter period than fifteen minutes. How far the foregoing lower limits must be exceeded so as to produce obstructive edema in dogs with hearts of a specified size depends on the age of the dogs, on various bodily conditions, on the circumstances of operation, and on the duration of the experiment. The production of obstructive edema is considerably facilitated by the occlusion of the root of the aorta, when a relatively small amount of venous inflow is sufficient to produce the lung condition. In the production of obstructive edema, the output of the heart may be diminished to a minimum, and the blood content of the heart and the pressures in the pulmonary artery, the inferior vena cava, and the right auricle may be increased to a maximum, all quite independently of the height of the arterial pressure and of the amount of venous inflow. As the dilatation of the heart after extirpation of the pericardium easily assumes a pathologic degree, edema of the lung usually occurs more quickly and with a smaller amount of arterial pressure and of venous inflow than when the pericardium has not been removed. Gaseous metabolism and energy consumption of the heart are decreased in obstructive edema of the lung. In all cases in which the experiments with the Starling heart-lung preparation were carried out to a conclusion, the following pathologic conditions were seen in the lung; increase in volume following on diffuse congestive edema unrecognizable macroscopically, atelectasis and compensatory emphysema, and splenization of the lower lobes.

Lancet, London

23 Gallstone Complicating Appendicitis. F. Deane.

15. **Bacteriology of Septic Wounds.**—The organisms which Fleming has found in these wounds divide themselves into three groups: (1) spore-bearing microbes of fecal origin; (2) nonsporing microbes of fecal origin; and (3) pyogenic cocci. The first group includes *B. tetani*, *B. aerogenes capsulatus* of Welch, and certain putrefactive organisms which Fleming refers to as bacillus X and bacillus Y. The habitat of all these is the intestine of man and animals, or in soil which has been manured with animal excrement. The nonspore-bearing organisms of fecal origin include the streptococcus, *B. proteus*, *B. coli* group, and "wisp" bacillus. The streptococcus is the most important member of this group as regards infection of wounds. It is present in almost every wound up to a late stage. From its appearance in the wound early, and in association with organisms which are of known fecal origin, Fleming assumes that the streptococcal infection is also a fecal one. The third group of pyogenic organisms comprises especially the streptococcus and staphylococcus. *Staphylococcus aureus* is almost the only organism frequently occurring in wounds which is not common in animal feces. It is noteworthy that *Staphylococcus aureus* is seen in wounds only in the later stages, and as they are present on the patient's skin, it seems likely that their appearance in the wound is largely due to an invasion from the skin around.

The bacillus X is a straight bacillus 5 microns long and 1 to 1½ microns broad, nonmotile, gram-positive, and sporing freely in all mediums. In agar or glucose agar stab cultures there is much gas production. Coagulated egg medium is liquefied. Milk is not clotted, but in three or four days it is peptonized. One cubic centimeter of a vigorous milk culture injected subcutaneously into a guinea-pig produced much local edema which persisted for three days and then disappeared. The same quantity of a broth culture had no effect. Bacillus Y is a long, slender, gram-negative bacillus, feebly motile, which shows close to or at one extremity an elongated spore. It was not so commonly found as bacillus X. It forms less gas in agar or glucose agar, and the liquefaction of albuminous material such as egg proceeds more slowly. The smell of all cultures is excessively putrid. This bacillus was not pathogenic for guinea-pigs. The "wisp" bacillus is a small, slender, gram-positive nonmotile bacillus, which is of common occurrence in wounds, especially in the later stages. It arranges itself into V shapes or is aggregated into small bundles, something after the fashion of the diphtheroid group. It is an obligate anaerobe. In pus this organism is usually to be seen inside the leukocytes, and it would appear to possess a pyogenic character, as it is usually to be seen in large numbers in wounds which are producing large quantities of pus, but which differ in no other respect from similar wounds from which the purulent exudate is much less.

24 *Ventrofixation of the Uterus. (Suites physiologiques et pathologiques de l'hystéropexie abdominale directe.) M. Muret.

25 Microscopic Study of Sclerocystic Ovaries, and Operative Conclusions. (La résection partielle des ovaires reconnus macroscopiquement scléreux ou scléro-kystiques, est-elle justifiée au point de vue microscopique?) J. P. de Figueiredo. To be continued.
26 Questions of Priority in the History of Medicine. (La réaction contre la culture allemande en Italie.) L. R. Sanguineti.

24. **Ventrofixation of the Uterus.**—Muret insists that ventrofixation of the uterus is not enough to ensure the complete cure of prolapse of genital organs unless the perineum and pelvic floor are made a good support besides. In two cases he found that the intestines had been gradually forced down into the pouch of Douglas, forming an actual posterior vaginal enterocele. The uterus in both had been fastened to the abdominal wall, but the pelvic floor had not been strengthened. He has found in the literature sixteen cases of ileus following ventrofixation by various technics. Such mishaps are avoided by fastening a large area of the uterus fundus high up on the abdominal wall, when the patient is elderly. With young women he leaves the fundus untouched, and fastens the lower part low down on the abdominal wall, suturing merely a narrow and superficial strip of the uterus wall. This results in the formation of a median ligament uniting the anterior wall of the uterus, just below the starting point of the round ligaments, to the abdominal wall above the pubic symphysis. If the ligament lengthens, the uterus returns to its normal position; if the ligament keeps short, the uterus is held a little higher than usual but there is no interference with pregnancy later. In 250 ventrofixations which he has done he has never known of complications on the part of the intestine later.

28 *Therapeutic Enhancing of Phagocytosis. (Action cytophylactique du chlorure de magnésium.) P. Delbet and Karajanopoulo.
29 *Importance of Epinephrin in Treatment of Wounded Soldiers. (Importance de la notion d'insuffisance surrénale et du rôle de l'opothérapie surrénale en médecine et en chirurgie d'armée) E. Sergent.
30 *Inflammability of Gas in Gas Gangrene. (2 cas de gangrène gazeuse du cou. Procédé de diagnostic différentiel avec l'emphysème souscutané.) Guéniot.

28. **Therapeutic Enhancing of Phagocytosis**—Delbet's experiments on dogs and in vitro have been confirmed by a few clinical experiences, all demonstrating, he declares, the remarkable "cytophylactic power" of a 12.1:1,000 solution of anhydrous magnesium chlorid. Before an intravenous injection into a dog of 150 c.c. of this solution, 245 microbes were found incorporated in 500 polynuclear leukocytes. After this injection, 681 were found incorporated among 500 polynuclears. In other tests the numbers phagocyted were respectively 71 and 308; 387 and 872. The effect seems more pronounced the more nearly normal the leukocytes. The solution does not seem to be toxic; no untoward by-effects were noticed in animals after injections into the cellular tissue, peritoneum or veins. In man he has never injected it into a vein, but has found it useful for dressing wounds and in subcutaneous injections. In one case of a suppurating wound after crushing of the knee, he was contemplating amputation but the phagocytosis under the magnesium chlorid improved conditions so that the limb was saved.

29. **Epinephrin for the Wounded.**—Sergent has been preach- since 1898 the importance of a deficit in suprarenal func- g as a factor in various syndromes. His experi- t a base hospital has confirmed the frequency of acute ance in one or both suprarenals from toxic-infectious es or hemorrhage. Also of sudden aggravation of usly latent debility of the suprarenals. Under ordi- ditions they are able to accomplish their task, but den stress they break down. Both conditions are almost daily in wounded and sick soldiers from Collapse was particularly frequent in typhoid rs who had been under special physical stress. ese cases large subcutaneous doses of supra- ded the men past this dangerous phase. Sim- have been noted in typhus, according to the account of a French medical officer returned from captivity in Germany. In several cases Sergent witnessed the subsidence of the algid phase in choleriform diarrhea under the influence of injections of suprarenal extract. Naamé of Tunis has reported success in cholera beyond all expectations, from the use of epinephrin as an adjuvant to serotherapy. Two of Sergent's patients had been brought in completely collapsed; the asthenia was absolute. One had long presented symptoms of abortive Addison's disease; the other had recurring attacks of asthenia following typhoid years before. Both presented the typical "suprarenal white line," hypotension, hypothermia and tendency to collapse, but both rallied promptly under suprarenal treatment.

The wounded are in such a state of shock, as a rule, that the extra shock of general anesthesia is liable to extinguish the flickering flame of life, unless the surgeon appreciates the important aid to be obtained from epinephrin. Sergent urges that the ambulances, the first aid stations and the trains carrying the wounded should be supplied with suprarenal extract to use in preventing or combating suprarenal insufficiency. Even if the patient's suprarenals are working properly, this treatment is a most excellent tonic for the cardiovascular system. In the collapse of typhoid he warns that the amount must be at least 2 mg. of the 1:1,000 solution, fractioned into four doses, and supplemented by 1 or 2 mg. given by the mouth. This combines rapid and intense absorption with slow and continuous absorption. He is convinced that many of his patients owe their lives to this technic.

30. **Inflammability of Gas in Gas Gangrene.**—Guéniot has found this a useful aid in differentiating gas gangrene from subcutaneous emphysema. On contact with the actual cautery there was a tiny spurt of flame; it was never enough to burn the tissues.

37 Trephining for Shell Wounds of the Skull. (Notes sur les suites opératoires de 33 trépanations pour plaies du crâne par éclat d'obus.) A. Gourliau.

31. **Abdominal Wounds in War.**—These three surgeons attached to field ambulances are all in favor of immediate operations for gunshot or shell wounds of the abdomen.

34. **Lumbar Puncture after Wounds of the Skull or Concussion.**—Baumel has found that lumbar puncture gave important information as to the extent and severity of the injury; it had also a marked beneficial influence as the spinal fluid was always under high pressure, even when there had been merely concussion without direct contact with the skull. The detailed findings in fifty-six cases are tabulated. The wound was the work of a fragment of shell in nearly all the cases. The polynuclears increase during an infectious process so that polynucleosis after injury of the skull renders the prognosis graver. In the cases with lymphocytosis alone, the meningitis, of which it is the index, can be only subacute. With simple commotion of the nervous system, lumbar puncture is the only rational treatment, as also with nonpenetrating wounds of the skull. It reduces also the disturbances from hypertension in cases of severe injury of the skull, while it gets rid of toxins and hastens the return of normal conditions. It should be done systematically, day after day, and seems to be absolutely harmless unless the pressure in the fluid is below normal to start with.

35. **Wounds of the Skull and Contusion of the Brain.**—Leriche devotes sixty-six pages to this study of wounds of the skull and the nerve lesions which accompany them. He has seen 397 cases in which the scrap of shell had apparently merely bruised the scalp. He always made an exploratory incision and trephined if the bone looked in any way abnormal, and seventy-eight in this group were traced to recovery or death. No matter how apparently insignificant the lesion, every wound of the scalp by a projectile should be incised and the bone examined, but the dura should never be incised if it is found intact, no matter how extensive the subjacent hematoma, contusion of the brain and immobility of the dura. High tension in the fluid at lumbar puncture is no criterion as to deep-seated lesions; high tension and an abnormal tint of the fluid reveal the existence of small foci of contusion of the brain which are not so much the work of the projectile as of the air concussion from the explosion of the shell. He found lumbar puncture a valuable aid in treatment. The details of eighty-seven cases are given, as also of eleven in which there was no direct wound but severe contusion of the brain or spinal cord from explosion of a shell or mine. The fluid keeps under high pressure for days and the patients exhibit paralytic phenomena or melancholia with stupor or jacksonian epilepsy. Edema of the brain and small hemorrhagic foci were found on trephining and lumbar puncture gave great relief as a rule.

44 Influences of Diseases, Especially Tuberculosis, on Growth and State of Nourishment of Schoolchildren. (Einfluss von Krankheiten auf das Wachstum und den Ernahrungszustand der Schulkinder.) Thiele.

42. **Tetanus.**—Pribram regards the localization of the spasms as of great importance for the prognosis; it is naturally graver when the muscles of the diaphragm and glottis are involved, even when all the other muscles are spared. Pain in the epigastrium is an early sign of involvement of the diaphragm. He accepts the duration of the incubation as dating from the moment of toxin production, not from the moment of the injury. Three signs differentiate tetanus from tetany: the lack of the facialis phenomenon, of the contraction of the hand, and of the isolated adductor spasms. The frequency of pneumonia in tetanus suggests that it is a specific complication. He was impressed with the fact that in a remarkably large proportion of his tetanus patients, and in nearly all of those that succumbed, signs of the status lymphaticus were manifest.

The best treatment of the wound consists in radical excision of all necrotic tissue down into fresh bleeding tissue. Anything inducing a scab favors development of tetanus. In one case no portal of entry for the tetanus bacilli could be found except peeling between the toes from sweat. The usual measures have no effect on the diaphragm-glottis spasms. All we can do is to hold back normal breathing and supplement it at need with artificial respiration; we can realize this by severing the phrenic nerve on each side, with or without tracheotomy, by injecting magnesium sulphate with the shoulders lowered, or by gradually limiting the normal breathing by large doses of morphin. The morphin has to be given in increasing doses up to 0.3 gm. per day; ordinary doses have no effect. Symptomatic treatment aims to ward off spasms, and this is imperative with diaphragm-glottis spasms as any one is liable to prove fatal. When all is in readiness for artificial respiration, these large doses of morphin need cause no apprehension, he says.

45. **Management of Typhoid in First Few Days.**—Koranyi has been studying the influence on the course of typhoid, in his 523 cases, of the care of the patients during the first few days. The mortality increased from 5.6 per cent. among those patients received at the hospital from the first to the fourth day of the disease, to 10.1 per cent. after the seventh day.

Jahrbuch für Kinderheilkunde, Berlin

September, LXXXII, No. 3, pp. 175-260

53 *Albumin Milk. (2½ jährige Erfahrungen mit Eiweissmilch.) V. Poulsen.
54 *Congenital Ichthyosis. O. Bossert.
55 *Etiology of Scarlet Fever. F. Schleissner.
56 *Relations between Otitis Media and the Various Diseases of Infants. (Beziehung der Mittelohrentzündung zu den Krankheiten des Säuglingsalters.) F. Scherer and O. Kutvirt. Commenced in No. 2.

53. **Albumin Milk.**—Poulsen makes the albumin milk a little different from Finkelstein's formula, using 9 parts casein to 8 parts carbohydrate instead of Finkelstein's 2 to 1. It also contains a larger proportion of whey, namely, ⅕ liter whey plus the whey from ½ liter buttermilk, thus ensuring a larger amount of salts. One liter represents 560 calories instead of Finkelstein's 420. Poulsen has found this albumin milk most effectual in chronic diarrhea in infants over a year old, but he summarizes in detail his experiences with 124 infants fed on this albumin milk and their development followed during the months and years since. He emphasizes the importance of constant vigorous stirring while boiling up. He passes the freshly clotted casein from 1 liter of full milk through a hair sieve at least ten times, after mixing it into ½ liter water and ½ liter buttermilk. The cane sugar is then added, dissolved in as little water as possible, and the whole is boiled up and passed through a hair sieve until it is nearly cold. Then it is chilled further in water and the bottles are filled and placed on ice.

54. **Congenital Ichthyosis.** — Bossert says that only one original case of this affection has been published in German pediatric literature, and he gives here an illustrated description of a typical case encountered at Breslau. The skin was hard as leather and had cracked at numerous points. This horny shell over almost the entire body prevented suckling and the normal play of the vital processes, and the infant lived only four days. It was the first child of healthy and well-to-do parents, and seems to be about the sixtieth case on record.

55. **Etiology of Scarlet Fever.**—Schleissner succeeded in twelve of twenty-seven attempts in inducing in monkeys a disease apparently identical with scarlet fever. He insufflated into the mouth and nose twenty-four hour bouillon cultures of streptococci from scarlet fever cases. The disease could be also transferred to healthy animals by smearing with secretions from the throats of those affected. It proved impossible to reinfect those in the latter group, indicating that immunity had been realized. Likewise all attempts failed at inoculation with filtrates of the bouillon cultures.

56. **Otitis Media in Infants.**—Scherer and Kutvirt here conclude their study of the relations between otitis media and the various diseases of infancy. They found otitis media in 18.6 per cent. of the cases of nutritional disturbances, and in from 6.6 to 25 per cent. of the affections of the air passages, the proportion being larger the closer to the eustachian tube. The vomiting with digestive disturbances, the *sneezing with rhinitis*, and the coughing with bronchitis and pneumonia explain the frequent involvement of the middle ear. Fully 22.3 per cent. of the infants with inherited syphilis had otitis media, and 30.4 per cent. of the tuberculous infants. In these two groups the ear trouble developed insidiously. In every case of parotitis there was also otitis media. The latter seems to be only exceptionally a primary affection. Otitis media is always a grave affection for infants, depressing the vitality, and it may even prove fatal. But proper treatment, as for adults, applied early is generally followed by prompt recovery, although a tendency to recurrence may be apparent into late childhood.

They call special attention to their three cases of convulsions (eclampsia) in all of which there was a suppurative otitis media. Paracentesis was followed by prompt subsidence of the convulsions and striking improvement in the general condition. The circumstances in these cases render the assumption plausible that both the convulsions and the otitis media were manifestations of intestinal infection and intoxication.

60. **Typhoid in the Inoculated.**—Bronner has been studying in particular the agglutination titer after inoculation. He tested for it in 104 cases with intervals of from one to seven months since the inoculation. He was surprised to find that the eighty-fifth day seemed to be the dividing line. Up to that day all responded positively to the agglutination test, but after the eighty-fifth day 47.2 per cent. gave no agglutination response. The intervals between the inoculations did not seem to influence the agglutination titer. This test cannot be accepted as a criterion for the diagnosis of typhoid with a titer above 1:200, and only in about 89 per cent. of the cases can it be utilized for the diagnosis. An increasing titer, regardless of the actual figures, strongly suggests typhoid if a month at least has elapsed since the inoculation. The course of typhoid is modified by the inoculations, but it still retains its typical character. The blood picture and urine findings are apparently not influenced if the interval since the inoculation is longer than two weeks. It is a little more difficult to cultivate the bacilli from the blood, and serologic tests cannot be depended on in fully one fifth of all cases after three months.

64. **Means to Prevent Injurious Action of Anesthetics on the Central Nervous System.**—Weber has been making a special study for years of the central mechanism for the innervation of the blood vessels, and the war has afforded him unprecedented opportunities for this research. Some of his conclusions were summarized in these columns June 5, 1915, p. 1949, as he applied in treatment of concussion of the brain some of the facts learned in his experimental work. The vessels shrink, instead of the normal dilatation, during mild muscular effort when the central mechanism for the innervation of the vessels is deranged. The standard test is by dorsal and plantar flexion of the foot, hanging free; in health this gentle exercise induces dilatation of the vessels elsewhere in the body (except in the brain). After local anesthesia there are evidences of perverted vasomotor functioning, lasting for one or two days, and in about half the cases there is disturbance in the vascular reaction. With chloroform general anesthesia, the same occurs but much more pronounced, the disturbances lasting from five to six days and the morbid vascular reaction occurring in every case and being still manifest from one to six weeks afterward.

He theorizes to explain these phenomena, commenting on the extreme sensitiveness of the central vasomotor mechanism to injurious influences brought by the blood. He also comments on the prompt way in which this mechanism seems to be steadied and brought back to normal under the influence of stimulation from alternating hot and cold douches. This report is based on fifty cases studied from this point of view and known to have had normal conditions before the anesthetic was applied. Tracings from two cases are given; in one the tests showed abnormal conditions persisting four weeks after the chloroform. The alternating hot and cold douches were then applied (as described in the abstract referred to above). and by the fourth douche all the symptoms had disappeared, including the muscular weakness, exhaustion on climbing stairs, profuse sweating on slight exertion, and headache—all part of the syndrome resulting from derangement of the central mechanism for innervation of the vessels. Ether seemed to exert an injurious influence to a degree about midway between that of local anesthesia and chloroform.

66. **Fat Embolism in Military Surgery.**—Bürger remarks that the clinical diagnosis of fat embolism in the lungs or in the organs of the greater circulation was never made during life in the cases in his experience. But the clinical picture as he describes it seems to be characteristic. Prophylaxis is extremely important in managing the wounded in war. The Esmarch bandage should be applied the same as for hemorrhage to ward off fat embolism in all cases of multiple fractures or single fracture in the severely wounded, especially the elderly and those weakened by disease or alcohol, those that have been run over by a vehicle or thrown from a horse or hurled by an explosion. Immediate application of the Esmarch bandage will not only prevent further destruction of fat tissue by the blood, but will prevent that already broken up from being transported elsewhere. Even Momburg constriction at the waist line might be advisable, especially with crushing injury of the pelvis. Judging from his experimental research, already disintegrated fat may become bound by coagulating blood, and thus the danger of embolism be averted. The Momburg constricting band should not be left on too long; half an hour should be sufficient. Before removing the Esmarch bandage, venesection might drain away any loose fat particles in the blood, but Bürger thinks that this is scarcely necessary. Injection of gelatin into the limb might favor development of thrombosis.

It is extremely important, he reiterates, to leave the severely wounded where they are; any attempt to move them to a distance is liable to bring on fatal fat embolism. It may be necessary to make ample provision for draining the crushed soft tissues. When a crushed limb has to be amputated, the danger of fat embolism must be heeded more than has been the case hitherto, and, for the same reason, delirium should not be allowed to develop or should be checked.

The toxic action of chloroform is magnified when there is fat embolism. Most physicians regard fat embolism as beyond all aid, but Bürger thinks that much can be accomplished by prompt diagnosis and opening up of the focus in the bone and tamponing it. Venesection also relieves the heart combating against the fat embolism in the greater circulation, kidneys, etc. Saline infusion seems contraindicated, in his opinion, although Gaugele advocates it. Stimulation of the heart he regards as useful.

In his experience, the onward passage of the fat emboli seemed to be independent of the heart force, and to depend rather on the nature of the fat and the construction of the lung capillaries. Diversion of fluids to the intestines, as with calomel, is liable to prove useful. If symptoms of pressure on the brain develop from venous stasis or hydrocephalus, leeches to the mastoid process might divert the fluid effectually, as also revulsion in the scalp by hyperemia induced by an irritating salve. Lumbar puncture may also aid in diagnosis and as a therapeutic measure, but it must be applied with extreme caution. After recovery from fat embolism, we must expect considerable damage from the passage of the fat emboli, and time must be given for repair, longer than would be necessary with the same wounds, fractures and contusions without the embolism. We may expect to have the patient complain long of general weakness, dizziness, ready fatigue, heart disturbances, dyspnea, or depression. Lumbar puncture may relieve or cure some of these persisting symptoms, supplemented by hot foot baths, air and sun baths and revulsive measures in general, warning impressively against overexertion either mental or physical. If possible the patient should be given light work and gradually resume his ordinary occupation.

69. **The Meat Extract Test Breakfast.**—Rosenhain has been giving Mintz' test breakfast a thorough trial. (It was described recently in The Journal, Sept. 18, 1915, p. 1067.) He tabulates the findings in twenty cases with parallel test breakfasts. They testify that the Mintz technic is reliable and highly instructive, but that it belongs to hospitals and laboratories rather than to general practice. The Ewald test breakfast answers practical purposes better and gives all the information needed as a rule in general practice.

84 Wounds of Peripheral Nerves. (Ein offenes Wort an die Kollegen.) W. Fürnrohr.

73. **Ingestion of Salt Checks Sweating.** — Link gave a number of consumptives in his care a level teaspoonful of salt in half a glass of water, that is, about 5 gm. sodium chlorid in 150 c.c. water, on the assumption that the loss of salt in the night sweats might be responsible for the depression felt after them. To his surprise he found that the patients did not sweat as freely as under other conditions. The salt evidently checked the production of the night sweats. Since then he has given salt systematically in this way to over a hundred tuberculous patients and the effect was almost invariably good. The salt even checked sweating under sodium salicylate and during the crisis in pneumonia. The possible causes for this action of salt are discussed at length and he reports further the apparently favorable influence of ingestion of a hypertonic solution of salt preliminary to long marches to prevent excessive sweating.

83. **Ring to Protect Open Wounds.**—A broad strip of roofing paper is slit at intervals along one edge, and the strip is then rolled into a ring to fit over the lesion. The slit edge adapts itself to the surface of the skin below. A sheet of gauze is laid over the top of the ring, held in place by a second narrower ring slipped on outside. The tar paper does not absorb secretions.

87 Vaccineurin in Treatment of Neuritis. K. Löwenstein.
88 *Nonsurgical Treatment of Anal Fissures. F. Schilling.

86. **Dyshormonism.**—Kohnstamm relates a number of instances in which thyroid or hypophysis extract or epinephrin caused a surprising change for the better in various morbid conditions from disturbance in internal secretions, superposed on or caused by the emotional stress of the campaign or resulting from concussion of the nervous system. He regards neurasthenia in soldiers as having a somatic basis in molecular disturbances or changes in the nerve tissue like those which distinguish magnetic from nonmagnetic iron. In several cases some of the symptoms of exophthalmic goiter had developed in soldiers and officers on active service, but it subsided under antithyroid treatment. A typical asthma or bronchitis was materially benefited in many instances by a combination of hypophysis and suprarenal extracts. In one case of exophthalmic goiter in a soldier, tachycardia changed to bradycardia as jaundice developed and then returned again as the jaundice subsided. Hypophysis extract seemed to combat insomnia effectually and also proved useful in a case of periodically recurring functional angina pectoris of vasomotor origin. As the attacks returned regularly ten days before the menstrual period he assumed that ovarian functioning was responsible for them, and hence aimed to give the antagonistic hormone in hypophysis treatment. Its action on the heart is the more striking as it contracts the coronary vessels instead of dilating them like epinephrin.

88. **Anal Fissures.**—Schilling relates that only nineteen were females in his forty-six cases of anal fissure. In bottle infants with lime-soap stools, the resulting fissures usually heal under addition of carbohydrates to the food. Superficial fissures heal under a protecting salve containing a little anesthetic. Others may heal under Peruvian balsam or ichthyol. He disapproves of caustic applications, and combats the spasms and constipation by injecting a local anesthetic into the muscle below the tear. Glycerin suppositories are irritating; he prefers a pint of soapy water or soda-oil introduced through a soft tube with a number of openings. Twice or once a day he injects into the rectum some astringent, 150 c.c. of a weak solution of tannin or 1 c.c. tincture of krameria in 200 c.c. warm water, or 0.25 per cent. solution of copper or zinc, the patient lying on his left side and straining to expel all the fluid. This exercise in straining while reclining helps to relax the sphincter. Later he applies a little balsam or ichthyol. There must be no straining at stool, as this congests hemorrhoidal nodules. The accompanying nervousness must be combated likewise. With patience and perseverance the fissures gradually heal over under this treatment, as a rule, the tear filling up with scar tissue.

100. **Nut in Bronchus.**—Telega gives the history of a patient who had had a nut in the bronchi for six years. The symptoms from it were those of advanced tuberculosis. The foreign body was finally coughed up, but the patient soon died from pulmonary hemorrhage.

101. **Pathologic-Anatomic Effects of Poisonous Gases.**—Pojarisky studied the pathologic changes from asphyxiating gases in forty cases; in six cases after an interval of from twelve to thirty hours, in twenty after two or three days, and in fourteen cases from three to eleven days after the asphyxiation. The principal changes that occurred within twelve hours after asphyxiation were marked edema of the lungs and partial atelectasis, and severe changes in the blood, especially in Bizzozzero's blood plates and in the walls of the vessels, the endothelium. The red corpuscles suffer but little. Owing to these changes in the blood, substances form which increased the coagulability of the blood, rendering it thick and unable to circulate. In many cases there was formation of white adherent thrombi. The blood changes and thrombi formation render the work of the heart very difficult, and the nutrition of the tissues suffers, which leads to asphyxia and death from pulmonary edema. Miliary hemorrhages in the brain are very frequent. After three days complications may arise, such as putrid bronchitis, partial pulmonic gangrene, pleurisy, embolism, hemorrhagic infarcts, etc. These complications may lead to permanent disability even if there is recovery from the asphyxiating gases.

105. **Mechanism of Neutralizing the Acidity in Stomach and Intestine Contents.**—Zaitzeff studied the mechanism of neutralization of the acid stomach and intestine contents on five dogs with gastric, duodenal or intestinal fistulas. Altogether, twenty-eight experiments were made, of which four were done on a dog with a pyloric fistula. He found that the neutralization of the acidity in the *stomach is done* by the pancreatic juice, which is also responsible for the neutralization of the acidity in the upper portion of the small intestine. In the lower *portion this is* accomplished by the intestinal juice and mucus. The acid fluids (contents) having been neutralized, are absorbed all along the small intestine, and do not reach the end of the latter. The source of chlorin in the stomach is the pancreatic juice, as the proportion of chlorin increases in the stomach when acids not containing chlorin, such as acetic, sulphuric or lactic acid, are introduced into the stomach. The less concentrated the acids introduced into the stomach, the lower becomes its acidity. In the pyloric portion of the stomach the acidity is lower than in the fundus, because of the presence of the pyloric alkaline juice. After introduction into the stomach of acid fluids, the stomach content acquires the properties of trypsin digestion, that is, proteins are digested in an alkaline medium. This also shows that pancreatic juice gets into the stomach under such circumstances.

106. **Treatment of Poisoning from Caustic Substances.**—*Dillon obtained excellent results in the treatment of poisoning with caustic substances such as glacial acetic acid, phenol, ammonium chlorid, sulphuric acid, etc., from lavage of the stomach always preceded by a hypodermic morphin injection to relieve the shock. The esophagus must be soothed and not irritated, which he realized by giving the patient by mouth pure olive oil, 200 gm. in twenty-four hours, keeping this up for seven or eight days if necessary. This was followed later by sweet cream, raw eggs, mucilaginous substances and butter, and gradually ordinary solid food is resumed. Water can be given in the form of rectal injections of normal salt solution, 100 or 150 gm. every two hours, or by the drop method. In addition the mouth should be kept clean, rinsing the mouth with some antiseptic solution, preferably hydrogen dioxid. Of 120 patients thus treated only one died. Three others did not reach the hospital until moribund and the treatment could not be carried out.*

109. **Prevention of Mercurial Stomatitis.**—*Almkvist has* published a number of works on this subject since his first report of experimental research in the *Nordiskt Mediciniskt Arkiv* in 1903. This stomatitis develops only when the blood contains mercury in a form that combines with albumin on and around the teeth to form an *irritating compound.* Prevention must be directed to keeping the cracks and crevices of the mouth clean of *albumin.* The *tooth powders* used must be of absolutely soluble material so that nothing be left to get into crevices, and all tartar must be carefully removed. Treatment should aim to sterilize all the crevices and he uses a syringe with long fine tip to force the disinfectant into the crevices. He has found hydrogen peroxid especially effectual when used freely in this way. If this is done now and then during the *course of mercurial* treatment, even the predisposed may be saved from stomatitis.

RELATION OF THE HOSPITAL TO THE COMMUNITY *

WINFORD SMITH, M.D.
Superintendent, the Johns Hopkins Hospital
BALTIMORE

To state that the modern hospital is a factor of great importance in the life of every community is to state a fact so well recognized, so oft repeated, that it seems almost an impertinence to say it again. Yet, strange as it may seem, there exist the greatest differences in standards, in fundamental principles, in organization, in scope of work, together with a great deal of ignorance on the part of the public, of physicians and of hospital administrators as to what hospital efficiency means. It might also be said that there is only one factor common to all and that is the uniform purpose of trying to make sick people well.

Consider for a moment the different methods of support for hospitals. In America we have two main types — the semipublic or endowed and the municipal or city hospital. I am speaking of general hospitals and therefore do not include the state hospitals for the insane. In this country it can be said without fear of contradiction that the best hospitals, those that have contributed most up to this time to medical education, to scientific work, and which have been managed with the greatest efficiency in the interests of the patients, have been the endowed hospitals. The municipal hospitals have been for the most part, and are still, interfered with by local politics, medical and otherwise, are insufficiently staffed, insufficiently supported and poorly managed.

In England we find a somewhat similar condition, the majority of the hospitals being supported by the subscription system. In Germany we find quite the reverse, the majority and the best hospitals there being supported by the state or the municipality and used for the broadest purpose of service, in that medical education and research are encouraged and supported everywhere.

In America we find the hospitals providing for both classes of society — the poor who cannot pay, and the more fortunate class, those who can. In England, adequate provision is made only for the poor. Sir William Osler has said that one of the greatest needs in the English hospital system is that provision should be made in the general hospitals whereby the well-to-do may receive treatment as good at least as that afforded the poor. In Germany the condition has, until comparatively recently, been somewhat the same.

We therefore see the widest differences with regard to support and scope of work, in the hospitals of three of the largest countries of the world; and these conditions typify those of practically all other countries.

What is the rational basis of support and what should be the scope of the work? Consider the condition in your own country. The state or city assumes the responsibility of providing for the insane, the defectives and those suffering from tuberculosis. The cities provide for the care of those suffering from contagious diseases and for a limited number of the poor who require treatment in a general hospital. But by far the majority of the poor must get hospital attention in those institutions which are supported by private philanthropy. It is the duty of some one to care for those too poor to provide for themselves. We have not yet accepted the principle that it is the duty of the rich to care for the poor. It would seem therefore that the duty rests with the city or state, or both. Now I am not arguing in favor of abandoning our hospitals which are supported by private funds, not at all, but I do wish to at least try to help to place the responsibility where it belongs. We are too accustomed to our present methods to make such a radical change without involving great sacrifice and great suffering, for on the part of the city and state authorities, our present methods are largely the result of lack of appreciation of the responsibility and the need. Furthermore, our system has worked well, but there is need that the responsibility be recognized and appreciated in order that the burden may not continue to be so unequally divided. That hospitals are obliged to accept state appropriations, made according to the whims of legislators, or according to the influence brought to bear, that they are obliged to accept per capita allowances from the city, which represents frequently not more than one-quarter, and rarely more than one-half the actual cost of caring for a patient, is neither in accordance with the principles of business nor equity.

The cost of hospital administration is increasing each year, and the financial burden for most hospitals is a matter of grave concern. The point which I wish to make is that, in the final analysis, the responsibility does not rest with the private philanthropist; and while it is in every way desirable to continue our system of endowed hospitals and to foster that particular kind of philanthropic spirit, it is at the same time absolutely necessary that the state and municipal authorities recognize their responsibility, recognize that these hospitals are doing a great public service, and when aid is needed, that the per capita allowance should be based on facts and at least approximate the actual cost of the service rendered.

---

* Chairman's Address, read before the Section on Hospitals at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

What should be the scope of work? By that question is meant, should hospitals provide only for the poor? It is an accepted fact that today a person who is actually ill with any serious illness requiring medical or surgical attention stands a much better chance of recovery if he receives treatment in a hospital. It is also generally conceded that, on the whole, the physician's private hospital, or the nursing home, does not supply the same advantages that can be obtained in the well-organized, thoroughly equipped general hospital. If these facts are accepted, then it follows that if a hospital is intended to serve the fullest needs of the community, it should provide, for those who can afford to pay, facilities at least as good as those furnished to the poor who cannot pay.

We have been considering the hospital in its relation to the community as an agency for the relief of suffering, and as such, whether endowed or supported by the municipality, it is a necessary factor in the preservation of health. The hospital is much more than that. It is an educational factor of great importance, both to the community in which it is located and to the country at large. Many of these hospitals are teaching institutions, furnishing the opportunity for bedside instruction and the practical experience for large numbers of students of medicine, who, when they have received their degree, go out to practice in that or some other community. Every hospital has its resident staff of physicians and surgeons, numbering all the way from one to a hundred, who serve in the hospital from one to several years. Here they perfect themselves, acquire a high degree of skill in diagnosis, treatment and surgical procedure, and in time go out to give the benefit of that skill to some community.

Furthermore, it is in the hospital wards and operating rooms that the senior members of the staff, by the study of large groups of patients, and by the experience gained in operating on large numbers of patients, acquire a skill and technic that has been such an important factor in the progress of medicine and surgery. In the laboratories, too, as a result of careful routine study, or of painstaking experimental work, new facts have been discovered, of the greatest importance in medicine and surgery, and to mankind.

The effect of this group of earnest, skilful workers in any community has a very practical value in the development of public hygiene, better sanitation, better living conditions and a higher plane of existence.

Then there is another most important group—the nurses. Every hospital of any size has its training school for nurses. In this school each year a number of young women are trained to give competent, skilful attention to those who are ill. We now recognize that good nursing is often quite as essential as good medical attention, and is just as often equally responsible for a favorable result. Hospitals turn out annually thousands of trained nurses, who in practicing their profession play an important part in maintaining the health of the community in which they work. The trained nurse is now called on to perform work which is vastly more important and vastly different from what was originally expected of her. In almost every phase of our civic and social life, she is called on to organize, to systematize and to teach, as private nurse, visiting nurse, school nurse, rural nurse, health department nurse, inspector and so on. The nurse is a most necessary and valuable aid to the physician, to the sanitarian and to social service. I cannot refrain from saying that it is high time that the medical profession and the public realize this, and that steps be taken to safeguard this profession from quackery and inefficiency, by establishing proper standards of education, which hospital training schools must meet, and by demanding compulsory registration for the nurse as well as for the physician, the pharmacist, the dentist, the osteopath and the barber. It will come and it will be the more to our credit that we show an intelligent interest and an early interest in bringing about this desirable result.

When we consider the work of the hospital in its broadest sense, we realize that it is not simply a place where sick people are cared for, but it is an educational institution of great value where those things are taught which mean health and happiness.

There is another side to the question, however. Has the hospital fully measured up to its opportunities, has it fully met the needs of the community? I think not; and I wish briefly to speak of a few of the possibilities for still further service. I do not pretend to say that there remain only a few questions to solve. Some hospitals are as nearly perfect as our present ideas can conceive, but many others are far from having attained that standard.

The first question which I wish to present to you is the need of a private or semiprivate service for patients of moderate means. The practice of medicine is now highly specialized. While people with ordinary ailments are satisfactorily treated by the average doctor, as soon as a person becomes seriously ill with any one of a large number of diseases with their usual complications, that person is no longer safe in the hands of the average doctor. If the doctor is intelligent and honest, he calls in some other doctor of larger experience and greater skill. He, in turn, may call in a specialist, who may advise a Roentgen-ray examination, after which still another doctor is consulted. Now, if the patient be a poor man, he may go to the hospital and in the public ward get all of this for nothing, or for a modest charge well within his means. If the patient be a man of large means, he of course has no difficulty. But if the patient is a member of that large class—those in moderate circumstances—earning a salary of from $1,000 to $2,000 per year, with a family to support, he cannot afford to pay the customary fee for such services, either within or outside of the hospital, for his pride prevents him from going into the public ward. What is to be done for him? In my opinion a hospital service between the public ward and the expensive private room, for the benefit of this class, represents a very great need. How shall this be provided? Obviously, it is not the duty of the city to provide such a service, the need of which arises simply because of the patient's pride and lack of funds. Equally obvious is it that funds given strictly for the benefit of the poor should not be diverted to this purpose.

Assuming, therefore, that this service is much needed, it is apparent that it must be provided by special endowment or by the use of a portion at least of the unrestricted funds. Boards of trustees should be educated to appreciate this need. Furthermore, it may safely be said that the amount required would probably not be larger, if any, than that which would be required to support the same number of patients in the public wards. In other words, the difference between the amount paid by the patient and the cost would not be much more in the one instance than in the other. It is taken for granted that while the patient could and would pay a moderate charge for privacy, he would not be willing, even if allowed to do so, to pay more than the usual ward rate for attention in the public ward. Therefore, the net cost to the hospital would be about the same in either case.

It is a subject which requires the careful consideration of hospital authorities. While I do not think it is a measure which should be adopted in a teaching hospital, because of the complications, it should be considered carefully by those which are not used for teaching, which represent the vast majority.

In line with this is the question of a pay clinic, or dispensary for the same class. The reasons for this are the same as those mentioned above, namely, the expense of getting competent advice when it is required from one or more specialists. There is a large class of patients who are able and willing to pay a moderate fee, but who cannot meet the regular fees of competent specialists. There are many who need such advice and who do not need to enter a hospital for treatment. The free dispensary is not for these, nor will they go to the free clinic and take their turn with large numbers of their less fortunate fellows, and yet they need a place where they can go and get just such advice as can be obtained in the free dispensary. Indeed, the fact that they have gone to the dispensary for advice has, in my opinion, been somewhat responsible for the talk about dispensary abuse. Yet many of these patients would gladly have paid a moderate fee and had no intention of imposing on any one, but were simply trying to get what they needed at a price within their means.

For this class, then some system needs to be devised by which they can get the necessary examination by one, two or three specialists at a fee within their means. Of course the argument against such a clinic will be that it interferes with the private physician. It is true it would interfere with the private physician, but if we recognize the need of such a clinic, we at the same time admit that the average physician does not fill the bill and cannot give the patient proper advice or treatment. Furthermore, it is an argument for fewer physicians better trained.

While a number of free dispensaries are necessary in every large city, there would not be need of more than one of two of these pay clinics. A consideration of the trend of modern medical practice, a superficial study of the desires and perplexities of a large number who seek advice from the hospitals, is sufficient to demonstrate that some provision should be made for those who can pay only moderate fees. Take as an example the clerk who earns from $1,000 to $2,000 per year and has a family to support. He makes both ends meet and that is all. It is for this man, as a representative of this class, that the pay clinic is needed.

The clinic should be organized very much as our efficient free dispensaries are organized. A few carefully chosen men, representing the different branches of medicine and surgery, should constitute the staff. The fees should be such that the patient could get competent advice at a total expense within his means, say for $10, and subsequent treatments or examinations for a small sum, say $1 or $2. The clinic could be run at night, so as not to interfere with the regular hours of the staff members. Such a clinic is urgently needed in every city of considerable size. The chief difficulty will be found in educating the rank and file of physicians to appreciate this need and to give their support. It is time that we gave serious consideration to this subject, for a solution of some sort must and will be found.

Finally, I wish to call your attention to one other problem that needs attention and which represents one of the weak points of our present hospital and social system. All hospitals are discharging, every day, patients whose physical condition requires some changes in the mode of life of the individual. The patient may be a stevedore or a truckman, with a weak heart, or he may be a mechanic who has lost a leg or an arm, or he may be partially paralyzed, or he may be suffering from any one of a number of conditions which make it impossible, or at least inadvisable for him to return to his old employment. These patients are being discharged day after day with advice, good advice to be sure, but which, the chances are, not one patient in ten can carry out unaided. The patient with the weak heart, who has always been a stevedore, and whom we tell not to do any work which involves a physical strain, is bound sooner or later to go back to the only sort of work he is familiar with, unless someone makes it his business to see that he gets employment suitable for him. This class of patients needs assistance simply to find suitable employment, and this aid can be supplied temporarily by someone in the social service department to whom this special work is delegated. But what of the man who has lost a leg, or an arm, or both, or who is permanently crippled? He is another and more difficult problem, for the only remedy is reeducation. He must be taught some work or trade which, even in his crippled condition, he can do as well as the man who is physically sound; or if that is impossible he should be taught something which will enable him to be, at least, partially self-supporting. To enable the individual to retain his self respect, when otherwise, as a useless member of society, he would lose it, is something well worth while. The hospital takes the patient in, patches him up and does a good job so far as it goes, but when the hospital sends that man out with advice which it is a foregone conclusion the man cannot follow, that is where the process falls short of being complete. Is this completion of the process the problem of the hospital? you may ask. I do not think so, and yet some agency is necessary to complete the work so well done up to this point, and the failure to supply such an agency means a tremendous waste of human material and oftentimes a repetition of work again and again.

I do not think it is a problem of the hospital, because it is a problem with every hospital, and for every hospital to attempt to do this work for its own patients means a great reduplication of work and a great waste of money. In my opinion there should be one central agency for the community, to which all hospitals could refer their patients of this class, with the proper prescription as to work to fit the condition. That agency would have to meet two problems; that of finding suitable employment for those who are simply physically weak, and the second and more difficult problem of teaching the cripples and the patients with the more severe cases of physical defects a new trade.

To solve this problem adequately is a big undertaking, but it is well worth while. It is a community problem, and an agency or institution to meet this need is just as much needed as a hospital. Consider the possibilities, the preservation of the self-respect and courage of these men and women, the finding for them, or the creation for them, of a useful existence, when unaided they are doomed to lives of idleness, uselessness and despair. It certainly presents great possibilities of increased efficiency in our present system.

We have had examples of the possibilities in the institutions for the blind, Dr. Hall's pottery at Marblehead, and Dr. Jaeger's Hospital of Hope in New York. All of those who have had much to do with hospitals will recognize the need.

I wish further to make the point that this work should not be based on appeals to the sympathy of employers, but on demonstrating or developing the fitness of the individual for the job. Sympathy employers may have, but they cannot be expected to clog their machinery with the unfit. I cannot at this time go into the subject at greater length. I wish, however, to urge the importance of this subject.

These are a few of the problems still awaiting solution and they loom up large. Ten years ago a hospital authority remarked that it seemed to him that most of the hospital problems had been settled. I hardly think we could agree with him, even now, only ten years later, for as I see it, the modern hospital is becoming an increasingly important factor in every community, both in the preservation of health and as an educational institution.

THE ESSENTIAL FACTORS IN THE DIAGNOSIS OF CHRONIC GASTRIC AND DUODENAL ULCERS *

GEORGE B. EUSTERMAN, M.D.
ROCHESTER, MINN.

This review is undertaken to emphasize proved clinical factors and briefly to consider various phases of experimental, clinical and therapeutic advancement in their application to the diagnosis of benign, chronic gastric and duodenal ulcers. Our observations are based on the study of 2,400 cases of gastric and duodenal ulcers operatively demonstrated in the Mayo Clinic from 1900 to 1914, inclusive, with an especial summary of the cases of 1913 and 1914.

DIAGNOSIS

A skilful anamnesis, in the absence of extensive clinical observations or direct roentgenologic evidence of a lesion, is still the most important factor in the differential diagnosis of lesions causing gastric disturbance. With regard to ulcer, characteristic chronicity or remission of symptoms is readily apparent in the case records in over 80 per cent. of all our proved cases. The principles emphasized by Graham[1] since his earliest observations are as effective today as then and are the accepted diagnostic criteria in a large daily experience. Pyloric and duodenal ulcers in which complications are not far advanced invariably manifest periodic exacerbations. Seasonal variations, especially of spring and fall, appear in almost 40 per cent. of all cases. Nervous and physical fatigue, infection and exposure, dietetic indiscretions, toxic intestinal disturbance, etc., are prominent factors influencing recurrences. Between seizures complete relief from symptoms is the rule although frequently in ulcers situated well up along the lesser curvature remission rather than periods of complete relief may occur. In general the greater number of these patients have had symptoms for from five to twenty years, in our experience, few less than one, and a constant average of twelve and one-half years. During the period of attack, pain or distress, variable in character and intensity, is the common and constant symptom in nearly all cases.

Of secondary diagnostic significance are the location, type and area of radiation of the pain. The time of pain and method of its control are of primary importance. The complex of chronicity and periodicity of attacks in which pain or distress and the usual association of symptoms repeated uniformly day by day during the attack and bearing a fairly definite relation to food intake and control is of primary clinical importance in the diagnosis of 80 per cent. of cases of uncomplicated peptic ulcers. In the remaining 20 per cent. this complex may be irregular, atypical or almost entirely absent; or the symptoms may be "mixed," owing to coincidence of disease in contiguous organs, which occurs in about 16 per cent. of all cases of ulcer. It is this group which often taxes the resources of the clinician, but errors in diagnosis do not easily occur if the possibilities are constantly borne in mind especially in cases (1) in which a perforative process or a painful spasm simulates hepatic colic, (2) in cases in which ulcers had become chronic and complicated when the first symptoms appeared, and (3) in cases suggesting a malignant process, the result of an extensive ulcer, hemorrhage, cachexia and perhaps a palpable inflammatory mass.

Clinical differentiation between gastric and duodenal ulcer is extremely difficult and in most instances wellnigh impossible. This has been the opinion of most observers. With great regularity late pain and the nature of hemorrhage in proved gastric ulcer may suggest duodenal lesion. Then, too, not infrequently the earlier onset of pain in some cases of duodenal ulcer, suggests gastric lesion. In about 5 per cent. of all ulcers coincident lesions in the stomach and duodenum are noted, an incidence which increases our difficulties. In our experience and in that of many other observers the Roentgen ray is of inestimable value. In this field it has its most practicable application besides occasionally furnishing the first reliable evidence to indicate the presence of ulcer; but too great reliance must not be placed on this; for, valuable as may be the information afforded by the Roentgen examination, it has its limitations. The degree of demonstrability of gastric ulcer is directly concerned with three factors: that is, position, size and depth of the ulcer. The direct sign of irregularity of the gastric contour (niche, accessory pocket) may be wanting in instances in which the ulcer is situated on the anterior wall, high up in the cardia and when it involves the pyloric segment; should it be shallow, "slit-like," it may not be successfully demonstrated.[2] Indirect and auxiliary signs, however, in combination with clinical data, may be helpful in establishing the diagnosis. The strikingly frequent occurrence of bulb deformity or hyperperi-

* Read before the Section on Practice of Medicine at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

[1] Graham, Christopher: Diagnosis Between Duodenal Ulcer and Gallstone Disease, The Journal A. M. A., Feb. 9, 1907, p. 515; Differential Diagnosis of Diseases Causing Gastric Disturbances, Northwestern Lancet, 1910, xxx, 139.

[2] Carman, R. D.: The Diagnosis of Gastric Ulcer by the X-Ray, Read before the Kansas Medical Society, Kansas City, Kan., May 5, 1915.

stalsis with residue in duodenal ulcer is worthy of note from both the point of diagnosis and localization.

The continuous or intermittent presence of altered or fresh blood in the gastric extract, the absence of evidence pointing to gross motor disturbances and the situation of pain and tender point to the left of the median line are strong presumptive evidence of gastric ulcer. Clinically, this general observation can be made: Uncomplicated types of duodenal and pyloric ulcer are invariably clear-cut throughout their life history; the longer the period between intake and pain, the lower the ulcer, as a rule; the more prompt the onset and the briefer the duration of pain, the higher the ulcer. In ulcer of the stomach proper this may not be so clear-cut as in duodenal or pyloric types, nor are the day-by-day symptoms so clearly defined. In ulcers well above the pylorus the symptoms are likely to be continuous, or remissions rather than intervals of complete relief are likely to be noted. The pain is not so often relieved by food; small amounts of food may give relief, while increased amounts may cause distress; more care as to diet is necessary; if bleeding occurs, hematemesis predominates; vomiting plays a more frequent rôle even in the absence of obstruction and affords relief; soda relieves pain when food does not; pain begins earlier, as a rule, often disappearing before the next meal, for obvious reasons, in the absence of stasis or marked hypersecretion. Thus the food-relief is minimized; but pain from one-half hour to two hours after food is quite the rule and is of diagnostic significance. Too much clinical significance cannot be placed on reliable evidence of gross hemorrhage in the presence of other symptoms characteristic of ulcer. This complication, however, occurs in only about 35 per cent. of all chronic gastric and duodenal ulcers. The association of hemorrhage with the ulcer-complex makes for safe diagnosis of ulcer in 95 per cent. of all cases. In 5 per cent. of all ulcers there is a silent bleeding type in which blood is regularly found in the stools but more or less complete absence of other usual clinical symptoms of pain, hyperacidity and food ease. Benign ulcer, unlike cancer, bleeds intermittently. Positive analysis of occult blood in the stool on limited examination was present in about 25 per cent. only of the cases studied. Hemorrhage has been noted in 2 per cent. of all cases of chronic appendicitis associated with marked gastric disturbance, while it is as high as 5 per cent. in chronic cholecystitis associated with the gastric reflex. In these cases the hemorrhage is probably due to primary follicular ulceration of the gastric or duodenal mucous membrane. More extensive observations on the frequency of occult blood, of general blood morphology and its diagnostic significance in ulcer are now under way and will be the subject of future consideration.

Briefly stated, in those organic conditions which most frequently cloud the diagnosis—chronic cholecystitis and cholelithiasis, chronic appendicitis, etc.—we obtain our greatest diagnostic aid from the irregularity of symptoms during the period of attack. This irregularity is chiefly concerned with the time of appearance of pain and the influence of food. Nothing follows in sequence day by day, perhaps due to the fact that the stomach behaves properly unless irritated by the contiguous lesion and this extrinsic lesion is irregular in its influence. Judging from our case records, chronic catarrhal or "strawberry" cholecystitis very perfectly and most frequently simulates the ulcer-complex. The features of chronicity and "spells" (of invariably briefer duration, however) with characteristic pain, hyperacidity and flatulency having some food relation, the absence of colic, icterus and localizing signs are not uncommon. In order to lessen diagnostic error, daily clinical observation, repeated gastric analyses under variable circumstances, examination of the feces and, finally, the therapeutic management based on the well-known principles laid down by Sippy[3] may be necessary. It is unnecessary to comment on the importance of having in mind and recognizing these types of chronic painful dyspepsia most frequently having their origin in these extragastric lesions. Of considerable moment, too, is the frequency of lesions coexistent in the gastroduodenal, biliary, pancreatic or appendiceal systems in which disturbances engendered by one may overshadow or make irregular the symptomatology of the other so that to the conceits of surgery must be left the ultimate diagnosis in too frequent instances.

Test-meal analysis so essential to gastric diagnosis has also its limitations. In the absence of definite evidence of blood, stasis, hypersecretion in the fasting contents, cardiac obstruction, etc., the findings are of value in so far as they are correlated with the clinical and roentgenologic data. They constitute a link, often a decisive one, in the chain of evidence. The instances of normal or subnormal acid value in the presence of a peptic ulcer occur in about 20 per cent. of all cases; on the other hand, hyperacidity and hypersecretion, even stasis of the first degree, are only too frequently associated with functional states, ptosis and extragastric lesions. These conditions would soon lead to diagnostic confusion if too much dependence were placed on a single or even a repeated gastric analysis. Again, on account of purely physical conditions a considerable residue may be overlooked as shown by the contribution of Harmer and Dodd.[4] This disadvantage can be largely overcome by the use of a lavage tube of proper consistency, calibration and ample fenestration such as is now in common use. The researches of Rehfuss[5] and his associates have made us revise our estimate of the normal contents of the fasting stomach. In selected cases the fractional study of gastric digestion by means of the same investigators' tube and methods has proved to be of practical diagnostic value. Hyperacidity is the rule in 60 per cent. of cases of gastric ulcer and hypersecretion, also in ulcers at or near the pylorus. These features, singly or combined, are noted in 75 per cent. of all duodenal ulcers. A considerable hypersecretion of 200 c.c. or more, likewise the recovery of retention contents of our modified Riegel meal after from twelve to fourteen hours invariably argues for a lesion or organic stenosis, especially if the findings are constant. The determination of gastric motility is of diagnostic importance second only to secretory function or disturbance and for obvious reasons the former is of especial interest to roentgenologists.

Carman and Miller[6] conclude that their bariumized carbohydrate-meal method is a more sensitive test for gastric motility than the modified Riegel meal as commonly used in our clinic; that the modified Haudek double meal method is more informative than tubing after a motor-meal test since the former not only shows delay of evacuation beyond six hours but also yields information as to hypermotile conditions. Their conclusions are based on a comparison of results of both examinations in 950 patients who came to operation. The lesions were as follows: appendix, 125; gallbladder, 311; gastric ulcer, 109; gastric cancer, 137; duodenal ulcer, 268. Of these patients 220 (23.1 per cent.) showed a six-hour barium residue; 131 (13.7 per cent.) had food remnants after fourteen hours or longer. The majority (209, or 90.4 per cent.) of the 220 patients showing a barium retention were found to have cancer, or gastric or duodenal ulcer. They further conclude that a distinct residue after six hours from the barium meal given under prescribed conditions was in 90 per cent. of instances indicative of grave pathology, and usually denoted obstruction at or near the pylorus.

From personal observation we can concede a more sensitive test for motility in this method, especially in case of intermittent or low-grade retention dependent on pylorospasm, incomplete stenosis and on lesions of the accessory digestive system. One may add that the comparison of results between the two methods is hardly fair, principally because of difference in the time element and other features which must be taken into consideration. The motor meal under proper circumstances will continue to be a most practicable index of gastric motility—a fact conceded by eminent roentgenologists and emphasized by clinicians following observations made from the results of both methods. By the latter method one has the additional advantage of being able at the same time to estimate the secretory function of the stomach.

STATISTICAL STUDY

Exclusive of those cases in which a consistent diagnosis of gastric or duodenal ulcer was made and medically treated, there were 1,078 cases operatively demonstrated during the years 1913 and 1914. Of these, 264 were gastric and 814 were duodenal. Coexistent lesions in both organs were noted in 44, or 4 per cent. The average ratio of gastric to duodenal ulcers is well shown in this series, about 1 to 3, that is, 75 per cent. of the ulcers were duodenal. Of the 264 cases of gastric ulcer, 171 occurred in males and 93 in females. The average ages were 47 and 44.5 years, respectively. The average duration of symptoms was 9.8 years. In about 80 per cent. the course was intermittent, free intervals alternating with "spells" of variable duration, regular (40 per cent.) or irregular (49.5 per cent.) in frequency. In 50 per cent. the complaint was continuous and progressive over periods of from several months to several years prior to operation. Irrespective of the situation of the ulcer, pain appeared within 4 hours after meals in 85 per cent. of the cases; in over 30 per cent. it was present within 2 hours, in 55 per cent. within 3 hours, regarded as constant in 3.8 per cent. and irregular in 3.4 per cent. Definite nocturnal pain only occurred in 6 cases, or 2 per cent. Pain was controlled by food or alkalies, or both, in 180 cases. The majority of these (84 per cent.) showed relief after food, while alkalies alone gave relief in 15.6 per cent. There was a fairly definite history of bleeding (hematemesis or melena) in 73 cases, or 27.6 per cent. of this group; about 41 per cent. had hematemesis only, 15 per cent. melena, while both hematemesis and melena were mentioned in 44 per cent.

Gastric analyses were carried out in 255 cases; 38 per cent. of these showed presence of altered blood in the extract. Gross retention was evident in 33.3 per cent. The average total acidity was 54; the average hydrochloric acid was 42. In 18 per cent. the acid values were normal or below. The absence of free hydrochloric acid was shown in 13 cases. Under such a circumstance the possibility of carcinoma, syphilis or associated disease was evident. Five of these patients have since died from malignancy, three now apparently show malignancy; in the others the advanced age associated with considerable fresh blood in the extract, gallbladder disease or other pathologic lesions explained the achlorhydria.

The generally accepted complex of ulcer was more or less definitely present in 81 per cent. of the 212 cases; irregular but suggestive in 6.8 per cent.; classified as irregular in 5.3 per cent. In the remaining 7 per cent. the picture was atypical or the record was incomplete. A primary diagnosis of gastric ulcer was made in 174 cases, or 66 per cent.; an alternative one in 21 cases (8 per cent.). Duodenal ulcer was the primary diagnosis in 47 cases (27 per cent.). The Roentgen ray gave definite assistance in 65 per cent. of the 113 cases examined in this series.

The situation of the ulcers was as follows: the lesser curvature in 167 cases, or 63 per cent.; the pylorus, 35, or 13 per cent.; total ulcers at or near the pylorus, 87, or 33 per cent.; posterior wall, 27, or 10 per cent.; anterior wall 6, or 2 per cent.; 2 gastrojejunal ulcers secondary to gastro-enterostomy. Multiple ulcers were noted in 15 cases, or 5.6 per cent.

The complications were: advanced cicatricial pyloric stenosis, 11.7 per cent.; evidence of perforation, 28 per cent.; perigastritis with adhesions to neighboring structures, 28 per cent.; questionable malignancy, 11.7 per cent.; appendiceal disease, 33.7 per cent. In less than 25 per cent. of all cases was there no complicating factor, a fact which illustrates the advanced stage of the process at the time of first examination.

Of 814 cases of duodenal ulcers 628 (77 per cent.) were males and 186 (22.8 per cent.) were females. This characteristic disproportion in sex incidence Wilkie[7] has probably explained on an anatomic basis. The average age was 43 years and the average duration of symptoms was over twelve years. The clinical course was intermittent in 95 per cent. of all cases, and periodic in 50 per cent. Continuous preoperative complaint of variable duration was noted in 26 per cent. In more than 85 per cent. the pain appeared in from two to five hours after taking food; in the remainder it appeared within two hours. Nocturnal pain only was given in 6 cases (7 per cent.). Definite relief by food was noted in 67 and partial or irregular relief in an additional 15 per cent. Relief by neutralization was present in 39 per cent. Hemorrhage was reported in 208 cases (25 per cent.) and was classified: melena, 8.8 per cent.; hematemesis, 6 per cent.; both melena and hematemesis, 10.5 per cent. The acid values averaged 20 per cent. higher than in gastric ulcer and in only 7 per cent. were they below the accepted normal standard.

[6] Carman, R. D., and Miller, Albert: The Roentgenologic Determination of Gastric Motility with a Comparison of the Results Obtained in a Series of Cases Examined Both by the Roentgen Ray and the Test-Meal, Arch. Int. Med., to be published.

[7] Wilkie, D. P. B.: Observations on the Pathology and Etiology of Duodenal Ulcers, Edinburgh Med. Jour., 1914, xiii, 196.

A primary clinical diagnosis was made in 543 cases (66.7 per cent.) and an alternative one in 67 cases; that of primary gastric ulcer in 88 cases (10.8 per cent.). This totaled 85.7 per cent., the usual average in all the series recently studied. Of 251 cases in which the tentative diagnosis of gallbladder disease was also made, 51 (20 per cent.) showed this disease present and 51 ulcers (22.3 per cent.) were shown to be chronic perforating. Reviewing the case histories, the ulcer complex was fairly regular in 71 per cent., suggestive in 7.2 per cent., and irregular in 13.2 per cent.

At operation advanced pyloric stenosis was shown in 251 cases (30.8 per cent.); perforation in 26.8 per cent.; periduodenal inflammatory disease in 23.5 per cent. Associated disease in the appendix occurred in 48 per cent.; in the gallbladder in 9.7 per cent.

A more detailed comparative study of the statistical end-results in these two groups serves to bring out the salient differential clinical features as previously mentioned.

ABSTRACT OF DISCUSSION

Dr. J. N. Hall, Denver: We have the very great advantage of knowing what we are discussing, since the diagnosis has been proved in every case. There is perhaps no other common disease so frequently and so closely mimicked in its symptomatology by several other diseases as is peptic ulcer. We have all seen patients treated for twenty years for gastric ulcer, but cured by the removal of the chronically inflamed appendix, with no ulcer present. I have recently had one of Ewald's patients so cured, and it is doubtful if he is surpassed in diagnostic ability along this line by anyone in the world. Chronic inflammation of the gallbladder, chronic gastritis of the hyperacid type, small omental hernias and even the tabetic crises, are other common causes of confusion in diagnosis. Whenever ulcer is suggested but the history is atypical, the evidence as to the possible presence of chronic appendicitis should be reviewed, for such a condition will often be found. I should personally lay more stress on the search for unilateral muscular rigidity, which is probably of more decisive value as evidence of a definite structural lesion than pain and tenderness combined. In no procedure is the possession of an educated touch more imperative. The appearance in the anamnesis of jaundice and biliary colic has been the cause of diagnostic defeat in many cases through failure to recognize that in duodenal ulcer the patency of the common duct may be compromised, either mechanically or through an infective process. We should doubtless give the appendix more credit than it now receives as a prime cause of peptic ulcer, since the commonly induced hyperacidity in chronic appendicitis is probably a potent factor. It is interesting to note that the essayist found the appendix inflamed in 30 or 40 per cent. of the cases. If the ulcer does not heal promptly under proper medical measures, operation should certainly be advised. One comforting thought under these circumstances is that we shall save more than enough lives through the finding of unsuspected cancer to balance the mortality rate. The fact that many ulcers may be found by opening the stomach or duodenum when they would have escaped detection otherwise, should be given due consideration. There are so many chances of finding cancer, pyloric or duodenal obstruction, serious adhesions, hourglass deformity, etc., that we practically always find more advanced pathologic changes than we anticipated. The acquirement of a drug habit or the development of arteriosclerosis, neurasthenic features or tuberculosis from the faulty nourishment must not be overlooked.

Dr. Max Einhorn, New York: I have mentioned on another occasion the reason for the discrepancy between the views of the Mayos regarding the frequency of ulcer and the views of other clinicians. The Mayos believe ulcer is two or three times as frequent as cancer. I have no doubt their work supports that opinion. But there is a difference in the material that comes to the surgeon and the material which comes to the clinician. Say I have twenty cases of ulcer, probably only one of those will undergo operation. The cases which undergo operation belong to those in which there is food stagnation, or the lesion is near the pylorus, and that is why the surgeons find duodenal ulcer so frequently. If we could open up all the ulcer cases, we would probably find ulcer of the stomach much more frequent than ulcer of the duodenum. As to differential diagnosis, I agree with Dr. Eusterman, that from clinical symptoms we can sometimes make a diagnosis, but usually we cannot do so. In the great majority of cases we will be able to make a more definite diagnosis on careful observation of the cases, especially as to the location of the ulcers. I have several cases in which the lesion was shown to be in the duodenum, whereas the symptoms would indicate gallbladder trouble. There are of course cases in which the two conditions are present—duodenal ulcer and gallstones. This sometimes can be found out before operation by careful examination. The duodenal tube and the examination of the bile and duodenal contents may furnish a great deal of information as to the presence of gallbladder trouble. It has been my experience that in gallbladder disease the bile is not as clear as it should be when we take it out fresh from the duodenum.

Dr. J. A. Lichty, Pittsburgh: An essential factor under this subject is the differentiation between the acute and chronic gastric and duodenal ulcers. The differences of opinion between the internists and the surgeons hinge largely on the failure to make this differentiation. The difference is just as great as between an acute ulcerative endocarditis and an old mitral lesion in a compensating heart. If we can differentiate definitely between the acute gastric and duodenal ulcer cases and the chronic cases with their consequent deformity or disturbance of function, we can very easily decide what are medical and what are surgical cases. A year ago before this section Dr. Joslin of Boston spoke of his results in gastric and duodenal ulcers. He found that most of his patients did not come to the internist until they had their disease six years, and they did not go to the surgeon until they had their disease ten years. It is useless for the physician and surgeon to accuse one another of neglect, etc., when in six years so much damage may have occurred that neither the physician nor the surgeon can expect satisfactory results.

The Reward of Scientific Study.—The student does not study Nature because that study is useful, but because it gives him pleasure, and it gives him pleasure because Nature is beautiful; if it were not beautiful it would not be worth knowing and life would not be worth living. I am not speaking, be it understood, of the beauty of its outward appearance—not that I despise it, far from it, but it has nothing to do with science: I mean that more intimate beauty which depends on the harmony in the order of the component parts of Nature. This is the beauty which a pure intelligence can appreciate and which gives substance and form to the scintillating impressions that charm our senses. Without this intellectual support the beauty of the fugitive dreams inspired by sensual impressions could only be imperfect, because it would be indecisive and always vanishing. It is this intellectual and self-sufficing beauty, perhaps more than the future welfare of humanity, that impels the scientific man to condemn himself to long and tedious studies.—H. Poincaré.

MEDICAL ASPECTS OF OPEN AIR SCHOOLS *

SHERMAN C. KINGSLEY
Director of the Elizabeth McCormick Memorial Fund
CHICAGO

Medical examination of employees is becoming the practice in the industries of our country. This has been found necessary by business men, first, to conserve the health and welfare of the individual, and second, to promote efficiency. Safety first methods and principles are becoming matters of first importance in the life of our country. Shop sanitation and proper working conditions are requisites in a first class business organization.

There are 20,000,000 schoolchildren in the United States. These boys and girls spend 11,415 years in the schoolrooms of the land every school day. This means a total every school year of 2,283,000 years. School attendance is compulsory.

Any business responsible for the expenditure of this amount of time would find it necessary to apply efficiency tests to be sure that working conditions were satisfactory.

Anyone who has visited schoolrooms and is aware of the enormous amount of time required from the boys and girls of the land cannot help wondering how much time is lost through drowsiness, inattention and half asphyxiation due to badly ventilated and overheated schoolrooms. Government in the United States concerns itself with the direction of the individual perhaps less than any other great nation of the world.

The public school affords our one most conspicuous exception to this rule. We compel the boys and girls to go into the schoolhouse and occupy school seats. We keep each one in the presence of the teacher and under the direction and supervision of the school authorities for a period of six to eight years, at least. Our theory is that each boy or girl reared in the United States should have at least a grammar school education. We now know that less than one-half ever finish the grammar school.

Through the work of our juvenile courts, settlements and vocational guidance bureaus, our children societies and other agents dealing with boys and girls, we are beginning to understand some of the pressing problems of child life.

Health inspection in public schools shows that 12,000,000 of our 20,000,000 schoolchildren have physical defects serious enough to interfere with school progress. Careful study in many cities further shows that from 2 per cent. to 10 per cent. of the total school population has physical defects so serious as to render school experience practically useless and to render it unprofitable to spend public money trying to educate them unless something is done to correct physical defects.

Advocates of the open air school believe that the time to spend time and money on the individual is when he is young and when such effort and expenditure will result in benefits which will accrue to the individual, and not wait until it is necessary to deal with them as chronic invalids or as finished dependents.

Open air school advocates believe that 100 per cent. of the schoolchildren should have their fresh air and hygienic rights. In many parts of the country there is no reason why all schools should not be open air schools all the year around, because the climate affords no serious obstacle.

In other parts of the country, the winter months constitute a problem, but for the major portion of the year, even in the colder latitudes, all schools can have open air conditions. Even in the winter months, open air conditions can be much more nearly approached through the periodic opening of windows to let in the fresh air.

The debilitated child affords a special problem and, as was said before, it is estimated that from 2 per cent. to 10 per cent. of the schoolchildren are of this type, and this would mean somewhere between 400,000 and 2,000,000 such children in the United States.

The Elizabeth McCormick Memorial Fund of Chicago has made the open air school a special feature of its work. In the school year 1913-1914, there were twenty open air schools in Chicago with an attendance of over 600 children. In the case of 590 of these children, fairly complete records were kept.

The Board of Education furnished teachers and school equipment, and the Municipal Tuberculosis Sanitarium of Chicago cooperated in furnishing nursing service and in providing food.

The Elizabeth McCormick Memorial Fund employed special physicians, furnished clothing and other service necessary to the conduct of the schools. The children selected were of the undernourished, anemic and tuberculous type, and came mainly from the congested districts of Chicago. The average size family represented by the children was 6.15. Average number of rooms 4 plus. There was an average of 1.8 tuberculous members in each family represented by these children. The average rent was a little over $12 per month. The average income in the families represented by the children was $7.02 per individual per month.

This study of income was made in the latter half of the year 1913-1914, when industrial conditions in Chicago were normal. This income is a little more than half the standard established by the Juvenile Court of Chicago as a minimum on which a family of the size represented by these children can live and maintain health and efficiency. The figure set by the Juvenile Court is $12.60 per individual per month for such families.

Seventy-five per cent. of the children were diagnosed as tuberculous, meaning bones, joints, glands, etc.; 20 per cent. were suffering from anemia, and malnutrition; 5 per cent. were suffering from other defects, bronchitis, heart disease, etc. In addition, 188 had diseased tonsils; 165 had adenoids; 466 decayed teeth; 152 defective eyes, and then there were other minor defects. The families of a majority of these children were known to the clinics of the Municipal Tuberculosis Sanitarium. There were many other unclassified defects. In addition to these conditions, hours of retiring, irregular meals, conditions of sanitation and cleanliness in a majority of the homes were unsatisfactory.

First hand acquaintance with these children throws strong light on the reasons why at least some of our children fall out of school at an early age and why they are so illy-prepared physically and mentally for the duties of life. They help us to understand why our general theory of a grammar school education for all the boys and girls reared in this country is not

---

* Read before the Section on Preventive Medicine and Public Health at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

being made effective, and why more than half of them never attain this standard, and why such large numbers leave school with only fourth, fifth and sixth grade preparation.

Advocates of the open air school state that a thorough knowledge of each individual child is necessary and that this knowledge should recognize the child's physical as well as his mental individuality.

TABLE 1.—WEIGHTS (BOYS) IN COMPARISON WITH NORMALS

Age	No. of Boys	Actual Average Gains Per Month	Normal Gains According to		
			Holt	Ch. Bd. Ed.	Boas
7	6	0.37	0.34	0.32	0.35
8	13	0.29	0.47	0.38	0.41
9	21	0.37	0.43	0.43	0.43
10	24	0.41	0.51	0.40	0.48
11	28	0.5	0.45	0.43	0.44
12	18	0.61	0.58	0.59	0.51
13	29	0.7	0.66	0.6	0.65
14	14	0.91	0.85	0.81	0.86
15	9	1.09	0.9	0.91	1.01
16	3	0.52	1.00	0.90	1.13

In order that careful medical work might be done, the Elizabeth McCormick Memorial Fund, for several years, has paid the physicians in the Chicago open air schools. This enables them to give the amount of time that is necessary adequately to deal with these children. The physicians have spent an average of about four hours a week on each of the nineteen schools. They find that it requires about a half hour to give each child a careful examination, and such examinations are made on admission, discharge, and once or twice during the year.

In addition, there is the daily running supervision which takes care of any special ailments, sees that physical defects are followed up and corrected, that children having elevated temperatures and who are indisposed, should be placed on rest. The nursing service which is furnished by the Municipal Sanitarium takes about an hour and a half a day of the nurse's time for each school. The nurse inspects the children daily, supervising taking of temperatures, taking care of any little injuries or physical needs, and visits the homes and helps to get the best possible cooperation with the school in the child's behalf.

TABLE 2.—WEIGHTS OF GIRLS IN COMPARISON WITH NORMALS

Age	No. of Girls	Actual Average Gains Per Month	Normal Gains According to		
			Holt	Ch. Bd. Ed.	Boas
7	4	0.24	0.33	0.36	0.35
8	10	0.45	0.38	0.35	0.40
9	27	0.44	0.36	0.39	0.40
10	20	0.44	0.52	0.44	0.45
11	28	0.55	0.5	0.49	0.55
12	33	0.65	0.86	0.65	0.76
13	21	1.02	0.77	0.80	0.83
14	22	0.85	0.71	0.90	0.80
15	4	0.52	0.65	0.74	0.70

Then there is a small number of children to each teacher. This makes it possible for her to know her children, and when she understands home conditions, physical needs and has the cooperation of nurses, social workers, juvenile court officers and other social forces of the community, she gets an understanding of her children that she perhaps never had before.

To begin with, she is usually chosen for her interest in the work and her general social as well as teaching sense. The children study under open air conditions. They have as much sunshine as possible and their work is made as varied and interesting as conditions will permit.

In some of the schools they have a daily shower bath, daily feeding and a rest period after the midday meal. The aim is to "weave all these features into a process of education and the hygienic way of life." Results are almost uniformly gratifying.

Children gain in weight, they increase in alertness, in spirit and interest and make better intellectual progress.

Improvement is also shown in the hemoglobin tests. The average gain in weight for these children in ten months was 4.95 pounds. This approximates closely what the gains of normal children of the same age and sex should be and is shown in the accompanying tables.

Tables 1 and 2 show that about half the children gain as much (or more) as normal children of the same age and sex, and about half gain a little less.

The following tables show the school progress of these children for their year in the open air school and the previous record of the same children in regular rooms.

TABLE 3.—SCHOOL PROGRESS OF 522 CHILDREN IN CHICAGO OPEN AIR SCHOOLS, SCHOOL YEAR 1913-14

1 child made three grades in this school year.
12 children made two grades this school year.
9 children made one and one-half grades this school year.
387 children made one grade in this school year.
113 children failed to make one grade in this school year.

TABLE 4.—SCHOOL PROGRESS OF 488* OF THESE CHILDREN PRIOR TO SCHOOL YEAR 1913-14 BASED ON THESE FACTS AND ASSUMPTIONS

First—The age and grade of each of the pupils was taken at the beginning of the school year 1913. Second—We assume that according to usual standards each child entered school between 6 and 7 years of age; that he continued in school, and that he should have made one grade each school year.

22 children averaged 0.50 to 1 year to a grade.
107 children averaged 1 year to a grade.
172 children averaged 1 to 1.50 years to a grade.
128 children averaged 1.50 to 2 years to a grade.
18 children averaged 2 to 2.50 years to a grade.
22 children averaged 2.50 to 3 years to a grade.
2 children averaged 3.50 years to a grade.
9 children averaged 4 years to a grade.
5 children averaged 5 years to a grade.
1 child averaged 6 years to a grade.
2 children averaged 7 years to a grade.

* Nine of the 522 children entered school in the school year 1913-1914; twenty-five had not completed one grade at the end of the school year 1912-1913, and therefore were not included in this table.

The open air school movement is spreading rapidly over the country. There is a deep interest in the physical welfare of schoolchildren, and it is the conviction of part of our people that the time to serve these children is when they are in the public schools; that it is not good business to allow them to sit for six or eight years with handicaps and defects which are preventing them from receiving the thing which the school wants to give.

New York City has 250 open window classes with the same number of children in each class as in the regular schools, and the promoters say the results are better than in closed rooms.

New York also has twenty-five classes for anemic children and in these classes there are twenty-five children, and here again they say the results are better than when these children go to the usual closed room. There is no feeding or rest period in these classes.

Many other cities have open window classes. In California and many other localities, the movement is spreading rapidly.

For the type of children we have been describing, we believe that something more than merely opening the windows is necessary if these children are to be restored to efficiency and made useful citizens.

In many places the penny lunch or diets of milk and crackers, sandwiches, or other less expensive methods of feeding are in vogue.

We believe that this work should have careful medical direction and supervision.

Children should not be subjected to extremes of temperature unless they are properly provided for it. There is no reason, however, why all the schools in the country should not approach much more nearly the open air schools than at present.

Even in climates where the winter temperature is a problem, windows can be opened at intervals and the rooms flushed with fresh air. The Creator has provided enough fresh air for all and almost any audience room is greatly improved by such frequent opening of windows to let the fresh air in.

One of our little boys in Chicago brought a companion to the school not long ago saying to the physician: "Say, Doctor, how sick has a feller got to be to get in this 'ere school?" The open air school advocates believe in giving all debilitated children in our schools the care and attention which will give promise of making them useful citizens, but they also believe that people should not necessarily be sick or debilitated in order to have their fresh air and hygienic rights accorded to them.

ABSTRACT OF DISCUSSION

Dr. B. Franklin Royer, Harrisburg, Pa.: We are indebted to Mr. Kingsley for placing before us in a perfectly sane and rational way some of the problems of school life, particularly the class of pupils requiring open air schools. Some of you may have been a little surprised to hear him make the statement that from 2 to 10 per cent. of schoolchildren require some form of special school care; and yet in many sections of the country the percentage runs even higher. In Pennsylvania we do medical inspection of schools perhaps on a larger scale than any other state. It is compulsory in districts of the first and second class; optional in districts of the third and fourth class. In fourth class districts the work is done by the State Department of Health. We have recently finished making an inspection of 468,000 rural schoolchildren; and in that group we found 70 per cent. defective, and 27 per cent. had defects of vision as shown by the crude test with Snellen's chart. Many of them would have shown other defects of vision had we been able to carry out more elaborate tests. What I more particularly want to relate, however, and it bears directly on the subject under discussion at present, is what we have recently observed in certain schools in the little coal town of Nanticoke, with a population of 8,000. Dr. Waters, the city medical inspector, in examining 365 pupils in the isolated eighth ward of that city, found a large number of the children having tuberculosis. He stood aside ninety-nine children in a school of 365 as probably having tuberculosis, and urged open air treatment. The physicians in the town made uncomplimentary remarks; the school board and local health board thought he was unduly radical and made diagnoses without proper information at hand, and suggested that he come to the state health department and ask us to make a confirmatory examination. We sent for this work Dr. Karl Schaffle, chief of our dispensaries, and Dr. Charles H. Miner, two of our best medical men, with large experience in examining tuberculous children. Nurses were sent along. A room was set aside where we might make physical examinations of chests of all suspicious children. To our surprise, out of a group of 120 children examined with great care, including the ninety-nine set aside by Dr. Waters, forty of them gave enough evidence of active tuberculosis to justify a diagnosis of this disease, and sixty were set aside as children who should undoubtedly have been in an open air school. That gave us a percentage of 17. Mr. Kingsley has put it at from 2 to 10 per cent. We have not attempted to work out the percentage in the better types of schools and in communities where well-to-do people live and better housing conditions obtain. However, Mr. Kingsley is certainly well within the limits for most communities.

In Nanticoke the school board was quite willing to cooperate, and immediately converted this entire school into an open window school, and are now planning to isolate in an open air school and teach separately those believed to be actively tuberculous, and to continue the great number of suspicious children in the open window rooms of the school now in operation.

The Department of Health has undertaken to correct conditions through the housing bureau, and has put enough pressure on the coal companies to make provision for building new houses outside the congested district, and we hope in this way to thin out and apportion to proper space the various families that are there, and eventually to do a great deal toward overcoming present conditions.

Dr. William C. Hassler, San Francisco: I would like to ask Mr. Kingsley and Dr. Royer whether in their sections they met with such opposition as the League for Medical Freedom, who object to the investigation of conditions in the home, and particularly among the schoolchildren?

Dr. Royer: School medical inspection was made compulsory in certain districts in Pennsylvania in 1911. No opposition appeared in these districts. The League for Medical Freedom, however, circularized every school board in districts of the third and fourth class, some 2,500 boards, where inspection was optional. A lot of them (1,500 districts of the fourth class) voted against inspection the first year. We took no note of the opposition and inspected in the districts where they refrained from voting against it. The next year half as many districts voted against inspection, even with the league's agitation continuing. The school boards have come around, fewer voting against it each year, and we are now inspecting practically everywhere. Their attack has been a complete failure. We have not opposed them at any time, and every blow they have struck has been a boost and has done us good.

Dr. N. K. Foster, Oakland, Calif.: I spend all my time as director of health in the Oakland schools. Five years ago I induced the board of education to build an open air school. It was in the yard of one of the larger schools, and it was decidedly open air. The east side was entirely open and the south and west sides had open louvers clear across, so there was never a lack of air. We filled this school by picking out all the worst defective children we could find in the large school, about twenty-three I think. At the beginning of school in August we weighed the children in both schools carefully and at Christmas time we weighed them again carefully. The children in the open air school had done the same work as those in the other school. We had not, as Mr. Kingsley speaks of their doing in Chicago, given them food or rest. The only difference was in the air. The children from the open air room had every one gained in weight and they showed a relative gain of 55 per cent. over the children from the inside. Their mental advance had been equally good, all of them being promoted although many had failed before when they were inside. Several of them even made two grades. Special teachers have often remarked to me how bright and wide-awake these children always are, in great contrast to those in the inside schools. There cannot be any question that we are stifling and destroying the vitality of many of our children by shutting them up in close, stuffy schoolrooms. The result of this in Oakland has been that we have from fifty to 100 new rooms, and every one of those rooms can be open air; that is, they are built in units so that the air comes in from two sides; the one side is fixed with windows that can be opened entirely, and on the other side windows can be opened so that there can be a cross draught. I think that the ventilating engineers with their wonderful schemes and ventilating machines are doing more damage to the schoolchildren than almost any other people—pumping in devitalized, dead air that has lost its invigorating qualities for them to breathe, keeping it at an even temperature without any disturbing currents, making many of the children in our schools stupid. I hope the time will come, and I hope the medical profession will let this strike deep into their hearts, that if we want to take any step to make our people strong and vigorous and well, it must be through open air schools.

Dr. F. E. Corey, *Alhambra, Calif.*: I have constantly asked our people, if the schoolchildren can be made better and restored to health by putting them in open air schools, why should we continue to keep the well children in closed schools. I have asked the school authorities in my community why they persist in building closed school houses when we know and have heard so much of the benefit of open schools, expending vast amounts of money to build architectural monuments to endanger the health of the rising generation. I believe that the mechanically ventilated school, just alluded to, is a menace to the health of future generations, and we ought to bring to bear all the influence we possibly can to defeat it. I have seen some such buildings, and they have distressed me beyond measure, and I cannot express too emphatically my disapproval and my desire that this matter may be agitated all over the country until we get some light into the minds of our school authorities. That is where the trouble seems to be.

Dr. Heman Spalding, Chicago: As to the question raised here about the opposition to school inspection, in Chicago we began the examinations without saying anything about it to anybody; just proceeded, and everybody wanted their children to be examined—almost everybody. Occasionally somebody would say he would not have his child examined. We said, "Very well. We don't want to examine him. Don't bother us. Just take care of your own child"; and we continued that way for some time. Then the League for Medical Freedom began to oppose somewhat, and through some means or other—I do not know what—we threw down physical examinations for a year. Then we began again, but at the present time physical examinations are made only of such children as come with a signed certificate from the parents giving consent. We get a pretty large percentage in that way—enough to keep our men busy all the time—and will continue in that way for the present. We have no law in the state of Illinois requiring physical examinations of pupils as they have in Pennsylvania. We are trying to get such a law. I do not have the figures to give. Mr. Kingsley has given his figures, but our figures are not available as yet to give you the details and results of our examinations.

Dr. B. F. Howard, Sacramento, Calif.: It has been well pointed out that the open air school is an important factor in the prevention of tuberculosis. I wish that some one might give us a definition of an open air school. We have all kinds of schools, from the country school with the cracks between the boards, to the city school with a goodly number of windows. I think with the open air school, or any school, we need, perhaps, quite as much what we might call an open air school teacher. I have been in a great many schools that could really be called open air schools if the windows were only properly opened, and that is particularly so here in California. We have all the facilities in the way of climate for conducting open air schools for all of our children; and yet one goes into schools where the windows are closed, most of the time. I would like to have in connection with this definition of the open air school some recipe for producing an open air school teacher.

Dr. L. M. Powers, Los Angeles: May I ask, Dr. Foster, if you have come to any definite conclusion which is better, for the boards of education or the health department to have control of the school inspection? I agree thoroughly with the doctor in reference to ventilation. I have been through all of that.

Dr. Foster: That is a question that would bring up a great deal of discussion. It does not matter whether the board of education or the health department handle it, so long as it is handled. It is merely a matter of private opinion whether the one or the other do it.

Dr. Thomas D. Maher, San Francisco: We have in San Francisco between fifteen and twenty open air schools, or cold air schoolrooms, and we also have one class of physically defective children, children who have been for some years under the observation of the Associated Charities; and we have in prospect, I am glad to say, an open air class for pretuberculous and tuberculous children. That is what we have in prospect for the coming year, and I am sure that we will find in the public schools many children not only suffering from tuberculosis, but pretuberculous children with enlarged lymphatic glands, and cases of that character. We have in California no mandatory laws compelling any school inspection. We are going along and meeting with only sporadic opposition.

Dr. Otto P. Geier, Cincinnati: Two queries suggest themselves to me as the result of hearing this paper. First, if the open air school does so much for the tuberculous child and for the pretuberculous child, why should we not at once take the next rational step and make all of our schools open air schools? Why should we wait until we find by physical examination that a child is pretuberculous before we begin to use this remedial agency, fresh air? I think we all go through the cycle. My attention in Cincinnati was first called to the open air school in connection with the tuberculosis hospital, and later on we got busy with our open air school to treat pretuberculous children; and I believe one of these days we will have to come to the proposition of treating everybody as pretuberculous and give them all open air treatment.

The doctors seem to fail singularly with a thing they are working with all the time, and that is the open air hospital. We have just finished building a $4,000,000 hospital, and we have done the usual thing—put some porches on it, and roof gardens; but the expense of removing patients to inadequate porches and the expense of moving up to the roof garden is prohibitive. I believe that when that hospital builder finally arises who has the courage to turn the hospital inside out and put the inside on the outside, and just a few dozen rooms on the inside so that they may be cared for, then we will make some progress in our hospitals.

Mr. Sherman C. Kingsley, Chicago: I entirely agree with the point of view mentioned here two or three times, namely, that all children should have fresh air and plenty of it.

The ideal of open air school advocates is fresh air and hygienic rights for 100 per cent. of schoolchildren. I do not pretend to know the truth about ventilation. Many scientific studies are now in progress. The scientific experts, so far, do not seem to agree even among themselves. What we understand now concerning the ventilating system in vogue is that windows and doors must be kept shut. Not long ago it was almost equal to separation from the service for a teacher to violate this rule. It is a question whether we protect anything but the ventilating system. My own belief is that whether you have a ventilating system or not, or whether you keep the windows closed and keep the air moving by mechanical process, sending it through the pneumatic laundry to be washed and returned, no matter what the process, I believe that the teacher and the children themselves will be benefited by frequent opening of the windows and letting in some of the air which is always in abundance on the outside of our buildings.

Over and over again, even in so-called ideally ventilated rooms in new buildings, I have seen adult audiences revive, freshen up and regain the look of human intelligence on the opening of windows. They freshen like a wilted garden after a shower.

It seems to me that some kind of mechanical device should be helpful in getting air into the inside of large buildings where there are inner rooms, corridors and recesses. There are days when the air is stagnant and does not move without some provocation. However, I feel that ventilating systems ought to be used and made to serve, and not venerated and worshiped. Air has qualities, not motives and impulses. We sometimes act as though it would be accommodating and do the thing which is expected of it, just because we expect it.

It is my belief, as I said before, that the efficiency of every school building in the land will be greatly increased by the periodical opening of windows and letting in the air. I believe that both teachers and pupils should be taught to open windows rather than to close them and to feel that opening them was something they never ought to do. We know that we all feel better in the open air. All you need to do to convince yourself, is to look at the children when they gather in the schoolroom on September 1 and then look at them again in June. The open air and outdoor life that they get in the two months keeps them going for the other ten.

THE SANITARY ENGINEER IN PUBLIC HEALTH WORK *

SAMUEL G. DIXON, M.D., LL.D.
Commissioner of Health, Commonwealth of Pennsylvania

AND

B. FRANKLIN ROYER, M.D.
Chief Medical Inspector

HARRISBURG, PA.

For efficiency, a public health organization in a representative form of government should, in our opinion, be directed by one versed in sanitary and practical medicine as well as in sanitary engineering. A little training in entomology and geology would add to the efficiency of the executive. He should be clothed with great police powers. The foundation of the organization should be a statistical division, including vital, morbidity and marriage statistics. Cooperating and depending on this statistical division, a medical division should be established, headed by a medical chief with an experience of at least ten years in general and special hospital work and in epidemiology. The medical associates should be those fitted for bureau work and for field service throughout the territory over which the department has jurisdiction.

Independent of the responsibilities generally recognized as belonging to a medical division, it is essential for the best work to have a system of hospitals for communicable diseases. In connection with the department there should be a corps of sanitary engineers and a well-equipped laboratory with workers in pathology, bacteriology and chemistry.

Divisions for tuberculosis sanatoriums, dispensaries and for the distribution of biologic products are necessarily required.

Another important division should be one on housing, headed by a sanitary engineer or a broadly educated medical man.

To promote economy and efficiency in all the other divisions, the department must have a technical purchasing and bookkeeping division.

With the divisions already mentioned it is desirable that there should be one on foodstuffs and drugs, including, of course, milk hygiene, and all these should be accompanied by a division of education and publicity, for in a representative form of government the police medical laws cannot be readily enforced if they are far in advance of the intelligence of the people. The publications of the division should be both medical and literary, and as important as any is the utilization of the newspapers, as the latter are the only publishing channel that reaches every fireside.

Our personal experience has also impressed us with the great necessity for doing medical school inspection, and, in handling communicable diseases, of having a well disciplined staff of licensed nurses; they may not only teach the children in schools, but also teach the poor in their homes.

With this discussion of the suggested divisions of the organization we can better understand the place of the sanitary engineer in public health work.

The medical division is informed, through the statistical office or division, of the undue prevalence of infectious diseases in any community, such as are transmitted by water, milk or foodstuffs. The sanitary engineer often plays a most important part in overcoming the trouble.

While the medical inspector is analyzing samples of water and milk, and studying the movements of the individual persons who have been ill, and the character of the food supplied to them, the sanitary engineering staff traces the source of these supplies and their ultimate distribution in the infected territory. The sanitary engineer often definitely locates the source of infection, particularly when the public water supply is at fault. His services may always be employed with advantage in the enforcement of such sanitary reforms as may be required to wipe out the source of danger and in planning for the elimination of further dangers from it. It is only when the engineering department cooperates closely with the various other subdivisions of a public health organization that the executive officer may properly control and combine their efforts, direct their several separate plans of investigation, harmonize their results and do the state's work economically and effectively.

The medical officer and the sanitary engineer must work together in field epidemics, particularly of water-borne disease; let this be direct or indirect. The medical officer takes precedence and reviews with local men both the probable source of infection and obscure cases of the disease. An engineer follows and enforces disinfection procedure as well as abatement of nuisances detrimental to health, and such general sanitary clean-up as may be required. From the coordinated studies of the medical and sanitary engineering services of a department the executive officer naturally draws his inference on which he bases judgment and plans reforms, determines results and anticipates further needs.

Profiting by the strictly medical experience gained in the suppression of epidemics of water-borne disease and the results of bacteriologic research, the sanitary engineer investigates and studies the water supplies of the state generally, and the watersheds of such supplies, for the purpose of protecting and furnishing a potable water to the people and for the purpose of preventing the occurrence of epidemics in large centers of population.

A very large part of the activities of the sanitary engineer in a health organization consists in making those studies for the executive officer that enable him to pass judgment on the plans of water works and sewerage works which are to be built to serve the various

---

* Read before the Section on Preventive Medicine and Public Health at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

communities of the state. It is from these preliminary investigations by the engineer that the executive officer determines whether the capacity of particular water works or sewerage works is sufficient for present and future needs, and whether such works are planned so as properly to safeguard the health of the public. In studies of this type the engineer has the assistance of the department's laboratory skill and scientific interpretation, in order to enable the executive officer to advise concerning the type of construction and character of the plant most likely to bring about desired purification, or pass final judgment on plans submitted.

Another important activity of the engineer in a health organization is supervision of water and sewage works already in service in order to hold responsible local officials up to the highest degree of efficiency in care and operation of the plant. Just as a chain is no stronger than its weakest link, so is the water plant or sewage plant no safer than the staff of its operators. Proper supervision may prevent disastrous results and in this supervision the engineer constantly needs the laboratory worker associated with him at his elbow.

Scheme of Organization

Scheme of organization of Pennsylvania State Department of Health.

In Pennsylvania no system of water supplies or sewers and no sewage disposal plant may be constructed or extended unless the plans and specifications therefor are first submitted to the department of health and carefully studied in the field by the sanitary engineering division. The facts thus obtained are carefully reviewed by the chief engineer, who then goes over the entire situation with the commissioner that recommendations may be made to the governor and attorney general for approval.

The sanitary engineer also patrols the watersheds, and in the patrol of the watersheds, seeks out and abates all possible sources of pollution. In the general work of the medical staff conditions are discovered that require the work of the engineering division.

Coordination is the key-note of the successfully organized public health department and the sanitary engineering division is one strong arm in such an organization. Let us take, for example, the plan of organization worked out in the Commonwealth of Pennsylvania (see chart). You will note in the scheme of organization that the sanitary engineer derives his authority directly from the commissioner of health and reports directly to him; that he is relieved of the details of purchasing his supplies and doing his own bookkeeping; that he works side by side with the medical division and the other important executive divisions of the organization, any branch of which may instantly be called on for aid and cooperative work.

The Pennsylvania Department of Health in the very beginning of its organization conceived the present plan of organization and later worked it out in detail. The commissioner of health has never at any time hesitated to use the engineering division or any other division of the department for the purpose of ferreting out troubles having any bearing on public health.

The need for a sanitary engineer and a well-equipped laboratory has been recognized for many years. Not until ten years ago did Pennsylvania appreciate this necessity and in the organization of her public health forces under the laws of 1905 legal provision was made for the employment by the commissioner of health of such engineering assistance and laboratories as might be necessary to carry on the work of the department.

A division of sanitary engineering was organized. This division has increased in size until now it contains more than 100 trained employees, all giving their entire time to the sanitary details of the health work of Pennsylvania and laboring in conjunction with the medical and other forces of the department.

With a population of over eight millions (8,380,000) and a surface area of nearly 45,000 square miles, Pennsylvania has need for this engineering organization, which I believe is larger than that maintained by any other state.

The protection of the purity of the waters of the state is the fundamental work of the engineering division. This is accomplished by preventing the entrance of sewage into the streams and by the purification of water furnished to the public from polluted supplies, or else by requiring that water be obtained from uncontaminated sources.

The importance of this work is self-evident, as an adequate supply of pure water is necessary in every municipality. The urban population of our country is increasing, and with this growth comes a proportionate increase in the amount of water used by each individual. The quantity of water which can be procured from unpolluted sources is generally insufficient for the needs of our modern cities. It follows that the large surface streams will be used more and more as sources of public water supply. These streams are usually contaminated and their use would cause an increase in the occurrence of water-borne diseases, such as typhoid fever and bacillary dysentery. While it is true that polluted water can be purified, it is equally true that purification works occasionally fail in their function, and therefore cannot be considered an adequate safeguard.

The only sure remedy is to remove the cause and to restore all streams to as cleanly a condition as is practicable by the employment of modern methods of stream protection; in other words, by preventing the discharge of raw sewage into the streams.

A law passed by the general assembly in 1905, entitled "An Act to Preserve the Purity of the Waters of the State for the Protection of the Public Health," furnishes the Pennsylvania Department of Health with the necessary authority for carrying on this great work. The engineering division bases its operations on the provisions of this law.

This act prohibits the discharge of sewage by persons into any stream or other body of water in the state, and also requires all municipalities desiring to extend existing sewer systems to secure a permit therefore, issued on unanimous agreement of the governor, attorney general and commissioner of health. These permits stipulate such conditions as may be necessary to subserve the general interests of the public health. This law also forbids the construction of water works for the supply of water to the public, whether by companies or by municipal corporations, unless a written permit shall have first been obtained from the commissioner of health and under such stipulations that the supply may not be prejudicial to public health.

A great deal of study and investigation of an engineering nature is required for carrying out the provisions of this law. The permits issued by the state authorities cannot be arbitrary decisions. They must, to be of value and to carry out the intent of the law, be based on sound engineering judgment. Over 2,000 separate studies and engineering investigations have been made in connection with the administration of this law. From the organization of the department to the present time sewerage conditions have been studied in over 450 separate municipalities and townships in the state, and 940 permits granted as prescribed by law. Every one of these permits was issued after a personal investigation by officers of the department and contains such stipulations as were considered necessary to subserve the general interests of the public health. Two hundred and twenty-five modern comprehensive sewer systems for municipalities and ninety-seven sewage treatment plants have been built under these permits, and many others are about to be constructed. Seven hundred and eighty permits for water works construction have been issued controlling the supply of water to over 700 separate municipalities or townships. Field investigations and studies were also made in each case and the permits included such conditions as were necessary to protect the public.

One hundred and seventeen water filtration plants are in operation supplying purified water under permits from the department of health to municipalities having a total population of over four millions, or approximately 50 per cent. of the entire population of the state.

The department's activities do not cease after a water filtration or sewage treatment plant has been built and placed in operation. Weekly reports covering the details of daily operation of the works are regularly filed with the department of health and these reports are carefully studied by experts, and suggestions for improvements are frequently sent to the different municipalities. In addition, a force of trained engineers is constantly traveling about the state inspecting these plants at irregular intervals. These precautions are taken in order that the public may derive the benefits that can only be secured when the works are efficiently maintained. Their value has been proved many times as the department's representatives frequently find that, due to carelessness or ignorance on the part of the operators, the precautionary measures provided by the designer of the plant and approved by the state have been neglected or entirely forgotten.

The department's attention is directed to the discharge of sewage not only from public systems, but also from individual houses in the townships of the state. A large force of inspectors is engaged on a house to house inspection in the rural districts and especially on the watersheds of the streams used as a source of water supply. Nearly one half of the watershed area of the 28,000 miles of streams in Pennsylvania has been covered in these inspections. In case of pollution of state waters from an overflowing privy or cesspool, from a barnyard, or from kitchen or bath wastes, the inspection seeks to bring about an abatement of the pollution, invoking the aid of the courts, if necessary. The department's aim in this matter is not merely to secure a temporary abatement, but also to require the installation of such apparatus or the adoption of such measures as will cause a permanent abatement of the menace.

During the year 1914 alone, 104,587 properties on 371 different watersheds throughout the state were inspected. Of this number, 25,300 were in an unsatisfactory condition; 13,107 pollutions were abated on these properties during the year.

From the beginning of the work of the department to the close of the year 1914 a total of 739,437 properties had been inspected or reinspected and 117,168 abatements had been secured through efforts of officers of the department on properties scattered throughout the state. The effect of this work on communities drinking water from streams which previously had been contaminated by these pollutions must be counted as one of the factors that has reduced the general death rate and especially the typhoid fever death rate.

DEATHS FROM TYPHOID FEVER AND LIVES SAVED

1906 to 1914 inclusive

Year	Typhoid Deaths	Rate per 100,000	Calculated Deaths 1906 Rate Obtaining	Saving as Compared with 1906
1906	3,917	54.8	.....	.....
1907	3,538	48.6	3,989	451
1908	2,450	32.4	4,064	1,614
1909	1,712	22.7	4,140	2,428
1910	1,892	24.6	4,216	2,324
1911	1,716	21.9	4,291	2,575
1912	1,310	16.5	4,367	3,057
1913	1,470	18.1	4,443	2,973
1914	1,075	13.0	4,518	3,443
			Total saved	18,865

The engineering division also aids some of the state institutions of the commonwealth. Most of these have extensive water works and sewerage systems and a number of them have been designed and constructed under the supervision of the engineering division, by means of separate appropriations secured from the legislature for the work. These systems not only protect the health of the patients in the institutions and safeguard the streams below, but they have many times served as models for similar plants for villages and boroughs throughout the state.

A great reduction in the death rate from many diseases has been noticeable in Pennsylvania. The reduction in the typhoid fever death rate, one of the best guides in water purification, has been especially marked, and in the ten-year period since the state department of health was organized has resulted in the saving of thousands of lives to the state.

In 1905, when the department began its operations, Pennsylvania was a typhoid-ridden state. The purification of the water supplies and the improvement in general sanitary conditions have been factors of tremendous influence in bringing about this marvelous reduction in the number of deaths from disease so often water-borne in origin. This combining of work essentially engineering in nature with medical work brings results and proves the value and propriety of utilizing the sanitary engineer in a public health organization.

ABSTRACT OF DISCUSSION

Dr. Victor C. Vaughan, Ann Arbor, Mich.: The work that Dr. Royer has presented as done by the Commissioner of Health of Pennsylvania is a very good thing. Pennsylvania certainly needed to do this kind of work. Western Pennsylvania, as the doctor says, was a hot-bed for typhoid fever; and it was not confined to Pennsylvania but to the whole country. It was not safe for anybody to come into the region around Pittsburgh because of the possibility of getting typhoid fever. I think that many states have found it necessary to make the sanitary engineering department of the state health work very important. I know we have in Michigan. For some years we have had a very competent state sanitary engineer as an official of the State Board of Health and an engineering department; and we have the same rules, the laws that Dr. Royer has got for Pennsylvania. They say that the medical profession is the only profession that buries its mistakes — puts them out of sight. That is quite as true of the engineering profession as it is of the medical profession; and faulty engineering in this country has added greatly to the death list. It has not only added greatly to the death list, but it has increased enormously the expenditure of money. I had a letter only a few weeks ago from the editor of one of the engineering journals wanting me to write an article for that journal showing the advantage it would be to the engineering profession to have engineers examined like physicians are examined. Now understand me — wanted me to write an article showing the great value that it would be to the engineer to have state boards of examiners for engineers, just as the physicians have. I wrote him that state boards of medical examiners were not for the benefit of the medical profession; they were for the benefit of the public; and the same reason would apply to the examination of sanitary engineers. If anybody questions it, simply come to Michigan and travel around with me for a few days. I can show where bungling engineers have buried millions of dollars so that they cannot be resurrected, and at the same time have endangered the lives of, and probably killed, many people. The sanitary engineer is an important and essential adjunct to any health department. The public has the services of the United States, represented here by Dr. Rucker, as recognition of that fact. You cannot do public health work without the sanitary engineer.

Dr. B. Franklin Royer, Harrisburg, Pa.: I am glad that Dr. Vaughan reinforced in a positive way why it is absolutely necessary that engineers' plans for water works and sewage works be submitted to a central health organization for review and approval. It is not only in the interest of the health of the community, but it saves municipalities untold sums of money. Plans may often be submitted by an engineer who is a very good civil engineer but a very bad sanitary engineer, and unless the entire plans are materially changed, would be entirely unfit for the community's public health needs.

Popular Instruction Concerning Diet.—There is one kind of instruction much needed by the American people, which would illustrate better than any other the desirable preventive functions of health officers and boards of health, namely, instruction concerning diet.—Prof. Charles W. Eliot, *Public Health*, September, 1915.

INTERMEDIATE TRACHELORRHAPHY

ITS USE AS A PROPHYLACTIC AGAINST THE PERNICIOUS EFFECTS SOMETIMES CAUSED BY LACERATION OF THE CERVIX

H. J. BOLDT, M.D.
NEW YORK

It is not likely that any one doubts that extensive lacerations of the cervix during childbirth may do much harm, or, as lately has been shown again, by the studies of Schottlaender and Kermauner, that occasionally they may favor the causation of cancer. These authors found, in instances of cervical cancer, the presence of a laceration in the immediate vicinity in nearly every instance. Does it not then behoove us, if only as a prophylactic measure, to repair cervical tears, *and to do this before pathologic changes, incident to the trauma, manifest themselves?*

I purpose to plead for such procedure, and especially that it may be done when the sacrifice of material tissue is not a necessity. My justification lies in the fact that those who have made a careful study of the results of cervical tears almost invariably verify the assertion made by Dr. Thomas Addis Emmet concerning their deleterious effects. In support of this I call your attention first to the careful study of Brooks Wells, "The Etiological Relation of Cervical Lacerations to Uterine Disease," made from the clinical material of the late Paul F. Mundé and published in the *American Journal of Obstetrics* for 1888; and then to the paper read by Clement Cleveland before the New York Obstetrical Society, entitled "The Necessity for Early Operation upon the Lacerated Cervix," and published in the same journal for 1887. What those papers stated at that time holds good today. The analyses made by the authors cited I could multiply several times from my own practice, having, before and since then, seen thousands of lacerated cervices from which I could verify the position taken by these writers.

It is true that the resulting ills have been exaggerated by some physicians, but this applies to most matters, everything depending on the point of view. Some, indeed, have gone so far as to say that every laceration, whenever found, requires repair. I see many patients with slight tears who have been told that they must have the lacerations repaired, although they have existed a long time — too long to do an operation without denuding the torn edges by cutting away tissue — and are causing absolutely no trouble.

It is not my purpose, however, to dwell on the pernicious effects that lacerations may cause. It is conceded by those who have observed such patients, that sometimes the tears may give rise to disturbances, which are usually in relation to the extent of the injury. My purpose, rather, is again to call attention to a slight operation, to be applied in properly selected instances, whereby eventual ailments due to such injuries may be prevented.

The thesis I presented for admission to the American Gynecological Society, in 1887, was on "Intermediate Trachelorrhaphy." Under the rules of the society at that time, no papers coming before it were permitted to be published elsewhere than in the records of its activities. My thesis, therefore, appeared only in the society's transactions for 1888. Now, after so many years of added experience with intermediate trachelorrhaphy, I deem it but proper to place it before the profession at large for what it is worth.

My analysis at that time was based on 3,000 women who had borne children, in which number there were 109 who had lesions that were directly traceable to the tear. While I have not since attempted another analysis, yet from the recollection of my observations I am constrained to hold a similar view today.

From the foregoing it will be seen that I do not claim that all lacerations are productive of pathologic changes; neither do I claim that there is any time limit as to symptoms showing themselves after the injury. According to Cleveland the average time in his cases was four years and six months; but this may be shorter or longer.

Montrose A. Pallen, whose assistant I was during the early part of my professional life, held that all tears should be closed immediately after delivery; but it will be conceded that this is not practical or necessary, except in case of hemorrhage from an exceptionally extensive tear. It is far better to wait until the effect of contusion has passed off and bleeding has ceased, so that one may inspect with exactitude. Moreover, many small tears heal spontaneously post partum. After, say from four to six weeks post partum, however, the genital tract should be inspected, particularly in primiparas, because for these the operation is particularly intended, and if a tear of some extent is found, it should be repaired.

TECHNIC

My present method of repair is simpler than formerly — so simple, in fact, that any one with a little surgical ability can easily adopt it.

The patient is placed in the lithotomy position and the customary disinfection attended to. If she is not hypersensitive and not nervous, no anesthetic is required, for the operation is not very painful.

The cervix is pulled down with a pair of well-working bullet forceps, and exposed with vaginal retractors. The bullet forceps are then adjusted, one pair in the line of the cervical canal on the anterior lip, and one pair similarly applied on the posterior lip. With a narrow but very sharp scalpel — sharp especially at the point — a superficial film of tissue is scraped off the torn surface, taking particular care that the angles of the tear are made raw. For sewing I usually use a full-curved, medium-sized Martin needle, which has cutting edges; but one may use any other needle, if more accustomed to it. A No. 2 chromic catgut is passed so as to include the entire depth of the tear. Usually two sutures suffice for each side of the tear. Sometimes only one suture is required for one side, it frequently being the case, in instances of bilateral tear, that the extent of the tear on the sides are unequal in extent. This also holds good for stellate tears. Care should be exercised in tying. The surfaces should be brought together just snugly, never too tight, so that the sutures may not cut into the tissue. No after-treatment is necessary, and the patient may be about as usual after the operation.

It will be seen from the foregoing that the operation is not applicable to any case in which the tear has existed long enough to cause pathologic changes, in which scar tissue is present in the angles. In all such patients the scraping, or making the torn surfaces raw, does not suffice. That is why I say that it is particularly applicable for primiparas who have not previously sustained a tear, and that in the case of every primipara it should be part of the accoucheur's duty to make a visual inspection in about four to six weeks subsequent to delivery, and then to repair any existing laceration (unless it be of negligible extent) in the way outlined.

It is understood that in scraping the edges scrupulous care should be taken to avoid the mucosa of the cervical canal.

39 East Sixty-First Street.

A METHOD OF TESTING MUSCULAR STRENGTH IN INFANTILE PARALYSIS *

E. G. MARTIN, Ph.D.
AND
ROBERT W. LOVETT, M.D.
BOSTON

The determination of the strength of partly paralyzed muscles in infantile paralysis, if made at all, has been done in the past by the roughest sort of guess, most often by pressing the hand against the contracting muscle. It was suggested to the physiological department of Harvard University in the winter of 1914-1915 that a more accurate means of estimating muscular strength would be of great value, and the method here described was formulated, with the following aims:

1. To enable a more accurate diagnosis to be made in the way of picking out the seriously affected muscles after an attack.
2. To obtain a means of indicating the muscles which were most promising for mechanical or operative treatment.
3. A quantitative measurement of this sort which would give a means of gaging the effectiveness of different modes of treatment.
4. A method of this kind might enable one to pick out from supposedly abortive cases certain cases in which remained a residual muscular paralysis too slight to be perceived by other methods.

To be of service the technic should be relatively simple and the results reliable. The method, which has been developed and used in a large series of tests extending over six months, seems to satisfy both these criteria to a reasonable degree.

The index of muscular power employed is the resistance of the muscle group to a steady pull sufficient to overcome it. A sling is adjusted in an assigned position over the part of the limb in which the muscle group to be tested has its insertion. The sling is fastened to an accurate spring balance through which the pull is exerted. The balance must be held carefully in a line at right angle to the axis of the part of the limb to which the sling is adjusted, and is read either at the instant the muscle yields, as in the test of plantar flexion, or when the member is drawn into an assigned relationship with the body, as in knee extension.

A standard technic has been worked out for each of the following movements: In the legs, plantar and dorsal flexion, inversion and eversion of foot; adduc-

* The funds for the pursuit of this inquiry were furnished by an interested citizen of Vermont.

tion and abduction, flexion and extension of the hip; flexion and extension of the knee. In the arms, pectoral, latissimus dorsi, anterior and posterior deltoids; forearm flexion and extension; thumb adduction and abduction. These include the important groups except the trunk muscles and the rotators, which are mechanically difficult to test reliably. The tests in detail will be described in a subsequent communication.

To be able to judge fairly the degree of impairment of an affected muscle group one must know what should be expected of the same group when normal. To this end we have prepared, on the basis of tests of a large series of normal children, tables of standard muscle strengths for all the groups listed above, for ages from 4 to 16 years. These tables give information not only of the normal strength of each group of muscles, but also of the relative strengths of the different groups.

To judge, on the basis of repeated tests, whether an affected muscle has improved or deteriorated, allowance must be made for possible variations in the vigor of voluntary innervation. To obtain data for this allowance we test regularly all the leg groups of both sides in cases that have any leg muscles affected, and all the arm groups when there is impairment of the arm.

Such changes of power as are shown by the *unaffected* muscles after a short interval are not referable to changes in muscular condition, but must signify changes in innervation. We can conclude, from the records of the unaffected muscles, what allowance to make for changes in innervation, and so determine how much of the change shown by the affected muscle is actual increase or loss of muscular power.

In favor of the method it may be said that successive tests at short intervals on the same subjects show the readings as to individual muscle groups to be, in a large percentage of cases, remarkably constant.

SUDDEN BLINDNESS DUE TO SUPPURATION OF THE ACCESSORY NASAL SINUSES

WITH REPORT OF THREE CASES *

H. H. STARK, M.D.
EL PASO, TEXAS

That the intimate anatomic relations existing between the nasal accessory sinuses and the orbital contents has caused much eye complication has long been well known, but it is only within the last few years that special attention has been given this subject, as is shown by the literature on the subject.

In the last three years I have had in my practice three cases of sudden monocular blindness, which were diagnosed as due to nasal suppuration, and cured by endonasal treatment. These cases were of such a nature that diagnosis was not easy, one case being diagnosed by the presence of central color scotoma for red and green; one by dilated pupil, and one by dilated pupil, color scotoma and involvement of the ocular muscle. These cases led me to investigate the ophthalmic literature, to see if by tabulating the symptoms of all cases reported there would not be found some more definite way of diagnosing the eye condition and locating the nasal trouble. I have collected from the literature 88 cases of sudden blindness from nasal disease, most of them with normal fundus (those that were not normal having only optic neuritis, with the exception of two which had a neuroretinitis), leaving out the cases that were complicated by a history of syphilis, tuberculosis, detached retina, uveitis, and including only two having orbital abscess. This confines the cases to that form which we recognize as retrobulbar neuritis. In 69 of these cases one eye, in 19 both eyes were affected. Of the 88 cases, 16 are from the English literature, 14 from the French, and 58 from the German, and date from 1839 to the present time. The French seem to have reported more in the early literature, but of late years the German reports have predominated. Of the total, 63 cases have been reported in the last ten years. In order that my own cases may be commented on under the separate heading of "Symptoms," I herewith give their history:

Case 1.—H. O. J., aged 35, came under my care Feb. 11, 1911, with the following history: In November, 1910, while he was standing on a steel cable attached to an engine, the engine started, throwing him in the air and causing him to alight on a steel rail on the right side of his head, cutting his ear in the median line and causing a fracture of the base of the skull with the usual accompanying symptoms of hemorrhage from the ear, etc. He was trephined within forty-eight hours and a blood clot removed; he remained unconscious for several days. After regaining consciousness, it was noticed that he had a paralysis of the right externus muscle, causing diplopia, due, undoubtedly, to involvement of the sixth nerve of that side. When referred to me, one month after the injury, examination showed that he had a normal vision in each eye, but up to that time had developed no movement of the right externus muscle. He was placed on increasing doses of strychnin, and his right eye covered with ground glass, to relieve him of the troublesome diplopia. He was under treatment for three months, with slight improvement, when he was referred to me again, May 2, with a history of the vision in the left eye suddenly becoming obscure April 28. He was able to read in the morning, but in the afternoon could only see objects indistinctly, the vision gradually growing worse up to the time I examined him, when the vision in his left eye was 21/100, vision in the right eye being normal. Examination of the left eye showed the pupil regularly reacting to light and accommodation; no fundus change was found, except a possible engorgement of the retinal vessels; peripheral field of vision, normal for white, but an absolute color scotoma for red and green; no sign of exophthalmos or orbital involvement; urine negative; no syphilitic history. At this time he gave no history of nasal trouble, and nothing was found on examination. Thinking there might be some syphilitic trouble, he was sent home and placed on increasing doses of potassium iodid. He returned to me on the twenty-second, vision having decreased to counting fingers at a few feet. The pupils were still normal in reaction; central color scotoma was still present, and no sign appeared of orbital involvement. Examination of the nose at this time showed pus coming from under the middle turbinate on the left side. Probing disclosed no uncovered bone; no involvement of the frontal or maxillary sinus could be found. The sphenoid was not probed, but there was no pus coming from this region. Diagnosis was made of retrobulbar neuritis, due to empyema of the ethmoid cells. In order to drain them, the usual preliminary operation of removing the anterior end of the middle turbinate was done, and he was placed on 5 grains of hexamethylenamin three times a day. There was an increased discharge of pus, and in five days his vision went up to 20/20; the color scotoma was still present; there was no marked decrease

---

[*] Read before the Section on Ophthalmology at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

In the cases of optic neuritis the seat of the trouble was:

Maxillary sinus	3
Maxillary and ethmoid	1
Maxillary, ethmoid and sphenoid	2
Ethmoid	18
Ethmoid and sphenoid	8
Sphenoid	8

Of the 52 cases, the ethmoid was involved in 33, showing the preponderance strongly in favor of the ethmoid cells in this trouble.

Of the choked disk cases, 1 was from maxillary sinus, ethmoid and sphenoid trouble, this being Halstead's[1] patient, in whom the left eye was blind from a right-sided suppuration; 1 other was Dubois'[2] patient, the posterior ethmoid being the seat of the trouble; location in the other 3 not being given.

It would be natural to think that the posterior cell would cause more pressure on the nerve by the closer proximity to it and the more confined area of the orbit in this location. Halstead's order of operation and results were as follows: Removal of the anterior end of the middle turbinate, entrance of the posterior ethmoid cells and sphenoid cavity. The condition began to improve, and in a week from that time the patient could count fingers held directly in front of her. Two weeks from the first operation, removal of the remaining part of the middle turbinate, probing and syringing the sphenoid was done, followed by slow improvement in sight. Three weeks later, the antrum, which was filled with pus, was opened and cleaned. Improvement continued after this until, five and a half months after operation, vision was 6/18. He ascribed the blindness and swelling of the optic disk to pressure from the sphenoid.

Fish[3] says that among 36 cases of optic neuritis found in the literature, 26 cases were of diseases of the nasal accessory sinuses. He, therefore, maintained that this etiologic factor should be credited with greater importance than is usually accredited it.

The direct nasal relationship was shown in 15 cases by improvement in the ocular condition following drainage; the 11 remaining cases were attributed to the same cause, although the connection could not be demonstrated by ocular improvement, as most of the cases presented more or less optic atrophy, while in others the treatment as advised was not undergone. In this paper he reports a case of optic neuritis from growth, as have others. Elschnig,[4] in discussing the significance of accessory nasal disease in the pathology of the eye, says that these cases represent about 15 per cent. of all optic nerve affections.

In the 43 cases of optic neuritis here tabulated, 38 patients improved with nasal treatment, showing this certainly to have been the causative factor in the large majority. From the analyses of these cases, we can safely say that blindness due to nasal sinus empyema, in addition to the retrobulbar neuritis, does, in about 50 per cent. of the cases, advance to such a stage as to cause an optic neuritis, and in a small percentage of cases goes on even to a choked disk; that all of these conditions are due possibly to the same cause, one being but an advanced stage of the other, and dependent to a certain degree on the location of the nasal involvement. None of my patients had an optic neuritis, but I ascribed this to the fact that they either had partial drainage from the affected sinus, or that they were seen early enough to prevent its formation.

PUPILLARY CONDITIONS

The condition of the pupil was one of the earliest signs of the eye involvement from the nasal accessory sinuses, Beer,[5] in 1817, giving the following classification: "Vicarious Amaurosis of Suppurating Coryza Without a Demonstrable Accumulation of Mucus in the Frontal Sinus." He says the pupil in this form of amaurosis is greatly dilated without losing its clearness, the iris is immovable and its pupillary margin is not regularly rounded, but angular. Under the heading of "Vicarious Amaurosis of Suppressed Coryza with Accumulation of Mucus and Pus in the Frontal Sinuses," he says:

> After the sudden suppression of severe coryza, the patient begins to suffer from pain limited to the root of the nose and the frontal sinus region, accompanied at the same time by a very considerable amaurotic amblyopia, affecting either one eye or both eyes together, and associated with various light phenomena, and a narrowed, perfectly round, but very pale black pupil, entire immobility of the iris and diplopia.

Others of the early writers reported dilated pupil, but this point seems to have been neglected in our later text-books. Recently Elschnig[4] has called attention to it as one of the symptoms in this type of amblyopia. In the cases investigated, the pupil of the affected eye was dilated in 18, or about 20 per cent., contracted in 4. In the patients with dilated pupils the sinuses affected were the following:

Maxillary sinus and ethmoid	1
Maxillary, ethmoid and sphenoid	1
Ethmoid	9
Ethmoid and sphenoid	2
Sphenoid	1
Not located	4

In patients with contracted pupils:

Ethmoid and sphenoid	1
Ethmoid	3

The cause of this symptom has seldom been commented on by the authors.

Trousseau[6] says, in discussing reflex ocular disturbance of nasal origin: "I have seen the disappearance of an apparently inexplicable unilateral mydriasis following upon the cauterizing of ulcers in the nose." He points out that there exists a true asthenopia of nasal origin, which yields only to the treatment of the nasal pituitary. While we are unable to say exactly, this cure may have been caused by a shrinking of the membranes, allowing pus to be discharged from one of the sinuses. This is the only paper assigning a cause for the dilatation. In my two cases, I thought it was a symptom of diagnostic value, pointing to the location of the pus in the anterior cells with pressure on either a ciliary ganglion or short ciliary nerve, but Halstead's case,[1] in which the dilatation came no doubt from the opposite sphenoid, and Gutmann's[7] case, in which he ascribed the trouble to the opposite antrum, make it look doubtful, although the latter patient had acute catarrh on the side of the affected eye, and there may have been an involvement of the nose on this side as well. But that the cause is not due to blindness alone is certainly true, or all cases would have a dilated pupil. That it is not due solely to the pus is true, for Richet[8] reports a case of dilatation caused by mucocele, while Varese[9] reports a case due to sarcoma of the superior maxillary sinus. However, this patient had involvement of the sinuses and improved after the ethmoids were drained.

[5] Beer: Vicarious Amaurosis of Suppressed Coryza without a Demonstrable Accumulation of Mucus in the Frontal Sinuses, Lehre von den Augenkrankheiten, Vienna, 1817, ii, 530.

[6] Trousseau: Troubles oculaires réflexes d'origine nasale, Bull. Méd, Paris, 1889, iii, 506.

Roemer,[10] in discussing absolute immobility of the pupil, says the lesion may be situated in the sphincter, in the short ciliary nerve, in the ciliary ganglion, in the motor root of the ganglion, in the trunk of the oculomotor nerve, or in the ganglion cells of the sphincter. If the lesion is situated posterior to the ciliary ganglion, physostigmin (eserin) will continue to act. If in front of it, the effect of the drug will be lessened.

Four cases of contracted pupil are reported. Hoffmann[11] reports a case in which there was supra-orbital pain, and ascribes the condition to involvement of the surpraorbital nerve and involvement of the oculomotor fibers supplying the sphincter pupillae, this case having exophthalmos. Von Eicken[12] reports a case, but ascribes no cause; this patient had diplopia and slight exophthalmos; it was due to suppuration of the ethmoid cells. Knapp[13] reported an interesting case with contracted pupil, irresponsive to light with no light perception in the eye, and a distinct optic neuritis, which improved after removing the anterior end of the middle turbinate. One week later the pupil reacted to light, but instantly dilated again; the pupil was normal on the twenty-third day after operation.

EXOPHTHALMOS

Exophthalmos was mentioned as a symptom 17 times, with the following sinuses involved:

Maxillary sinus	4
Frontal and ethmoid	1
Ethmoid	7
Ethmoid and sphenoid	1
Sphenoid	1
Not located	3

This should point to this symptom as coming more frequently from the antrum and ethmoid, possibly because of their having a larger surface given to making up the bony wall of the orbit. Elschnig[4] says in unilateral infections, one half of the cases present a slight exophthalmos, measurable by means of Hertl's ophthalmometer. This close observation by Elschnig makes it seem as though exophthalmos had been present in many cases and not diagnosed by observation. In Gutmann's[7] case, all the conditions were ascribed to the antrum on the opposite side, but, as noted under "Pupillary Conditions," there was an acute catarrh on the affected side, which might have been a sinus involvement. Sommer, in discussing Meyer's[14] case, reported a case in which there was exophthalmos, which was ascribed to frontal and ethmoid involvement, and which at postmortem examination showed advanced caries of the sphenoid bone with normal sphenoid cavity.

The external muscles were involved in 11 cases, as follows:

Maxillary sinus	3
Maxillary and sphenoid	1
Ethmoid	4
Ethmoid and sphenoid	2
Sphenoid	1

showing, as in exophthalmos, the predominating influence of the antrum and ethmoid.

RESTRICTION OF VISUAL FIELD

Berger[15] says, in 1887: "I was the first to observe a narrowing of the visual field following upon disease of the nasal fossa. A short time after my communication, analogous observations were published by Zeim, Killam, Hamilton and others." Eighty-two of the total number of cases were published after Berger reported restriction of the peripheral field as one of the symptoms, but only three cases of restriction could be found. Birch-Hirschfeld[16] claims that the restriction is of later date than the central scotoma, and emphasized the fact that central scotoma, first relative, then absolute, is the first symptom. Van der Hoeve[17] and others emphasize the point that the first symptom is the enlargement of the blind spot for color, believing this to occur exclusively in involvement of the posterior accessory sinuses.

The three restricted fields were: Maxillary sinus 1, ethmoid 1, and frontal 1; all of them being cases of long standing, which strengthened Birch-Hirschfeld's assertion that restriction comes later.

SCOTOMA

There were fourteen cases in which scotoma was mentioned, but all of them were not confined to the central field. They are divided as follows:

Maxillary sinus	1
Maxillary, ethmoid and sphenoid	1
Frontal and sphenoid	1
Ethmoid	10
Sphenoid	1

Snellen[18] reports a case of the right eye being blind, left eye with visual acuity of 6/60; temporal hemianopsia cured by opening the sphenoid. Onodi[19] reports a case of suppuration of the posterior ethmoid cells and of the sphenoid sinus, associated with optic atrophy of long standing on the right side, with optic neuritis and temporal hemianopsia on the left side;

the left eye improved slightly after operation. He points out that the posterior ethmoid cells are not infrequently closely related to the optic canal, the bony wall being very thin in all these cases. Gutmann[20] reports one case of right-sided central scotoma, with temporal narrowing of the field, which result he ascribes to the action of toxins arising from empyema of the ethmoid cells. His patient was operated on with subsequent loss of vision. Van Gilse[21] reports a case in which the patient in the course of a coryza underwent a loss of vision in the right eye with pain, right-sided headache and slight swelling, slight peripheral restriction of the visual field, central scotoma for white and color, enlargement of the blind spot for color, and an absolute annular scotoma. Removal of the middle turbinate was followed by a narrowing of the scotoma; opening the posterior ethmoid cells had no influence on the eye symptoms; incision of the sphenoid one week later gave no improvement of the eye. When the frontal sinus and anterior ethmoid cells were opened three weeks later, the frontal sinus was found to be healthy; one ethmoid cell was filled with mucopus. On the day following operation, the exophthalmos had practically disappeared, as also the annular scotoma. This is one of the cases clearly demonstrating the fact that many sinuses may be involved without being entirely responsible for the condition of the eye; the symptoms in this case showing no marked improvement until after a solitary anterior ethmoid cell was opened.

W. L. Meyer[22] reports a case of bilateral central scotoma, in which he opened the right and left ethmoid cells, on account of the profuse nasal secretion, with no definite pathologic findings; vision first improved, then became slightly aggravated on the right side.

In considering this symptom, we are led to believe that the field for white and color is very frequently markedly significant, pointing to more definite location of the nasal trouble; bitemporal hemianopsia naturally pointing to a sphenoid involvement. The field could be easily explained if we considered the symptom to be due solely to pressure, as the anatomic structure of the different orbits might be such that pressure was not equally applied, thus causing a restriction of the nerve at different points. Many investigators have shown that the sphenoid cavity is of such irregular shape and location that it could cause, in addition to a temporal, a bitemporal hemianopsia. It would be natural that a sphenoid cavity could be so placed that it would cause a temporal or bitemporal hemianopsia.

CENTRAL SCOTOMA

The most definite sign, and one on which most reliance can be placed, is that of central scotoma, the process, no doubt, being the formation of the central scotoma which, in time with the increased pressure, causes a restriction of the field. Central scotoma was reported in twelve cases, it being the only symptom in one case reported by Fuchs,[23] which was due to involvement of the ethmoid and sphenoid. However, Panse[24] reports a patient with left-side amblyopia, with light perception, who had been unable to see for eight days; the left pupil was larger than the right, sluggish in its reaction, optic papilla and retina slightly blurred; the middle turbinate was removed with slight improvement as a result. In this case a central color scotoma was never demonstrated; a Wassermann was positive, but, in spite of the syphilitic base, a nasal operation induced a temporary improvement.

Jessop[25] reports a case of a small color scotoma for red, associated with exophthalmos, in which he found an endothelioma on the greater wing of the sphenoid.

ENLARGEMENT OF THE BLIND SPOT

Enlargement of the blind spot has been so recently brought to our notice that sufficient data have not yet been accumulated from which to judge its value. In addition to Van der Hoeve's claim, de Kleyn[26] looked for this symptom in a large number of nose cases in his clinic, in diseases of the nose and the anterior sinuses, but found a normal blind spot for white and color. Whereas, in fifty-two cases of disease of the postnasal accessory sinuses, an enlargement of the blind spot for white or color was noted in forty-six cases of extensive posterior ethmoiditis or sphenoiditis, in all cases the eye symptoms were much improved, the majority entirely cured by nasal treatment. Van Gilse[21] in his case reports it. Dubois[2] failed to find it in a case of left-sided papillitis with negative nasal findings. Panse[24] reports a case of bilateral disturbance of vision, in which the optic papillae were congested; the visual field showed enlargement of the blind spot; no unusual findings in the nose, but the middle turbinate was removed and the ethmoids exposed. Three weeks later vision was improved to 5/6 and 5/8, optic disk normal. Recently Onodi[27] has given statistics on 100 cases from his clinic in Budapest. Among 70 accessory sinus empyemas, ocular changes were present in 47 cases; negative findings in 23; central scotoma was present 6 times, 3 times bilateral; 1 combined with an enlargement of the blind spot, and 2 with optic neuritis; enlargement of the unilateral scotoma occurred in 3 cases of empyema of the maxillary sinus and the ethmoid cells, bilateral scotoma in a case of empyema of the ethmoid cells, the sphenoid sinus and frontal sinus, respectively. Enlargement of the blind spot was present 38 times; 28 times alone, and 6 times associated with central color scotoma. Narrowing of the visual field occurred once. In bilateral empyema, the blind spot was enlarged, but only on one side in part of the cases. In unilateral empyema, enlargement of the blind spot was noted 11 times on the same side, and 7 times on the contralateral side.

Marbreiter[28] reports 100 cases of empyema examined in two years in the nose and throat clinics of Strassburg. When possible, the examination was made before and after the operation. Enlargement was always more frequent for color than for white. Her cases do not agree with those of Van der Hoeve and de Kleyn, who consider the presence of enlargement of the blind spot indicative of empyema of the posterior sinuses. She found it many times in diseases of the anterior sinuses. This symptom, unquestionably, has great possibilities as a diagnostic point, which will be shown by further investigation.

Recently Loeb[29] has reported a case of scintillating scotoma, cured by operation on the ethmoid sinus.

CAUSE

Hajek[30] recently said that the teaching of a common rhinologic origin for retrobulbar neuritis did not rest on a solid basis so far as actual proof is concerned. He has repeatedly obtained temporary improvement after opening the ethmoid labyrinth, without pathologic findings, but he has also frequently had no success at all. In some of the cases, assumed to be those of rhinologic origin, in which he had decided to operate, spontaneous cure occurred in the course of time. Other patients who were operated on became totally blind after a transitory improvement.

Baumgarten[31] reports a case in which the patient suddenly became blind in the right eye with normal ophthalmic findings, in which, on removal of the middle turbinate and opening the sphenoid, he found nothing but thickened mucosa. In the same paper he reported a case in which the patient had loss of sight in one eye within three days. Four months later pressure atrophy of the optic nerve was seen; removal of the ethmoid bulla and incision of the anterior sphenoid wall showed only thickened mucosa. Subsequently more posterior cells were exposed, with improvement of vision. The thickened mucosa in this case shows that there must have been some inflammation existing. It is extremely doubtful on opening a cavity of this character, with the amount of blood occurring during an operation, that one can always tell the presence of a small amount of pus, and a small amount is all that is necessary to do mischief.

De Schweinitz,[32] speaking of edema of the lids from maxillary sinus disease, says that if the disease is of long standing, it assumes a positively brawny consistency, showing, no doubt, a cell proliferation. He quotes Dr. Walter Williams in saying that he has seen edema of the lids when only a few drops of pus have been in the cavity of the antrum.

Various theories have been expressed as to the cause of this form of amblyopia—pressure, circulatory disturbance and toxemia. That pus alone is not responsible for the condition is shown by Hajek and Baumgarten's report, and that the same condition of the eye may be caused by a noninfectious growth is illustrated in articles previously quoted in this paper. The one theory that seems to fit all cases is that of pressure. This pressure may be of two kinds, gradual and sudden; sudden pressure, which I believe is illustrated in my three cases, is no doubt due to the sudden rupture of the bony wall separating the sinus and the orbit without rupture of the periosteum, thus bringing immediately direct pressure on the orbit and its contents, causing disturbance of the functions of the nerves and interference with the circulation. The gradual pressure is, no doubt, due to the inflammatory condition, suppurative or nonsuppurative, being transmitted from the sinus to the orbit with or without infection, possibly enlargement of the vessels with cell proliferation. It is doubtful whether the toxins are directly responsible for the central scotoma, but they no doubt play an important part in producing a low-grade cellulitis. This theory is borne out by de Kleyn and Gerlach's[33] postmortem study of a case of empyema of the maxillary sinus with erythema, intense conjunctiva and edema of the lids, in which they described a circumscribed infiltration just opposite the sphenoid sinus, and continuation of the infiltration toward the septum along a vein, an interstitial optic neuritis with numerous vacuoles in the optic nerve.

I believe we can safely say that all the symptoms enumerated can be ascribed to the same cause, one being simply a different degree of the other, the primary stage being a slight involvement, the maximum stage represented sometimes by orbital abscess or direct infection. Other cases in which there is no orbital infection and a loss of vision coming on after slight improvement, to my mind show the shrinking which takes place after the cause is removed, which shrinking causes constriction of the optic nerve. If we accept this theory, it not only explains this condition, but explains many cases of muscular asthenopia, and possibly, many cases in patients who have defective central vision, which has been ascribed to amblyopia ex anopsia.

ABSTRACT OF DISCUSSION

Dr. James W. Dunn, Cairo, Ill.: Oculists have long been intimately acquainted with the important rôle affections of the frontal and maxillary sinuses play in the production of disturbances of vision. This is not surprising when we recall the comparative ease with which diseases of these cavities are diagnosed and the more or less prominent symptoms such as displacement of the eyeball and interference with its motility associated with pathologic conditions here that have broken over into the orbit. Not until recently, however, have we endeavored to learn fully the part affections of the ethmoid cells and the sphenoidal sinuses play in producing visual disturbances. Investigation has now taught us that a few bilateral and many unilateral cases of obscure interference with vision are dependent on diseases of these latter cavities.

The relations existing between the optic nerve and the posterior ethmoid cells, the sphenoidal sinus and the posterior part of the frontal sinus are not constant. Usually the sphenoidal sinus bears the most intimate relation to this nerve, but at times the latter may be almost completely surrounded by a hyperdeveloped ethmoid cell. Again, the intimate relation existing between the optic nerve and the sphenoid sinus and ethmoid cells on account of the thinness of the bony plate intervening in normal conditions may be made more intimate by the failure of complete development of this partition. Thus the liability of the nerve to injury from pressure in all cases of disease in these cavities is increased occasionally by congenital dehiscences. Thus also is the nerve made liable to direct involvement through continuity of tissue. Unilateral central scotoma, enlargement of the blind spot and postoptic neuritis are significant of disease of the posterior ethmoid cells and sphenoid sinuses. This is particularly true if there are no indications of central brain lesion, no external ocular manifestations, and no ophthalmoscopic evidences in the case.

All the cases reported by the essayist are visual disturbances from empyema of the ethmoid cells. That the seat of trouble was in the posterior cells in Case 2 is patent from the report. This is not so evident from the reports on the other two cases. When, however, we recall the slight interference with motility and the absence of displacement of the eyeball in these cases we are justified in concluding that these were similar to Case 2. Indeed, it seems probable that Dr. Stark would have found more conclusive evidence in his examinations than he did had it not been that these were the cells causing the eye complications. My conviction is that, generally speaking, those cases of interference with vision from diseases in the frontal and maxillary sinuses are easy of diagnosis, but the really puzzling ones are those from affections of the sphenoid sinus and posterior ethmoid cells.

Of the fifty-two cases of involvement of the optic nerve collected by the essayist, in forty-two the seat of the trouble was either the ethmoid cells or sphenoid sinuses, or both. This is in accordance with what we would suppose from the anatomic facts brought out.

Dr. Otis Orendorff, Canon City, Colo.: The case I wish to report is of especial interest for the reason that it is complicated with neurasthenia and dental disturbance. I was wrestling with the case just at the time I received a copy of the paper by Dr. Stark. May 11, 1915, Mrs. H. C., aged 27, housewife, mother of three healthy children, always enjoyed reasonably good health, but for several years was subject to numbness in left side which her physician attributed to hysteroneurasthenia; had slight pyorrhea; subject to headache for years, aggravated by stooping, etc., as well as on fixation; no history of catarrh or throat trouble, but a slight mucous discharge and sneezing for one month. This would not be of diagnostic importance for the reason that it occurred in the hay-fever season. Vision failed suddenly in the right eye the day before the consultation. The pupils were both slightly dilated and sluggish; right worse; right eye turned out and up occasionally and patient complained of diffuse haziness and deep tenderness, and at times there was slight injection. The ophthalmoscope showed in the right eye possibly slight haziness but a normal fundus could be distinctly made out: the left a little retinal hyperemia. Refraction: Right .1/10 not improved. Left, $8/10-^{1} + .50 = 8/10-^{1}$, May 13, 1915, refraction and examination under homatropin with the same result. She was advised to consult a dentist, who reported the upper wisdom teeth unerupted and severe pyorrhea of the first lower right molar, this tooth being very loose, but there was no tenderness or indication of retained pus about the teeth. May 15, pain on movement and deep pressure in right eyeball. Right vision reduced to fingers at 6 feet. Ophthalmoscope still negative; pupil more dilated and practically no reaction. Although the nose had appeared normal, cocain and epinephrin were now applied, which revealed a little bulging in the right ethmoid and an enlarged middle turbinate pressing on the lateral wall of the left cavity. However, these conditions were not so marked as in other noses in which they give no trouble whatever. There was a small drop of pus very high in the right cavity. Suction and posture brought no more. There was not sufficient vision in the right eye to take the fields, but in the left eye they were normal.

A competent internist reported positively that there was no general condition that would account for this woman's trouble and insisted that the disease was hysteria. I now made a tentative diagnosis, acute retrobulbar neuritis secondary to an acute ethmoiditis, and promptly opened up the anterior ethmoid and found plenty of pus in the upper portion, but none in the lower cells. For some reason there was a serious hemorrhage. Recovery was uneventful. Examination, May 18, showed R.V. 1/10; May 20, R.V. 3/10; May 24, R.V. 5/10; June 8, R.V. $8/10-^{1}$, L.V. 8/10. Incidentally the right third molar was appearing. Fundi normal. The patient noticed that clearing begins at the upper part of the field. While the rôle that the teeth are playing in this case is uncertain, there can be no doubt that the chief etiologic factor can be found in the ethmoid sinus.

Dr. Hans Barkan, San Francisco: I have seen some cases which simulate these, one this year and five or six before that, which are of special interest. The first was a case of sudden blindness in a young person; such cases occur most frequently in young people. They proved to be in all multiple sclerosis. This condition should always be borne in mind in seeing a one-sided blindness or occasional bilateral, complete and acute in its onset, with or without some involvement of the nerve. We do not need the usual classical triad, namely, scanning speech, tremor and nystagmus, any more to diagnose multiple sclerosis. A missing patellar reflex, a one-sided corneal anesthesia or absent abdominal reflexes, for instance, are enough to be at least suspicious, especially when combined with an acute retrobulbar neuritis. Three of the cases I have seen have been accompanied by considerable headache; practically all of them have cleared up in four or five days from blindness to practically normal vision by rest and sweating. It is of particular interest to me that some of these patient came saying that they had had these attacks once or twice before, but that vision had returned in a few days and they had not bothered to see an ophthalmologist. Since hearing Dr. Stark's very interesting paper I have felt still stronger about this question of mapping out the blind spot. I consider it of practically no value unless done by Bjerrum's method. There are certain points to be observed in taking it. The patient will give a somewhat smaller blind spot when the object is led from within the blind spot outward than if from the periphery toward the blind spot. There is another point I have not seen mentioned which was pointed out to me some years ago; in examining the fundus we know that the course of the vessels from the disk outward varies considerably; in some people they run more grouped together than in others. In this case if the mark be led toward the blind spot along the direction of these vessels a blind sector corresponding to them will often simulate an enlargement. I personally believe the value of this method in these cases to be problematical.

Dr. Walter R. Parker, Detroit: Anatomically the accessory sinuses offer the greatest possibility for optic nerve infections. Clinically, however, the proof of the sinuses being the sole etiologic factor in any given case is comparatively rare. The coexistence of optic nerve lesions and sinus infections does not necessarily prove a causal relationship. The possibility of some general disease being responsible for the changes in the nerve should not be overlooked. Three or four years ago I saw a case of retrobulbar neuritis in a patient with sinus infection in which the neural diagnosis was hysteria. Eighteen months later she showed unmistakable symptoms of multiple sclerosis. The examination of a case of optic neuritis is not complete which does not include that of the rhinologist. Only by reports of carefully prepared cases, such as the author has given us, will this subject be cleared up.

Dr. Robert W. Miller, Los Angeles: It has been my fortune to deal with quite a number of these cases in the past few years. I have also seen a few cases of optic neuritis due to diseases of the teeth. In conferring with specialists in other sections I find that many of them are accustomed to see these cases with a considerable, and perhaps rather increasing, frequency. Some competent observers in Chicago, where we would expect to find frequent occurrences, do not find them very often. We note what Dr. Parker has just said as to the infrequency of such cases in his experience. My impression is that if we look for them more constantly, we shall find them more frequently. It is but a very little step from the cases of sudden blindness to those which develop more gradually. More gradual development of blindness has been the rule in the majority of cases I have seen. One or two of the speakers have mentioned the importance of the general health, and I would emphasize the necessity of carefully bearing in mind the influence of general diseases and the ability to recognize all forms of disease. We should often invoke the aid of the Roentgen ray in diagnosis.

In the treatment there are two points to be especially borne in mind. In the young patients whose tissues are soft and easily influenced, in whom we have not a great amount of hypertrophy of the bony structure, it is an excellent way to put them to bed, employ local and general therapy, including hot baths, and we often secure improvement or recovery without surgical intervention. When we have made up our minds that we are dealing with a surgical case, it will be preferable not only to remove the anterior end of the middle turbinate body, but do a partial or practically complete exenteration of the ethmoid labyrinth. This insures drainage, instead of leaving the matter in doubt. The well-known variability or lack of uniformity of the ethmoid structures in different skulls, together with the fact that we are dealing with a condition of retention, seem to me to fully justify this view.

Dr. W. H. Roberts, Pasadena, Calif.: Some years ago I did a combined extraction for cataract on an old man, with good results. About a year following the operation he came in saying he could not see with the eye operated on, and gave a history of having contracted a severe cold some six or eight months previously. He had had deep-seated pain on the side of the affected eye. After some weeks' duration he had a discharge of pus from the nose which relieved the pain, but the vision of this eye was entirely gone. The ophthalmoscope showed optic atrophy. A sphenoidal abscess had caused pressure on, and atrophy of, the optic nerve.

Dr. E. H. Cary, Dallas, Tex.: The question of nasal pressure, per se, in the sinuses producing the blindness described by Dr. Stark does not seem the correct explanation to me, for we have symptoms ranging from slight vasomotor disturbances to blindness occurring in people who have nasal defects, hypertrophic and cystic middle turbinals giving nasal pressure with adhesions, as well as ethmoidal disturbances where there is neither pus nor secretion. I think it is wise and opportune to report such cases and to relate all such observations with the idea of bringing the ophthalmic point of view back to the relation between the nose and the eye. The eye and ear hospitals, which have magnified the importance of these organs to the exclusion of the nose, have materially lessened their students' chances for correct view of the whole. There must be more than mere interchange of ideas; the ophthalmologist must know the nasal possibilities. Having been trained as an ophthalmologist, no one ever charged more cases of iritis and associated eye disorders to syphilis than I have, but syphilis can be thrown out as cause in many cases, similar in type, yet differing sufficiently for an observer to be able to place the responsibility where it belongs. An ethmoidal, turbinal, or nasal ridge, either or all the cause of a nasal reflex, is easily and promptly curable.

A schoolteacher gave a history of recurring attacks of an extremely painful left eye where the vascular let down was marked; some exophthalmos was noticed and vision had been reduced to 2/200. Such attacks occurred at intervals over a period of two years, made more violent by a cold. When seen the blood vessels of the deeper structure in and around the globe near the inner canthus and lower lid gave the typical appearance the vessels always have when a nasal reflex is at fault. Intra-ocularly the patient had a detached retina, and this was the first case I had ever seen which in any way clinically backed up the theory that detachment was due to faulty secretion of fluid of the ciliary processes. Hence, in operating on the nose for the cause, I refused to trephine for retinal condition and awaited results. Within two weeks she had absorbed the fluid back of the retina sufficiently to see 16/70. The history of the case was that the retina had been detached for two years, whereas here we had a suppression of secretion, due evidently to delayed or interrupted impulses governing the ciliary body and processes. I have seen secondary glaucoma produced from too many impulses, or an exaggeration of secretion, and relieved from this same cause, by the use of similar operative procedures.

Dr. H. H. Stark, El Paso, Tex.: I found the blind spot enlargement of such a conflicting nature that I feel one is unable to judge of its diagnostic value without further investigation, and as Dr. Barkan says, it is hard accurately to determine. I was waiting for some one to bring up the question of multiple sclerosis in such cases, as did Dr. Parker. The eye symptoms of this disease are so much like the cases I have reported that I feel it quite possible for nasal sinus suppuration to be an etiologic factor in sclerosis of the brain and spinal cord. Dr. Cary speaks of a case of detached retina. In the literature collected for this paper, I find one case of blindness due to retrobulbar neuritis, which was caused by sinus suppuration. This patient had a detached retina, but the blindness was due to the pressure on the optic nerve and orbital contents, and the cause of the detached retina was considered the same. This case was not included in the report, as only clear cases of retrobulbar neuritis without complication were tabulated.

POSTOPERATIVE DETACHMENT OF THE CHOROID

WITH ESPECIAL REFERENCE TO ELLIOT'S OPERATION FOR GLAUCOMA *

HANS BARKAN, M.D.
SAN FRANCISCO

I have chosen to present this subject because, apart from the articles by Marshall and Hudson in the English ophthalmic literature, there are none but isolated case reports to be found in the American; and because I have paid particular attention to its occurrence, especially in postoperative cataract and glaucoma cases, since my attention was first called to the occurrence of postoperative detachment of the choroid in the clinic of Professor Fuchs.

There are, broadly speaking, four classes of detachment: (1) tears of the ciliary body with the aqueous percolating into the suprachoroidal space; (2) traction on the choroid and retina by organizing masses in the vitreous; (3) hemorrhage in and beneath the choroid from ruptured vessels; (4) inflammatory detachment. *Restitutio ad integrum* is possibly only in the first group, and this group, whether due to tears of the ciliary body, as Fuchs believed, or to the causes which are to be described later, is the only group to be considered under the class of postoperative detachment.

According to de Wecker (Graefe-Saemisch Handbuch) von Ammon first observed the condition, succeeded by Stellwag von Carion, Virchow and Iwanoff; these all being postmortem observations. The first clinical description we owe, as we do so many others, to von Graefe; the first clinical description and postmortem examination in the same case to H. Knapp, who diagnosed detachment of the choroid, believing it due to an underlying tumor. Necropsy findings, however, showed a collection of serous fluid.

Reuling and Marshall both gave early anatomic descriptions of the condition. Fuchs, in 1900, wrote the first classical monograph on the subject, in which he mentions that only ten cases have been reported since Knapp's case in 1868. The occurrence of a few cases in the clinic directed his attention to the matter and careful observation by himself and his assistants of all postoperative cataract and glaucoma cases in the next few months established the fact that postoperative detachment of the choroid in these cases was nothing unusual and seemed to occur with about equal frequency, whether the case was one of simple extraction or glaucoma iridectomy.

---

* Read before the Section on Ophthalmology at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

The opinions as to the nature and origin of the ophthalmoscopic findings in the cases reported before Fuchs' study are the following: Haab believed them to be cysts and explained their rapid disappearance to the bursting of the cyst wall. A cyst, however, could not grow in a few days to a considerable dimension because the delicate tissue of the retina would tear. In addition, the visible protuberance would disappear instantly after the rupture of the cyst, which it does not do. Finally, the practically retained function of the retina at the place of detachment speaks against the cyst theory. Velhagen believed them to be cyst-like detachments of the epithelium of the ciliary body. With the great expanse of the choroidal detachment, the epithelium would have to be detached not only over the ciliary body but further backward over great areas of the choroid, which, in view of the slight attachment of the epithelial cells to each other, is not to be thought of. Lindemann believed that he was dealing with swollen and blood-stained cortical masses in the vitreous after extraction. This view is entirely in contradiction with the appearance of the choroidal detachment, as well as with the fact that after iridectomy and glaucoma operations, absolutely similar detachments are to be seen. These various theories existed until Fuchs' classical description in which he so depicts the occurrence of choroidal detachment that I will simply quote his description.

> We are dealing with cases of senile cataract. . . . The course of the operation is usually a normal one, the same being true of the course of the healing in the next few days. . . . However, if the anterior chamber is shallow, it has disappeared entirely without there being any sign of rupture of the wound or filtration of the scar. Simultaneously, the eye is soft. Focal illumination, as well as the inverted image, will disclose the detached parts of the choroid projecting in hemispherical form into the vitreous. This detachment may take place soon after the operation, or may take place a few months afterward. It progresses to a certain height and then very quickly—within a few days—it recedes, the anterior chamber at the same time becoming deeper and the tension of the eye again becoming normal.

With lateral illumination, the hemispherical projections are of various shades of yellow and brown without visible vessels on the smooth surface, without folds and without movement. If examined in the inverted image, the choroidal detachment appears very dark, sometimes almost black, and if it be a very flat one, it can be diagnosticated only by the appearance of a dark shadow, the border of which forms a convex line posteriorly.

In 318 extractions with iridectomy the percentage of choroidal detachment was 4.4; in 175 without iridectomy 5.1 per cent., and it was to be noted that in the cases of detachment, one-fourth were complicated extractions in the sense that there was either vitreous loss, or cataract delivered in the capsule. In 111 iridectomies for glaucoma the percentage of detachment was 10. In examining some of these eyes which had previously been operated on for cataract, Fuchs found tears of the ciliary body in enough cases to make him feel that aqueous percolating through these tears into the suprachoroidal space could very well account for the choroidal detachment; that this does not happen immediately after the operation he explained by mentioning the possibility of the tears being, in the first few days, filled with blood and coagulated serum. That this explanation will not necessarily fit all cases is evident from the fact that in many operations after which choroidal detachment has occurred, no instrumental interference with the angle of the chamber or of the iris has taken place at all; and yet choroidal detachment has taken place.

Meller (1911) believes as Fuchs does that the detachment is caused by aqueous beneath the choroid, but traces the path of the aqueous in a different fashion; instead of as Fuchs does, through the pupil, anterior chamber, and tears in the ligamentum pectinatum into the suprachoroidal space, through the ciliary body directly into the suprachoroidal space. Aqueous is secreted in greatly increased quantities after operations and he believes that under certain conditions, possibly due to the nonrupture of the ciliary epithelium, some of this aqueous forces its way back through the ciliary body directly beneath the choroid.

Marshall's earlier view—serous exudation from choroidal vessels, and Hudson's later view and the result of his pathologic examinations—correspond well and seem to suit most cases more completely than either Meller's or Fuchs', though the probability cannot be denied that the mechanism of Fuchs as well as that of Meller may by itself cause an *ablatio* in certain cases and may form a contributing cause at least in some percentage of the entire number. Marshall and Hudson believe that the serous exudation arises from the choroidal blood vessels, particularly from the thin-walled choroidal veins, and that under conditions of abnormally low intra-ocular tension, an abnormally free transudate of fluid from these vessels occurs, which again stops when tension is reestablished. That an abnormally low tension is a necessary coincidence with choroidal detachment is plain from clinical observation as well as from the pathologic findings of Hudson. The microscopic evidence of pronounced edema of the ciliary body, which we would expect to find if the aqueous transudated directly downward, is lacking, and it does seem that the anatomy and construction of these parts is such as to form an effectual barrier to the passage of fluid from the region of the processes to the suprachoroidal space. The objection to the ideas of Fuchs has already been mentioned.

In a series of 574 pathologic examinations of eyes which had clinically been of low tension and which included perforating injuries, shrunken globes, corneal ulcers and iridocyclitis, it is to be remarked that tension when noted, as it was in approximately 90 per cent. of the cases, was found low in every one which pathologically showed a detachment. (It is not stated, however, whether these tensions were taken with a tonometer.) Meller himself asserts that the eye is not soft because there is a choroidal detachment, but because there is a leaking spot in the eye from which aqueous is constantly sickering. The choroidal detachment has only taken place because the eye has become soft and one cannot therefore say that the eye stays soft as long as the choroidal detachment persists, but that the choroidal detachment persists as long as the eye stays soft. In this way, it is to be understood why the choroidal detachment increases in size; when the opening in the chamber shuts, normal tension is reestablished, the secretion of aqueous sinks to its normal amount (its excess secretion having been, in Meller's opinion, the direct cause of the detachment; in Marshall and Hudson's opinion, the excess secretion from the choroidal veins having been the cause) and with establishment of this normal tension, the choroidal detachment disappears. There has never been a case noted of disappearance of the *ablatio* while the chamber remained shallow.

If we grant the universality in some degree of choroidal detachment in all cases of marked and quickly occurring low intra-ocular tension, and I personally am inclined to do so, because in every condition of decreased tension the eye will in some fashion attempt to restore its equilibrium, and is, I believe, more likely to do so by excessive fulness of the choroidal system of veins than by any other means: then tears in the ligamentum pectinatum must be looked on as accidental complications rather than the usual cause for the detachment.

Fuchs says in his argument against active exudation as the cause of the detachment, "An active exudation cannot be brought into relationship with a decrease of tension." Not in a closed globe, certainly, but in one in which there is an abnormally rapid escape of fluid by abnormal channels, an exudate of any kind or consistence can form with no relationship whatsoever to the tension.

Heine's operation of cyclodialysis offers a striking illustration. In his many cases he has observed choroidal detachment only once. Yet here is the ideal tear through the ligamentum pectinatum and a detachment of the ciliary body. It is true that pathologically studied, these eyes have shown that the tears are very rapidly filled with blood and within a few days fibroblasts appear and active tissue and scar formation obliterate the path of the spatula. Here again we have no choroidal detachment, I believe, because there is no sudden reduction in tension. In the great majority of eyes in which choroidal detachment is observed, there is a decisive lessening of the volume of the eye with the advancement of the iris and lens diaphragm, and of the vitreous, added to a certain amount of scleral rigidity, and large and abnormal channels of outflow for the aqueous—all factors in low tension. We know too that the more sudden and the greater the change in tension the more frequent is choroidal detachment; in cataracts about 4 or 5 per cent.; in glaucoma iridectomies about 10 per cent.; in the Lagrange sclerectomy about 20 per cent.; finally, in the Elliot, from 10 to 15 per cent.

Schur, in 1913, made the first reference to choroidal detachment in Elliot's trephine operation, closely followed by Paderstein. Since then, single case reports of its occurrence in Elliot's trephine operation have been published, and Elliot himself mentions its connection with his operation very briefly in the book dealing with his operation. Now, it has struck me in reviewing the American literature, that this most interesting detachment of the choroid after cataract and glaucoma operations is seldom noted clinically; Elliot glaucoma operations have been reported frequently in the last two years, the cases varying in number from case reports of six or ten to case reports of twenty or thirty. Some of these papers describe in detail both operation and the course of healing, and yet in very few instances is the occurrence of an *ablatio* mentioned. Knapp, however, in 20 cases noted it three times; in two, hypotension existed for from six to eight weeks; Quackenboss also mentions the late reestablishment of the anterior chamber and choroidal detachment in one case: but, in the main, it is conspicuous by its absence in the history of the cases; and yet we know from Meller's statistics, and I know personally from examination of a goodly number of these cases, that choroidal detachments occur in from 10 to 20 per cent. of glaucoma operations.

Now it is true that these detachments can be and often are evanescent; that they often occur as early as the second or the third day after the operation; that they may exist for only two or three days; and perhaps the fear of early postoperative examination of cataract and glaucoma cases has kept us from noting this condition more frequently. I have never seen untoward events happen in the examination for choroidal detachment the day following operation, by projecting through the pupil the light of a Priestly Smith lamp by means of the plane or convex mirror of one's ophthalmoscope, and asking the patient slowly to look down, upward, right and left. This, moreover, need not be done if the chamber is not shallow, for if the chamber is not shallow, there is no choroidal detachment. The number of chambers remaining shallow or entirely absent, especially in a well-performed Elliot operation, is numerous, and in practically every one of these choroidal detachments can be detected.

I have had the opportunity to observe eyes operated on by Elliot's method from the day of operation to the day of dismissal from the hospital in a comparatively large number of cases—175. These were all operated on with as large an iridectomy as we could obtain. The tension of the eye before operation did not seem to affect the frequency of choroidal detachment after trephine. Of those that showed detachment, as many were of a tension of 30-35 mm. as were of 40-50 mm The percentage of detachment was 9. In all of these the chamber was very shallow or entirely absent. In many cases, the patients were sent home without the chamber having reformed and were not seen again. Vision was not interfered with and was as could be expected from the general condition of the eye. On the day of dismissal, the field of vision in 120 of these cases was recorded (the others for some reason—glaucoma absolutum, small fields, stupidity—could not be taken) and the area corresponding to the choroidal detachment was found in the fourteen cases observed to be no different than the one taken before operation. In one case, while the object was seen, it was described as being very blurred. Twelve of the detachments occurred on the temporal side; two on the nasal side; and one superiorly. None was seen on the inferior aspect, an observation which agrees practically with the location of the detachment in cataract operations as described by Fuchs. The area of the trephine opening in all these cases was marked by a pellucid, thin, rather protuberant conjunctiva, depressed easily with a spatula, and undoubtedly draining very freely. That this was in direct connection with the detachment is certain.

Meller has reported the only case of recurring detachment in Elliot's operation: it recurred six months after the operation, the scar being extremely cystoid; no direct rupture could be ascertained. The eye was very much softer than usual at dismissal and the patient complained of a sudden blur of vision. This patient, as all the others, recovered in a few weeks, the chamber reforming.

In the cataract and glaucoma cases observed by me in Lane Hospital—thirty-two cases of cataract, sixteen of glaucoma—choroidal detachment occurred in the former in no case, in the latter in two cases. I attribute the absence of detachment in the cataract cases (though the total number of cases is of course too small to draw any general deductions), to the fact that our cataract patients are kept flat on the back with both eyes bandaged longer than in the European clinics, where, as in Fuchs' clinic, it is the habit to get the patient up the day after operation. There, in my daily rounds among from forty to fifty cataract and glaucoma cases, shallow chambers, usually without external signs of rupture of the wound, were not at all an unusual thing to find on the third or fourth morning and were regarded rather lightly; and, in fact, seldom had deleterious consequences.

In conclusion, I would state:

1. Clinically demonstrable postoperative detachment of the choroid takes place after cataract operations, with or without iridectomy, in about 4 per cent.; in Elliot's trephine operation, in about 10 per cent.; in Lagrange's sclerectomy, in about 20 per cent.; it does not occur in linear extraction, or simple iridectomy.

2. The sine qua non for its existence is low intraocular tension, caused by abnormally rapid escape of aqueous through the wound, extending over some interval.

3. The chamber is not shallow or absent because of the detachment; the detachment is secondary to the condition of the chamber.

4. The fluid responsible for the detachment is derived, probably, from the choroidal blood vessels, and not improbably from the veins.

5. Choroidal detachment is of relatively frequent occurrence after Elliot's trephine operation, and should, if for statistical purposes only, be looked for, and its occurrence noted in all cases of Elliot's operation.

ABSTRACT OF DISCUSSION

Dr. W. H. Roberts, Pasadena, Calif.: Dr. Barkan has called our attention to a fairly frequent sequel of operations for cataract and glaucoma. Postoperative detachment of the choroid has undoubtedly been overlooked by the majority of eye surgeons, as so few have made note of it. Fortunately, such detachment has but little clinical significance, as the choroids all become reattached, whether recognized or not, and no treatment is required. The cause of the detachment is purely speculative, as is the source and course of the fluid, as Dr. Barkan has pointed out. Lowered tension, the result of a leaky anterior chamber, is probably the chief cause. This would appear to be proved by the more frequent detachments of the choroid in operations favoring aqueous drainage and in direct proportion to the quantity escaping. Following cataract operations Dr. Balkan reports 4 per cent. to 5 per cent.; following broad iridectomies for glaucoma 10 per cent.; following the Elliot trephine operations or sclerostomies 15 per cent.; following Lagrange sclerotomies 20 per cent. Just how the fluid reaches the suprachoroidal space cannot be positively determined. Dr. Barkan has mentioned several theories. One that he did not refer to is a cyclodialysis caused by postoperative traction on the iris, following the iridectomy, which enables the anterior chamber to empty itself into the suprachoroidal space. Verhoeff, in a recent article (*Arch. Ophth.*, xliv, No. 2, p. 134) mentions a detachment as probably due to a cyclodialysis, in which he removed the eye, and on sectioning it, he says "no traces of a present or past cyclodialysis could be found, but no doubt a small one could have healed without leaving any visible trace." I doubt if it would be advisable for all operators, who find a postoperative empty anterior chamber, to subject their patients to such an examination as would be necessary to diagnose a detached choroid. It would subject the recently operated eye to more of a strain than would be good for it, and might cause the separation of the corneal section in cataract cases.

Dr. J. M. Ray, Louisville, Ky.: The first case I saw I did not recognize as detachment of the choroid. It occurred in a cataract case in which on making the first dressing oblique illumination showed a brownish mass coming forward into the coloboma that at the time I thought was a detachment of the retina. In this case there were two mounds with a depression or valley between. I watched this carefully and studied it with the ophthalmoscope at my second dressing and could make out very well the elevations. To my surprise by the time the wound was well healed and the anterior chamber reformed the mass had disappeared. In 1909 soon after the trephine operation came into general use I saw a case with my associate Dr. Lederman in which there was a brownish mass to be seen through the peripheral coloboma and the man complained of inability to see below. After studying this case carefully I recalled the former case following the cataract operation, and the diagnosis then seemed easy. Soon after the trephine case I saw a third in which quite a brown mass was visible with the ophthalmoscope and the patient complained very much of inability to see below. In this latter case the mass did not seem to protrude forward as much as the first two cases. In the course of time all these eyes became good eyes. There was no further evidence of any detachment. They did not seem to interfere with the remedial effect of the trephine. Dr. Knapp in his book on "Ocular Tumors" reports and illustrates a case following cataract operation.

Dr. Frank C. Todd, Minneapolis: I am one of the many who have not observed their cases with the ophthalmoscope after operation, during the time when the detachment can be seen. Dr. Barkan made the statement that such a detachment has no clinical importance and I am wondering if that is positively true. I have trephined in seventy odd cases. I have observed a number in which the vision diminished after trephining, where the tension was reduced, and where the vision remained lower than normal. It occurred to me in reading Dr. Barkan's paper that this lesion might be present to so low a degree that it could not be observed with the ophthalmoscope. I have not made observations soon after the operation, but something of this kind may have taken place which accounted for the poor vision in those eyes with very reduced tension, and I would like to have Dr. Barkan's opinion as to this character of cases.

Dr. Harold Gifford, Omaha: I must confess that I have overlooked a number of these cases. I know I have done this because it is only recently that I have begun to look for them systematically after dilating the pupil, and in about twenty-five trephinings I have found three detachments of the choroid, while in three times that number that I had done previously without subsequent dilatation of the pupil, I found only one detachment of the choroid. In one case the patient had a double detachment, one at each side. The reason for the frequency of this occurrence after trephining must be sought in the long continued hypotension. It cannot be due to the traumatism; that is, to the traumatic enlargement of the opening between the anterior chamber and the superchoroidal space; otherwise it would be more frequent after cataract extractions.

Dr. Edward Jackson, Denver: I have seen no postoperative detachments following trephining, but I have done only a few trephinings. Dr. Barkan dismissed in a sentence or two the subject of spontaneous detachment. I have one case that seems to have a natural place in this discussion. About eighteen months ago I saw a man who had been complaining of impaired vision for several weeks, and on making an examination with the ophthalmoscope found the choroid pushed forward in the region of the macula. Vision was reduced to 1/15 of normal, and the swelling gave the appearance of sarcoma. In six months the vision was 6/10 normal. He gave no history of injury to the eye, although I made a very careful inquiry concerning this point. Spontaneous detachment is more frequent than we realize. This case certainly would not have been observed had it not involved the region of the macula.

Dr. Hans Barkan, San Francisco: In regard to Dr. Roberts' remarks concerning the danger encountered by the patient in undergoing an examination for detached choroid, I will say that in Europe where I accumulated the great majority of these statistics the examination, fortunately, is not considered so serious. I have, however, kept it up in a small number of cases and have found there is no trouble about it. Of course it is to be remembered that when the chamber is not shallow there is nothing to be gained in making the examination. Therefore, the number of eyes that you might endanger are confined to those cataract cases in which there is no chamber. Where there is at the end of twenty-four to thirty-six hours no evident external cause for the absent chamber there is absolutely no danger in making the examination. In regard to Dr. Ray's observing the valley between the choroidal detachment, there are two explanations for that—the choroid and sclera are firmly attached to each other and the suprachoroidal space is obliterated by an old choroiditis or that a vortex vein entering at the bottom of the valley should naturally hold down at this point the choroid. Dr. Todd's question rather sticks me. I can only say that in these cases in which there were fourteen out of 150, or 10 or 11 per cent., we did not notice any bad effects in the lowering of tension. Perhaps the bad vision in the cases he mentioned may have been caused by the axial myopia that took place and by the wrinkling of the cornea with its consequent irregular astigmatism. I certainly cannot explain it on the basis of the choroidal detachment.

In reply to Dr. Fenton, both Professor Fuchs and Professor Meller advocate that there is no logical reason why a patient should not be given the benefit of this saving operation in addition. Pathologically speaking, there are some very good reasons why the operation should be performed, and undoubtedly the trephine hole shows more tendency to remain open; as iris lying beneath it otherwise tends to form a substratum of connective tissue and adhesions block up the hole. Whether as large an iridectomy as was performed is advisable or not, I am not in a position to say. A great percentage of these cases came in a state of advanced glaucoma with high tension. Among the operations there were not as many incipient glaucomas as there were acute glaucomas and chronic inflammatory cases; therefore it was quite easy at that time to do as large an iridectomy as possible, as the high tension almost invariably caused a fairly large prolapse of the iris into the trephine hole.

In regard to the question asked, Heine's cyclodialysis of course seems the ideal condition for a choroidal detachment to take place, but Heine in his many operations noticed choroidal detachment only once; this I take as strong proof, in accord with Dr. Gifford, that it is the sudden lowering of tension which is responsible for the detachment; we note here that the tension is lowered only temporarily and not markedly.

Factory Inspection.—According to a statement of the National Child Labor Committee, although Georgia has a child labor law, it is a dead letter on account of the failure of the legislature to provide for a factory inspector. At present the Commissioner of Commerce and Labor of Georgia is charged with the enforcement of the child labor law, in addition to his many other duties, and he is provided with only two office assistants. The bill to provide for an assistant factory inspector to enforce the child labor law was favorably reported by both house and senate committees at the last session of the legislature, but no action was taken. Dr. J. A. McKelway, secretary for the Southern States of the National Child Labor Committee, cites this as proof of the need for a federal child labor law which could be enforced by federal inspectors.

EARLY DIAGNOSIS OF INTUSSUSCEPTION

IRVING M. SNOW, M.D.
BUFFALO

An intussusception, though of rare occurrence, is one of the most dangerous surgical conditions of infancy. If the obstruction is recognized early the intestine may quickly be released by operative treatment.

My object is to review clearly the early symptoms which occur when there is still time to save a patient too young to localize or to describe his sufferings.

To diagnose intussusception during the second or third day is usually easy, but this delay is fatal.

Why does intussusception occur in babies? The conditions favorable to the invagination are a long mesentery and active, irregular peristalsis. The circular muscular fibers of the small intestine contract, and an upper segment of ileum is driven through the narrowed lumen. Sometimes the beginning invagination is released spontaneously. Peristalsis is increased by the obstacle and several inches of intestine are pushed into a lower segment; with the intestine the mesentery is also dragged in, aggravating the obstruction and nipping the intestine. The obstruction usually occurs in the lower ileum and the mass of bowel is pushed through the ileocecal valve and drags the cecum and colon with it.

As the intussusception is attached to the mesentery, the tumor moves in the arc of a circle and may be rotated to any region of the abdomen.

The effect of this accident is:

1. To produce agonizing pain; the crying of the baby often indicates the exact moment of the obstruction.
2. To arrest the fecal current and stop digestion and to cause vomiting.
3. At the site of the obstruction acute swelling and congestion occur, forming a tumor, hindering the release of the invaginated intestine and causing bleeding and a discharge of bloody mucus through the colon.

Thus we have the four principal symptoms: pain, vomiting, an abdominal tumor, and discharge of blood and mucus from the rectum.

PAIN

Nearly always the baby is breast-fed and of good disposition and digestion. Suddenly, without apparent cause, the child cries bitterly. *Illustration:* A fat, nursing baby of 6 months suddenly awoke at 6 a. m., and cried most piteously. This was the exact moment the telescoping commenced. The patient always cries, sometimes continuously, sometimes intermittently. The child's face is pinched and suffering, pale, cyanotic. A dangerous condition of shock is evident at a glance. The physician is most successful who listens to the mother's story of the baby's unusual sufferings and takes alarm quickly. After a few hours the symptoms of shock may disappear and the pain cease for a few hours. This amelioration is due to an edema of the intestines, and is also seen in strangulated hernia. Beware of this deceptive lull. A fatal condition is progressing and most mistakes in diagnosis occur because the physician arrives when the baby is a little better.

VOMITING

Associated with the initial pain is vomiting due to shock, arrest of the intestinal current and regurgitation of duodenal fluid. The vomiting may occur every hour or two, may cease for a while and return. It is aggravated by food and laxatives so often given. Vomiting is rarely absent in acute intussusception. During the whole period of obstruction the baby refuses food and eventually rejects what it swallows. Fecal vomiting is infrequent. Although vomiting is an every-day occurrence with bottle babies, it must be emphasized that the intussusception patient is usually breast-fed, with a healthy digestion.

ABDOMINAL TUMOR

The abdominal tumor of intussusception is a mass of telescoped ileum, cecum, colon and mesentery. It may be found in any quarter of the abdomen rotating on an axis of mesentery. The tumor is insensitive; feels like a walnut or a potato; may be localized at one time and later disappear under the liver or in the pelvis. The abdomen is generally soft and may be thoroughly palpated. Often the tumor is undiscovered and the physician's diagnosis must be made from other symptoms.

Protrusion of the bowel through the anus is a late symptom indicating the telescoping of long areas of intestine. It may simulate a prolapsed rectum. The rectal mucosa, however, is easily replaced; a mass of intestine is not.

A digital examination of the rectum should be made in every suspicious case.

Sometimes no information is gained; sometimes a hemorrhage follows; sometimes the soft fleshy mass of incarcerated intestine is felt high in the rectum. A bimanual examination may discover a mass of telescoped bowel.

Early, at times, when the child is not crying, the abdomen is soft and relaxed. Later there may be distention. Peritonitis is a rare, late development. Often the irritation of the obstruction causes an effusion of peritoneal fluid.

Adhesion of the bowel wall is unusual; I have never seen it. The chief obstacle to reduction is swelling. The surface of the intestine is often purple from congestion and the bruised appendix in a condition leading to inflammation. After the obstruction is relieved a persistent diarrhea may show the damage the intestinal mucosa has suffered. Some children have a fairly good heart action for a day or two. Fever is not a symptom of intussusception, yet many cases have a rise in temperature after a few hours, probably from intestinal toxemia.

COURSE OF DISEASE

If the telescoped bowel is not released within twenty-four or thirty-six hours the baby will surely die of pain, vomiting, exhaustion, shock and toxemia from poisons exuded by the injured intestine. Death takes place in from two to seven days. Spontaneous sloughing of the intussusception has been reported. I saw one case, but the child died suddenly a year afterward, probably of intestinal stenosis.

The physician, in dealing with a supposed intussusception in a baby, faces dangerous possibilities. To wait may be to lose the child's life. To advise and force a dangerous operation in case of a mistaken diagnosis is a disgrace.

Several times I have anxiously watched a baby who was vomiting and in pain and have seen the symptoms spontaneously cease.

When a suspicious case is seen it should be closely watched. Much mischief is caused by giving food and laxatives. To give opiates for pain is to mask the symptoms until it is too late to act. An experienced clinician will quickly realize he is dealing with a serious atypical case, not one of infantile indigestion and colic.

BLOODY MUCUS STOOLS

The jamming of the intestine produces swelling, congestion and irritation. As a result blood and mucus exude from the lower end of the obstruction and flow from the anus, either as a hemorrhage or as bloody mucus dysentery.

A bloody mucus stool suddenly passed from a healthy baby is almost pathognomonic of intussusception and was absent in but one of my sixteen cases. The patient may pass one or two small fecal stools, the contents of the lower bowel; afterward nothing but blood and mucus.

The intestinal hemorrhage may occur early; first a gush of bright red blood and then bloody mucus, possibly after a digital examination or taking a rectal temperature. The finger or thermometer is withdrawn covered with blood, and bleeding follows.

Occasionally the intestinal hemorrhage is observed after the first day, too late for an early diagnosis.

When the incarcerated intestine has been pushed deep in the lower bowel there may be rectal tenesmus and bloody mucus stools which simulate dysentery.

When intestinal obstruction is complete the constipation is absolute and no gas passes the anus. The question should be asked: Has the child passed gas since it was taken ill? An intussusception may be excluded if large amounts of gas have been discharged, but small amounts of gas may leak through the nipped bowel. Twice in my experience the mother observed the passage of gas although a subsequent operation showed a dangerous intussusception.

One should always suspect an intussusception when a healthy breast-fed baby suddenly cries, vomits, passes bloody mucus stools and shows symptoms of shock. The surmise becomes almost a certainty if the thermometer or examining finger is covered with blood.

A roentgenogram of the intestines after an injection with bismuth is strongly advised. Three times I have seen the symptom-complex of intussusception confirmed by this method. All three patients were operated on and recovered.

A surgical consultation should at once be called and the responsibility shifted to the surgeon.

As to the operation, much depends on the surgeon's skill and speed. A minimum amount of anesthetic should be carefully given. The operator should not eviscerate the child to find the obstruction. The incarcerated intestine should be pushed, not pulled out; the appendix should not be unnecessarily removed. The proportion of operative cures of intussusception steadily increases.

A successful, experienced surgeon has several times said to me that if a case of intussusception was seen early operation was easy, and the credit of saving the life belonged to the physician who could at once recognize an atypical case.

ILLUSTRATIVE CASES

Case 1.—Ileocecal intussusception with early diagnosis. James, an artificially fed 11 months' boy weighing about 17 pounds, had easy digestion with no food vomiting, though his weight had been stationary for a month. At a night feeding—10 p. m.—a slight increase was made in the food. At midnight the baby commenced to vomit and cry and continued to vomit frequently until the next noon. The last vomited fluid was yellow, a regurgitation from the duodenum. With the vomiting the baby suffered from pain, crying paroxysmally and seeming in utter misery. The baby passed a fecal stool at 6 a. m. and the mother thought that the child passed gas during the night.

A rectal injection given during the morning was almost instantly expelled. No food or laxatives were given from the onset of vomiting.

Seen at 1 p. m., thirteen hours after the vomiting had commenced, the child was crying from abdominal pain. Temperature 100.5; heart sounds strong. No abdominal mass was felt on palpation. After the withdrawal of the thermometer from the rectum there came a gush of fluid blood and mucus. Nothing was felt on digital examination. Nothing was elicited by bimanual examination.

The condition suggested an intussusception: A baby in good condition was, without adequate cause, attacked with severe abdominal pain with vomiting and the discharge of blood from the rectum. From 1 to 5 p. m. the vomiting ceased and the baby seemed easy, without pain. There were five small fluid, bloody stools. The improvement during the afternoon did not dispel the idea of intestinal obstruction, as bitter experience has taught me that in a case of intussusception, after a fierce onset of pain and vomiting, a lull in the patient's misery may occur from edema of the intestinal mucosa.

The surgeon agreed with me that the case was one of intussusception and a roentgenoscopy was done; but little bismuth could be injected into the rectum and the picture showed the obstruction to be in the left lower quadrant. The operation showed the mass of invaginated intestine in this region, but neither the surgeon nor I could feel any abdominal tumor.

Operation by Dr. Marshall Clinton, twenty hours after beginning of illness, showed a large amount of serous effusion from peritoneal irritation. The invaginated intestine lay about the sigmoid flexure; about 20 inches of ileum had been pushed through the ileocecal valve and the cecum, ascending and transverse colon had been jammed into the left lower abdominal quadrant. The serous surface of bowel and appendix were much congested. The ileum was slowly pushed out from the colon; there were no adhesions; the appendix was removed. Length of operation about twenty minutes. There was no vomiting. The baby was feverish and had frequent stools for a week. It was fed on breast-milk. Recovery was complete.

Case 2.—Early diagnosis. Helen, aged 3 months, was partly nursed and partly fed.

November 6 at 3 a. m. the child took the bottle well and slept until 6 a. m., when it attempted to nurse and seemed ill, and cried as if in pain. She commenced to vomit and passed two stools. During the morning she cried a great deal, vomited five times in three hours and had six small stools of mucus and blood. Occasionally fluid blood flowed from the rectum. Examination was made two hours after symptoms began.

On palpation to left of navel a sausage-shaped mass 1½ inches long was felt; it was not tender. The abdomen was relaxed. On rectal examination, nothing was felt. Blood flowed from the rectum directly afterward.

Four hours after the onset of symptoms a surgeon agreed with me that an intussusception existed. There were:

1. The sudden onset symptoms in a healthy child.
2. The occurrence of vomiting, pain, bloody stools, and presence of an abdominal mass.

A large rectal injection of warm water was given, after which there was relief for several hours from vomiting and pain.

A surgeon, Dr. Clinton, was called. He found the child easy and comfortable. The abdominal mass had disappeared, displaced by injection. Both the surgeon and I felt that an intussusception existed and that the temporary amelioration was a deceptive lull.

Roentgenoscopy at 4 p. m. showed intussusception in the right upper quadrant. Some bismuth passed, the obstruction showing closure of the lumen of the bowel was not complete.

Operation was performed at 7 p. m. No abdominal tumor was felt during the late afternoon. Blood leaked several times from the rectum. Four inches of the ileo-invagination were pushed out. Relief from the intestinal obstruction occurred with rapid improvement.

Case 3.—Intussusception with late diagnosis, in a 6 months' old fat baby, breast-fed. May 22, at 6 a. m., the child, previously in perfect health, commenced to cry as if in pain (acute), and grew white as if in a faint. It was given an injection, also castor oil and a hot bath. It was quite ill during the day, would not nurse, and during the afternoon had several discharges of bright red blood from the rectum.

May 23: The child was quite collapsed; vomited through the day and had three or four stools of mucus.

May 24: Fifty-two hours after the onset, 10 a. m., the heart was rapid and feeble. Temperature 99. The child was depressed, had passed no gas or fecal matter since the beginning of its illness. Rectal examination was negative. A mass was felt in the lower quadrant of the abdomen by palpation.

At operation, about sixty hours after the onset of symptoms, a gangrenous appendix was removed. The duration of operation was fifteen minutes.

The mass felt in the left lower adbominal quadrant was a mass of invaginated bowel. The ileum had penetrated into the cecum for 6 inches; the ascending colon was pushed to the left of the umbilicus; the lower ileum and colon were intensely congested; the ileum was easily pushed or pulled out of the ascending colon; the appendix was strangulated and gangrenous.

The child was in good condition after the operation but died in two hours.

Case 4.—Intussusception, diagnosed as a case of dysentery. A girl, aged 5½ months, breast-fed, was well until July 19, when it seemed in pain and passed a number of stools of pure blood. It was sent as ill with dysentery to the Fresh Air Mission Hospital.

July 20 and 21: Occasional vomiting occurred of a yellow fluid. Frequent stools of mucus and bright red blood were passed, but no fecal matter. There was a suggestion of a tumor in the left and lower quadrant.

July 22: Temperature 102. The child was in great pain, crying for a day at a time. There was no suggestion of collapse. The abdomen was not distended. There were numerous stools of mucus and blood. A tumor was felt in the left lower quadrant. The child vomited fecal matter during an irrigation. The introduction of the tube into the rectum was very difficult. Rectal examination showed the intestine occluded about 2½ inches from the anus, by a mass of intestine. The finger in the rectum pushed back the intestine out of reach.

Operation at Children's Hospital about eighty hours after the beginning of symptoms.

An abdominal incision 3 inches long was made between the navel and pubis. Some serous fluid escaped. There were no adhesions. A large mass of intestines was crowded into the region of the sigmoid flexure. The entire colon was slightly congested. The ileum was invaginated through the ileocecal valve. The small intestine, easily pulled out, occupied the interim of the cecum, ascending, transverse and descending colon.

On the surface of the ileum, 9 inches from the ileocecal valve, was a depression like a dimple, on the surface opposite to the attachment of the mesentery, perhaps the beginning of intussusception.

The surface of the intestine was brownish here, not gangrenous.

The child collapsed at the close of operation. Two hours after the operation its temperature was 106.5, pulse 240. Death soon followed.

CLINICAL AND ELECTROCARDIOGRAPHIC STUDIES ON THE ACTION OF DIGITALIS *

ALFRED E. COHN, M.D.
NEW YORK

It is extraordinary that, after continuous use for 130 years, the study of the action of digitalis retains so vital an interest, not only in clinical medicine, but also in experimental pharmacology. This interest has been quickened by the fundamental investigations of James Mackenzie on the mechanism of the heart beat and by the construction by Einthoven of a galvanometer suitable for registering the action currents of the heart.

I mention James Mackenzie especially, because in the bewildering variety of studies which he has stimulated he has, almost alone, kept in view the essential objects of investigation in the domain of cardiovascular disease. These are, first, the study of symptoms suggesting the presence of incipient heart disease, and second, the study of the mechanism of heart failure and its treatment. His study of the disturbed rhythms of the heart was undertaken to ascertain whether they had a vital relation to these subjects, and to learn whether an appreciation of their significance would aid in understanding altered function.

I doubt very much whether the disordered rhythms of the heart, taken by themselves, presented a subject of fundamental interest to Mackenzie, and in that, too, he has differed from his followers. The reader remembers, no doubt, that he called his book "Diseases of the Heart"; but its theme may be said to be the arrhythmias in their relation to heart failure. This view of the arrhythmias gives them a new significance in studying the action of drugs. They can be made to serve as important indicators in estimating the value of therapeutic effects. Mackenzie's work, therefore, provides an important reason for reexamining the action of digitalis. Just as it was important to recognize the arrhythmias and to appreciate their significance, it was necessary to have far more accurate and more satisfactory methods of registering the motions of the heart than arterial and venous tracings, which record only the motions of the vessel walls, and in many instances record them badly or not at all. The string galvanometer, although it is not a substitute for them, has come to replace the older methods by one eminently practical, free from error due to the personal equation and reliable within the limits of its capacity. This instrument has made Mackenzie's work more easily available. Its use, as I hope to show, has made possible the introduction of added criteria for recognizing the action of drugs. Mackenzie's new conceptions and Einthoven's new instrument, reported almost simultaneously, made therapeutic investigation from a new point of view desirable.

I want to discuss the effects of digitalis on heart rate, on conduction, on the electrocardiogram, on blood pressure and on diuresis. But because there is still a very distinct divergence of opinion between practitioners of clinical medicine and pharmacologists, as to how digitalis acts, I must take account of the views of both in presenting the subject. But the matter is not simple, for clinicians differ in the results of their observations, and pharmacologists on the interpretation of experiments.

The school of Schmiedeberg still maintains that the main action of a digitalis body is on heart muscle; the school of Gottlieb, while it does not deny to digitalis bodies a cardiac action, still maintains the view that it has an important action on the walls of the arteries. Both schools find that the drug increases the excursion of the heart in contraction, both believe that it elevates blood pressure, both believe that it increases the amount of renal secretion.

It is perhaps not an overstatement to say that in a general way clinicians have been too much influenced by these experimental results and have felt obliged to find that the administration of the drug in patients results in parallel phenomena. It requires a very small experience in treating patients suffering from heart disease to find oneself disappointed because the expected results did not occur. And when discrepancies were noticed, the discovery was not often followed by an effort to explain them. The subject was often dismissed by finding fault with the potency of the drug or by discovering an idiosyncrasy in the patient. But even if drugs were always potent and there were no individual idiosyncrasies, it is extremely likely that patients would continue to react in different manners to the drug. And the reason for that must be that individuals, although they suffer from what in a general sense is called heart disease, yet present a great variety of clinical pictures.

If the cardinal symptoms of heart failure alone are considered, rapid pulse, disturbed rhythm, high blood pressure, dyspnea, pain and edema, it becomes clear that patients do not usually present all of these signs at once, that some present one or two of them, or a group. It must be apparent that the pharmacologic experiment does not take this diversity of circumstances into consideration; the experiment is done under artificial conditions, and the doses which are employed bear no relation to those permitted in clinical medicine. There can be no question of the usefulness to therapeutics of these experiments; as guides, they are indispensable, but it must be clear that they neither replace nor parallel the clinical conditions we must treat. That there has consequently been a divergence between the results of pharmacologists and clinicians in a practical sense was inevitable. The responsibility for it is probably shared equally by both. Pharmacologists have dealt usually with simple normal conditions; clinicians with complex pathologic ones.

In therapeutics, divergent accounts of the action of the digitalis bodies are also found. For instance, they are sometimes said to reduce the heart rate, and to act almost as specifics; others deny such an action. In the presence of fever their use is discouraged by some as valueless. In the domain of valvular defects a variety of indications and contradictions for giving the drug prevails; some regard these as unimportant. Until recently, some avoided it in cases of high systolic arterial pressure, because it was reputed to elevate this to dangerous limits. Some, again, have detected a striking effect in a short time (Marvin), while others have recently reported that it has no effect on pressure at all. Its effect on diuresis has, on the whole, been commonly held and has been gained on account of the disappearance of edema, when this sign of heart failure is present.

---

* From the Hospital of the Rockefeller Institute for Medical Research.
* Read before the Section on General Medicine, College of Physicians, Philadelphia, Dec. 14, 1914.

A drug having apparently such very powerful actions as digitalis must be extremely valuable and must gain in usefulness if its modes of action are carefully studied and precisely recorded. It has been no easy task to reconcile the divergent views drawn from experimental experience, and equally difficult to understand the contradictions expressed by reliable clinicians. We have therefore been engaged in the Hospital of the Rockefeller Institute in the attempt to understand and to reconcile these differences, in order to make more available the data of experimental pharmacology, and to ascertain whether the indications for the use of digitalis could be simplified if patients were grouped with a view of delimiting the conditions in which uniform results might be expected. For these purposes it has been deemed wise to study digitalis in the human subject, because in the first place it is about its action in patients that information is wanted, because, in the second, that information can, in practically all respects, under present conditions be satisfactorily obtained, and because, in the third place, the study can be made not only without any prejudice to the patient, but, indeed to his advantage.

It is apparent, if the cardinal symptoms of heart disease during heart failure are considered, rapid pulse, disturbed rhythm, high blood pressure, dyspnea, pain and edema, that not all patients present all of these complaints, and that each patient suffers from only a selection of them; of these symptoms the most obvious basis for the arrangement of patients into groups for the purposes of treatment, especially at the present time, is rhythm. Rhythm, it will be remembered, was the subject with which Mackenzie started. The basis has, in point of fact, been found extremely serviceable, for in a general way it has been said that the drug acts on cases of auricular fibrillation very successfully, and has even been called, erroneously of course, a specific; while in cases presenting a sinus rhythm it has been said to fail. We have therefore divided patients primarily into fibrillators and nonfibrillators. On the question of rhythm, pulse rate also depends, and we regard these two factors together, but not, of course, as the same. The second basis on which patients can be divided is the question of edema and the retention of water, involving the question of salt metabolism, and these two symptoms may also be regarded as phases of a similar disturbance. The third basis on which we have found it useful to study patients has been on the basis of the height of blood pressure. We do not, of course, pretend that a classification such as this presents all the points of view from which either heart failure or the treatment of heart failure can be viewed; it omits important symptoms such as dyspnea and pain. Often these are cardinal, often they are secondary signs. But, after much consideration, we have adopted it as a useful working plan for testing the effect of drugs. The classification then, is as in the accompanying tabulation.

CLASSIFICATION OF PATIENTS

A. Normal rhythm..	a. Without edema.	1. With normal blood pressure 2. With high blood pressure
	b. With edema	3. With normal blood pressure 4. With high blood pressure
B. Auricular fibrillation	a. Without edema	5. With normal blood pressure 6. With high blood pressure
	b. With edema	7. With normal blood pressure. 8. With high blood pressure

The group of patients which presents the simplest form of disease is the first one, in which the rhythm of the heart is normal, there is no edema and the blood pressure is not elevated. This is the state found in a patient who, if he presents himself for treatment at all, is in an early stage. It is naturally understood that an early stage of heart failure does not by any means suppose an early stage in heart disease. It is, on the whole, the simplest kind of heart failure which one is called on to treat. The general physiology of such a patient presents the nearest approach to the normal. It is the effect of giving digitalis to him to which we have confined our attention and with which this report principally deals. It is clear that often he requires no drugs; if digitalis is given him it is important to determine what effects are to be expected, and also how the expected effects are to be recognized. This is the method of experimental pharmacology, and the results obtained in this way can be most nearly compared with experimental conclusions. They can be made also to serve as a basis for considering the effects on the more complicated groups.

I have mentioned earlier the topics I mean to discuss, but it is well to dwell for a moment at this point on another. Aside from changes in the physical signs which some clinicians believe themselves capable of appreciating, we have no means whatever of estimating alterations in the functional efficiency of the heart, referable *to the heart itself*. If it were possible, an accurate estimation of contractile force would be the most important single measure to take, but for this we have no satisfactory criteria. Observations on blood flow, blood pressure, estimations of volume output, electrocardiography, have all been equally disappointing. Those effects reported earlier, of changes in the magnitude of ventricular contractions gained in experiments, are more recently admitted (Joseph) to have been obtained by doses far too great. The much smaller doses now used are still much larger than are permitted in therapeutics, but even these fail to show marked changes in the extent of the excursion of the ventricular wall which were formerly held to indicate the nature of effective digitalization. The methods employed in pharmacology are not superior to those now available in clinical medicine. Both are on a par in respect to obtaining objective records of this phase of digitalis action. We must believe, therefore, that if digitalis increases the ability of the ventricles to pump blood, it does so by means of a change which is more subtle than can be distinguished by our methods.

The most important alteration we look for traditionally is in the pulse, or better, the heart rate. This is the first subject we have investigated. For the present we omit fibrillators from consideration. The reduction in the rate of the heart is an effect of digitalis on which we have been taught to rely, both by pharmacologists and clinicians. It is, unfortunately, an effect which we have not found constant in the type of case we are considering. We know also that it fails to reduce rate in the tachycardias of a paroxysmal nature, in those of exophthalmic goiter, and in those of fever. That the pharmacologist could report such an effect depended, no doubt, on the size of his dose. That the clinician believed it to occur depended until recently on his not distinguishing between fibrillators and nonfibrillators. The brilliant reduction in rate was found in the former. It was also found in the sinus rhythm when edema was present; but neither group of patients is at present under discussion. In the absence of edema, a reduction in rate may be said to occur principally in the hypodynamic and unstable heart, in the heart which for unknown reasons undergoes spontaneous alterations in rate. In hearts of this nature, a natural tendency to reduction is accentuated by administering digitalis. Aside from these, the majority of individuals do not respond to therapeutic doses of digitalis by a fall in heart rate. When amounts equal to 0.4 gm. of leaves a day are given for five to seven days, ventricular slowing does occur, but it occurs as the result of the blocking of the auricular impulses. The latter continue at an unreduced speed and do, as a matter of fact, usually exceed their initial rate. In view of the continued initial, or, in most cases, accelerated auricular rate, it is doubtful whether one may speak of a digitalis slowing of the heart as a primary phenomenon. It depends obviously on the disturbance of a function other than that of stimulus production. We have been led to conclude from our observations, therefore, that digitalis slows the sinus rhythm only in the group of hypodynamic hearts, and that to produce slowing is not a primary function of digitalis in therapeutic doses.

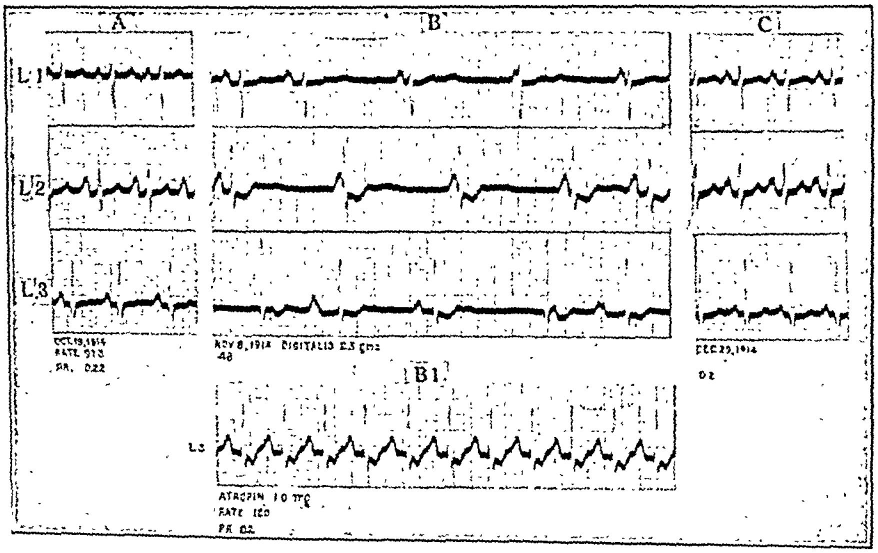

Fig. 1.—Divisions of the ordinates equal 0.1 millivolt; divisions of the abscissae equal 0.04 second. *A*, before digitalis was given; three leads (Einthoven) are shown. *B*, after 2.5 gm. of digitalis had been given; inversion of the *T* wave is shown in Leads 2 and 3; the curves in Leads 1 and 2 show a type of nodal rhythm described in the text. *B 1* was taken a few minutes after *B*; atropin, 1.0 mg. was injected; it shows that the rhythm of the heart returned to normal; the inverted *T* wave persisted; Lead 3 is shown. *C* shows the three leads; the curves were taken when digitalis had been completely eliminated and the curve had returned to the outline of the control, *A*.

Mention has been made of the blocking of auricular impulses after a sufficiency of digitalis has been given. It is a phase of its action to which Mackenzie drew attention clinically and von Tabora in experiments. Mackenzie, and more especially Lewis, believed it to be produced only when the conducting fibers between auricles and ventricles were previously damaged, more especially by rheumatic inflammation, as evidenced by the fact that the auriculoventricular interval was unduly lengthened. We have been able to show that an action on conduction can invariably be observed in patients, varying from simple lengthening to block. An effect on conduction may therefore be set down as a usual effect of giving the drug, apart from specific preexisting injury. An evidence of delayed conduction can be observed very early after the administration of the drug has been started. We have noticed it within forty-eight hours. In many instances, the auriculoventricular interval gradually lengthened during the succeeding three to five days until partial heart block occurred. We have believed it possible to maintain conduction time at any length we have thought suitable, by controlling electrocardiographically the amounts of digitalis requisite to produce the effect desired. Not all cases, however, show the gradual lengthening in conduction which I have described: block then occurs with extreme abruptness within a few hours. After the administration of digitalis has been terminated, alterations in conduction usually continue about two days. In the exceptional case, it may persist for two weeks. If gastro-intestinal symptoms have occurred, they do not persist beyond two or three days.

The occurrence of delayed conduction has been dwelt on for the purpose of showing that in certain cases, probably in a large number, the fact that digitalis is acting on the heart can be ascertained early in the administration. When the sign is obtained, it is definite. The problem which arises for decision is whether or not it is a sign which indicates a beneficial action on the heart. For a definite answer on the basis of this sign alone, more experience is required. A greater degree of digitalization can be obtained; but we may learn that on obtaining this effect, the maximum which is desirable has been reached.

When full doses of digitalis have been given, sufficient to cause delayed conduction, abnormal heart rhythms are commonly seen. They have been much described and occur as exaggerations of the normal sinus arrhythmia, extrasystoles, partial heart block, and rarely auricular fibrillation. We shall omit further mention of these. One arrhythmia which is still practically unknown as the result of giving digitalis may be described here. In this form none of the auricular beats is blocked; auricles and ventricles both continue to beat and do so almost at the same rate (Fig. 1). But there is incomplete coordination between them, so that a fixed relation ceases to exist. They must, however, be closely related. The conclusion cannot be escaped that they have an origin in common, or two related origins. If it is a common origin, the lack of exact coordination must depend on a shifting of the site of stimulus production, similar to one we have described in the ventricles, possibly complicated by changes in conduction; if it depends on two competing stimulus-producing foci, they must be actuated by a common factor. It is a matter of interest that we have found arrhythmias of this form associated only with various forms of intoxicants, notably digitalis. Robinson and Auer have seen it also in the presence of anaphylactic shock.

Aside from the lengthening in auriculoventricular conduction which, as has been said, begins in many cases soon after digitalis treatment is initiated and can be taken as an indication that an effect on the heart is being obtained, even though no change in rate has occurred, another new sign in the electrocardiogram appears to be one of great importance. This sign is an alteration in the size, shape, and direction in the *T* wave (Fig. 2, *A* and *B*). If digitalis is given to a patient whose electrocardiogram contains a *T* wave pointing in the usual upward direction, the first change noticed is usually a diminution of the height of this wave, usually in the third lead first, and later in the second. The first lead may also show changes, but relatively speaking, less frequently. The change may be noticed as early as twenty-four hours to consist in a diminution in the height of the wave, but at the end of forty-eight hours this change is more distinct and the wave may by this time have become iso-electric. At this time or, more often, later, it becomes inverted. Instead of becoming iso-electric or inverted, it may become diphasic, and in a number of cases of this sort it is easy to distinguish *T* waves consisting of two parts, a first portion which becomes inverted and then returns quickly to a second portion which represents the end of the original wave. The diagram (Fig. 2 *A*) explains this relation. The dotted line represents the altered portion of the curve. There are, of course, many electrocardiograms in which, for pathologic reasons, the *T* wave is originally pointed in a downward direction. If digitalis is given to such patients, the direction of the *T* wave is altered, and during the action of the drug may be directed upward (Fig. 2 *B*). An especially beautiful example of this variety we have found in a case of complete heart block. Usually the negative *T* wave becomes deeper, especially in the third lead. That the change is due to digitalis is proved by the fact that when the drug is stopped, the *T* wave returns to its original size and shape. The length of time required for it to return to its initial condition varies between five and twenty-two days. To be certain of the change, we have repeated the observation a number of times in the same individual, and to be certain, also, that it is not dependent on a pathologic heart, we have shown it to exist in persons whose hearts are quite normal. It is a sign, then, that the heart is digitalized, and it is a sign which appears early. It appears at a time when no change in conduction need have occurred. It appears in the absence of any alteration in rate. The factors on which the change in the *T* wave depend, we cannot explain precisely at the present time. That it is an evidence of an alteration in the contractile substance of the heart is an inference which is naturally drawn from the circumstance that at the present time the electrocardiogram is generally regarded as the expression of changes in the electric state of the muscle. Whether, in a clinical sense, the change in the *T* wave is to be taken as an indication of beneficial or not beneficial action, it is impossible to say, though there seems little reason to question the fact that it is.

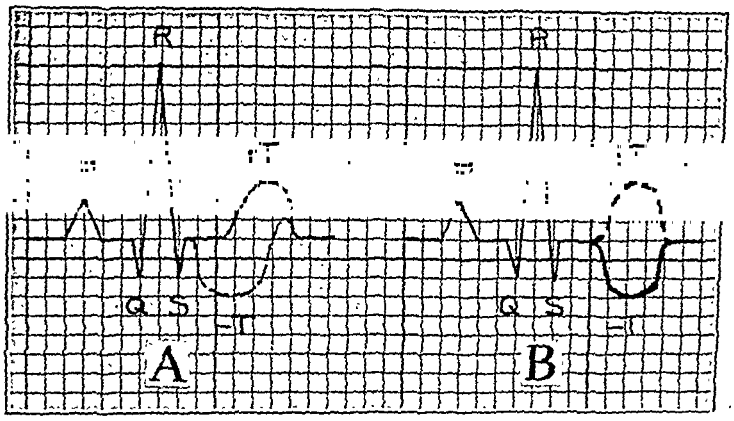

Fig. 2.—*A*. The solid line represents the normal outline of the electrocardiogram. The *T* wave is directed upward. The dotted line shows the change which occurs in the *T* wave under the influence of digitalis. *B*, in a similar way, shows the change in certain cases when the *T* wave is initially directed downward. Under the influence of digitalis it turns upward.

Many matters for consideration arise in relation to the sign. It is a matter of discussion just now, for instance, whether the effect of digitalis on heart muscle depends on an intimate combination of the drug with the muscle (*Speicherung*) in which digitalis is destroyed or consumed, or whether it acts merely by virtue of its concentration in the circulating fluid. In the latter case, the signs of its effect disappear promptly with the withdrawal of the drug, with the diminution in its concentration. The drug is not consumed and, if the solution is recovered, may be used with equal efficiency in a succeeding heart. The essential point of difference is as to whether or not the drug is actually consumed when it is given. In both cases it must, of course, be excreted. If the drug acts merely by virtue of its concentration, a rapid excretion may be expected, and its composition may, of course, be altered; it need not necessarily reappear as the original substance. In the case of its being consumed, its composition on excretion would naturally be altered, but one would expect the rate of its excretion to be much delayed.

In view of what has been said of the change in the *T* wave, under the influence of digitalis, and more especially of the dependence of the change on alteration in the heart muscle, it is difficult to escape the conclusion that a degree of great intimacy in the combination between the drug and the muscle must have taken place. It is clear that the influence on the muscle may outlast the presence of the drug, but it is difficult to believe that an action of such prolonged duration (three weeks), after giving the drug has ceased, can depend on a simple matter of concentration.

Two criteria have, then, been shown in electrocardiograms to indicate surely the fact that digitalis is acting on the heart: the first in the slight but definite lengthening in conduction, the second the very curious and very constant alteration in the *T* wave. Even if no slowing whatever of the heart occurs, we may be certain, by virtue of finding one or both these phenomena in electrocardiograms, that definite digitalis action on the heart has taken place. Rate, the criterion for which we looked and on which we relied, fails us, but in its place we have these other and surer ones. If these statements prove to be correct, they necessitate an alteration in the indications for the use of digitalis. It is not a drug, at least in the cases we are considering, which alters the rate of the heart—it is a drug which, by virtue of its combination with heart muscle, has a bearing on contraction, an effect which is evidenced by its effect on the *T* wave. It appears, then, that the groups of cases in which the drug was supposed to be of value have decreased in number, that is to say, those in which an effect on rate was expected, while groups in which new indications for the use of the drug may be found in the light of muscular and conduction effects we may hope will increase. In consequence, many patients with heart disease from whom digitalis has been withheld may, with new criteria, be drawn into groups for whom it is indicated.

In contrast with the action of digitalis in nonfebrile patients, it is worth referring to the well-known and often mentioned failure of the action of digitalis in cases of fever. Its general failure has been dwelt on by Mackenzie, whose opinions have recently suggested an investigation of the problem to Gunn in Cushny's laboratory. Its failure in pneumonia, in particular, has been dwelt on by G. A. Gibson of Edinburgh. Similar views in regard to the reputed impotence of the drug are no doubt held in this country. Elsewhere, as in Krehl's clinic, it is usually given and thought to be beneficial. It is not exactly clear what is meant by a failure of digitalis to act in the presence of fever. As an antiphlogistic it need not be considered. What is usually wanted in fever is an agent either to slow the pulse or to increase its strength. It is no doubt a general experience that digitalis does not slow the pulse in fever, and its failure to do so is the complaint most often made. That failure in this respect is not unexpected is clear from our experience in nonfebrile cases. Whether it strengthens the pulse or, in other words, increases the force of ventricular contractions, is an effect which has also been much discussed. Satisfactory objective measures of this are not available, but there is much clinical, that is to say, subjective evidence on the part of observers favoring the idea that it exists. In the absence of evidence bearing on contraction, [illegible] evidence can be supplied to show [illegible] action during fever of a nature precisely similar to that already described in nonfebrile patients. This evidence consists, as in the nonfebrile, in its influence on the auriculoventricular interval and on the *T* wave. Here, as in the nonfebrile cases, the changes begin within from twenty-four to thirty-six hours and persist for days after defervescence and after the giving of the drug has been stopped. Whatever its nature, it is clear that the same sort of support can be given the heart by digitalis during fever as in its absence. That this is the sort of support that the heart demands may be open to question. It is an error, therefore, to regard its action as a failure until its efficiency from actual, rather than from incorrect points of view, shall have been examined. Possibly as an aid to contraction, much may be gained from its use; but the expectation of obtaining an action on heart rate must be abandoned.

There is, however, a group of febrile cases in which digitalis acts efficiently on rate. In our experience these have not been patients exhibiting the normal sinus rhythm, but patients showing auricular fibrillation or auricular flutter. These rhythms appear spontaneously during attacks of fever and disappear spontaneously afterward. Occasionally the ventricular rate in such cases is inordinately high, the high rate itself being a predisposing factor toward heart failure. The most desirable thing to accomplish in these instances is a reduction in rate. By the use of intravenous doses of strophanthin, one might expect to block the greater number of auricular impulses which cause the acceleration of the pulse and to reduce the ventricular rate to reasonable limits. In several patients in whom the abnormal rhythms were found, strophanthin was injected and has acted in the described way. Under these circumstances this method of treatment has seemed to us a life-saving remedy. It may be mentioned that, except for its greater speed in action, strophanthin is not necessary and that exactly similar results in cases of flutter have been obtained by the use of digitalis by mouth. The effect on rate which digitalis has on auricular fibrillation and flutter, when these occur in fever, is precisely the same as in the nonfebrile state, and the results obtained are precisely the same. We are led to believe, therefore, although we have reached no definite conclusion, that there is no difference in principle between the way digitalis acts in fever and in nonfebrile conditions. One might venture the suggestion that, from the point of view of heart rate, and from the point of view of an emergency, the possession, in certain cases, of a heart beating after the manner of auricular fibrillation or flutter may, in fever, be a valuable asset, for it is in these rhythms that digitalis, by blocking auricular impulses, is able to slow the pulse rate. It may be mentioned, incidentally, that fever patients having auricular fibrillation initially are not necessarily prejudiced in the outcome of the disease by the abnormal rhythm.

Another topic long a subject of conflict is the relation of digitalis action to blood pressure. Clinicians have often withheld the drug from patients having high pressure in the fear of producing unpleasant consequences, as, for instance, cerebral apoplexy. One of the most recent contributions to this phase of the action of digitalis has been Marvin's. His investigations with a single dose of the tincture in normal medical students led him to conclude that, after five hours, an elevation of from 10 to 15 mm. Hg occurred in systolic pressure, and that the effect of this persisted for fifty hours, when the curve resumed its initial height. Many exact studies have been made in recent years, notably by Mackenzie, Price, and Lawrence. These and other investigators have failed, on the whole, to find pressure changes resulting from the administration of the drug. The form of this statement demands a certain modification. The clinical reports bear the defects mentioned earlier—that they are based on cases indiscriminately selected, or not grouped at all. They include cases with high pressure and cases with low. The heart mechanism, in itself an important factor, is, especially in the German reports, not considered. The estimation and interpretation of pressures in auricular fibrillation, as will be shown in another place, present problems much more intricate than those in the sinus rhythm, and the results of investigations indicate a different response to digitalis.

In the group of patients under consideration, those with sinus rhythm, without edema, and with a moderate or low systolic pressure, we have seen no substantial alteration in the level of either the systolic or the diastolic curve. Our conclusions are like those of other more recent observers. The few opportunities we have taken to verify the observations made by Marvin have failed in establishing results similar to his. In the cases we have studied, then, no alteration in pressure was found. In so far as the older fears are concerned, it is apparent that digitalis must be considered a safe drug to use.

Vascular effects, however, aside from changes in pressure, may be produced, and the untoward or beneficial nature of these requires consideration. A specific vascular action, not dependent on heart action or on pressure effects, has been advanced and held by the school of Gottleib. Gottleib, while admitting a cardiac action of digitalis, nevertheless maintains that the peripheral action of the drug is the one by virtue of which its prime effects are produced. More recently clinicians, employing optical methods of registration devised by Frank, have again taken up these aspects of digitalis action, and reports are now being published of alterations in reaction of the blood vessels, notably in the tension of the vessel walls, when they are under the action of the drug. It is the results of these investigations, far from satisfying as yet, which demand further study in order to establish the assurance that the vessels of the body, and more especially of the brain and meninges, do not become subject to injury as the result of giving digitalis.

The last phase of the action of digitalis which I wish to discuss is the relation of the drug to the excretion of urine. The foxglove obtained its initial reputation because diuresis was so enormously increased when it was administered. For almost a hundred years it was supposed that this was the one and most striking of its effects; but now the situation in regard to this phase of the problem is less simple. The questions now being discussed relate first to when digitalis does, and when it does not, increase the amount of urine, and, second, when it does, by virtue of what mechanism this result is brought about. The first problem, whether or not the amount of urine is increased, is a clinical problem and can be definitely solved. In the patients in the group under consideration, it may be stated definitely that no increase in diuresis takes place. It is, of course, remembered that these patients have no edema. The problem as it relates to patients having edema is naturally different, and involves other factors; but in the simplest form of case, no increase in the amount of urine takes place. So far, digitalis cannot be considered a specific diuretic. In experiments the situation is different, because there, although obviously edema is likewise absent, it is almost universally maintained that increased urinary flow takes place. But the clinical and the experimental conditions are not quite parallel, because in the latter, doses which have usually been employed are much larger than normal, that is to say, from three to fifty and more times the lethal dose for man; and because the method is an acute method, for the drug is given intravenously, or under the skin, and the effect is observed under the conditions of surgical operation. But, although the clinical and experimental conditions present results so divergent, it may be interesting to enumerate the theories which are given in explanation of the occurrences observed in experiments, the more in that they discuss factors which must be considered in the diuresis which occurs when digitalis is given in edema. As may have been supposed, three possible explanations have been urged, first that the experimental diuresis depends on a local vascular action in the renal vessels; second, that it depends on the general elevation in vascular blood pressure, and third, that it depends on the increased force of the heart's action. It will be noticed that none of these explanations refers to an action on renal epithelium. But this phase of the discussion of digitalis action scarcely bears on the problem now being considered, and may consequently be dismissed.

We return to considering the effect of digitalis in patients of our group. Diuresis, as has been said, does not occur in any stage of the treatment. When the cardiac effects are clearly discerned, as in the auriculoventricular interval and in the state of the *T* wave, no alteration in output is found. Intake is, of course, maintained level. But later, when dissociation occurs, and gastro-intestinal symptoms have taken place, the output actually diminishes. On account of loss of appetite, and, in some cases, of nausea and vomiting, the fluid intake naturally falls and accounts satisfactorily for urinary decrease. In view of these considerations, the conclusion is justified that a specific effect on urinary output does not occur as the result of giving digitalis to the class of patients under discussion. This, in itself, is not a significant contribution to an understanding of the pharmacology of the drug, but in another place it will be shown that it has an important bearing on the drug's action in edema.

No consideration of the action of digitalis on the various functions of the heart, on rate, on conduction, on contraction, and on circulation, is complete without a reference to the nature of this action. For many years a war of words, the two most prominent of which were "myogenic" and "neurogenic," was fought. This fight was waged on the question of the conduction of impulses in the heart. The battle became a drawn battle; no decision could be reached. Anatomic studies showed that both nerve and muscle elements were inextricably associated in the heart in general, and in the special muscular systems as well. The effort to distinguish the functions of one tissue from those of another became impossible, and the struggle was abandoned.

The same words, "neurogenic" and "myogenic," have in a similar way formed centers around which another battle has been fought, the battle to elucidate the mechanism of the action of digitalis. Fortunately, these battles have been less violent, and the lesser violence was probably due to the fact that it was always more than half suspected that neither one side nor the other was altogether wrong, and, in fact, that both sides were partially right. Our studies, it seems to us, indicate that this is so. So far as atropin may be taken to be a drug acting especially on the ends of the vagi, a release of the heart from a phase of digitalis action by its use indicates a nerve action of digitalis (Fig. 1 *B*). So far as digitalis has other effects, which atropin does not release, it may be inferred that it has an action directed more especially to muscle. Both effects can be observed at the same time, as we have seen, and by virtue of them another struggle, one may hope, has been terminated.

Our studies have, then, led us to draw a number of definite conclusions in regard to the way digitalis acts, and to find new criteria in the *T* wave and in the effect on conduction for detecting when the drug is acting. It seems important to emphasize the fact that it is essential to distinguish differences which patients suffering from heart disease present, and to study them in groups, with these differences in mind. Rhythm certainly offers a prime basis. The effect of digitalis on rate and on a number of other capacities varies with the nature of the disturbed function. In the use of the drug in pneumonia we have found it to have an action essentially similar to that found in the nonfebrile. In the absence of edema, we have not observed a diuretic effect. Evidence has been found which indicates persistence of action, longer than can be accounted for if the drug acts only by virtue of its concentration. We have shown that digitalis has a twofold action on the heart, nervous and muscular. We believe that clearness of indications will result only if the exact mechanism of the action of the drug is ascertained; for only when these are clearly met, can rational treatment be instituted.

NEW METHODS OF PYLOROPLASTY FOR CONGENITAL PYLORIC STENOSIS *

ALFRED A. STRAUSS, M.D.
CHICAGO

In recent years, the operation of posterior gastro-enterostomy for congenital pyloric stenosis has become more and more popular. This is largely due to the remarkable results of H. M. Richter of Chicago and Charles L. Scudder of Boston. The former reports twenty-two cases, with only three deaths, which surpasses anything thus far recorded in literature. While it is true that Richter and a few other surgeons who have made a special study of the technic of this operation on infants have achieved wonders with posterior gastro-enterostomy, many of our most eminent and skilful surgeons can claim no such results. All surgeons, even including those who recorded the most brilliant results, will admit that this operation is too much of a surgical procedure for the emaciated and moribund infants who have been brought too late to the surgeon, from failure of early diagnoses, or too long a period of medical treatment. It was an experience with exactly this type of cases that led us into a detailed study of this condition, and in turn caused us to devise the new operative procedure to be described later.

Case 1.—Of two cases which came in February, 1915, to Dr. Abt at the Michael Reese-Sarah Morris Hospital for Children from out of the city, one was an extremely emaciated moribund infant, 11 weeks old, who was treated for an acute gastritis before admission. The child started to vomit at 2 weeks, and continued for nine weeks, up to the time when seen by Dr. Abt. There was also a history of constipation. On examination, a tremendously distended upper abdomen, with the characteristic peristaltic gastric waves, was noticed, and a tumor was felt on palpation. In spite of the moribund state of the child, it was decided to operate, as it seemed the only chance the child had for recovery.. A posterior gastro-enterostomy was performed, with all the precautions as to shock and technic as detailed by H. M. Richter, Scudder, and Downes of New York. The tumor at the pylorus was olive-shaped, about the size of the terminal phalanx of the thumb. On its anterior upper quadrant was a peculiar ridge of muscle extending from the midportion of the tumor to its duodenal end, and which had an appearance similar to a tuberosity on a bone. The tumor was white, anemic in appearance, hard to the touch, and of the consistency of cartilage. We also noticed that exposing the stomach produced not nearly the shock that handling of the small intestine produced. The latter action caused the child to become pulseless, and to stop breathing. When the small intestine was returned into the abdomen, and the operation stopped for a time, the pulse reappeared, and the breathing became regular again. When the small bowel was handled again, the child again went into a complete collapse. The duration of the operation was twenty-five minutes. The patient did well for ten days, when it started to vomit. This continued for thirty-six hours, when the patient collapsed and died.

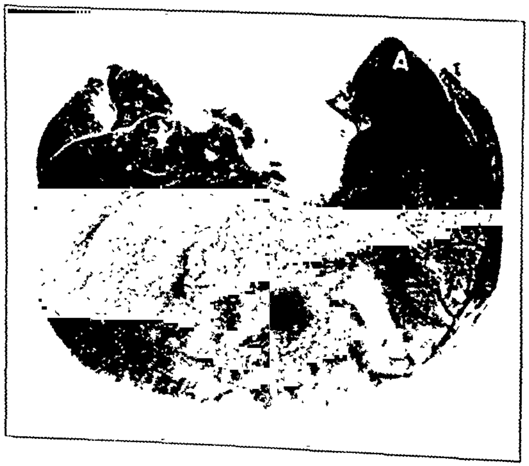

Fig. 1.—Tumor with pyloric ridge (*A*).

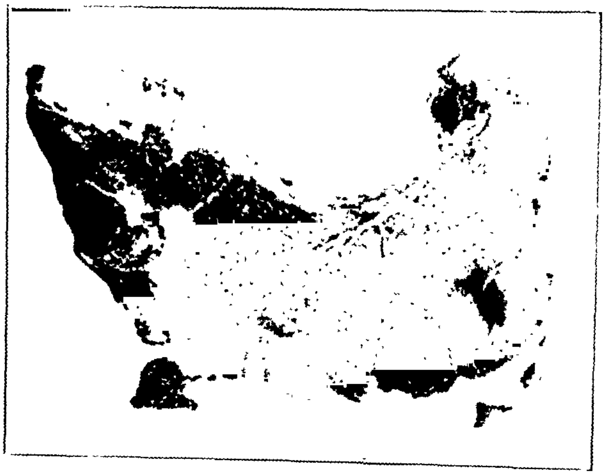

Fig. 2.—Tumor with pyloric ridge (*A*).

Case 2.—The second case was that of a child, 8 weeks old, who had vomited for six and a half weeks, who was also in a moribund condition. Posterior gastro-enterostomy was performed. The stomach was extremely dilated. The pylorus had the typical tumorlike enlargement, with the usual ridges on its upper anterior quadrant. The child went into collapse, and died six hours after the operation. Duration of the operation was twenty-two minutes.

Necropsies.—The necropsies showed that the stomach in both cases appeared to be more the normal size than at the time of the operation. Both stomachs were put through the water test, and both gastro-enterostomies appeared watertight. In the stomach of the first case a 14 F. catheter could be passed through the pylorus, but none in the second case. Both cases had the typical tumor, with its ridge, as described above (Figs. 1 and 2). On cross section (Fig. 3, the pylorus revealed the enormous hypertrophy of the circular muscles, and in some areas also a hypertrophy of the longitudinal muscle, especially where the ridgelike processes appeared (Fig. 3A). The intermuscular connective tissue bundles (Fig. 4) were also enlarged, and seemed to be involved in the process. This coincides with the findings of Dr. Abt, in 1900, and Lewis and Grulee.[1] The mucous membrane was thrown into longitudinal folds (Fig. 5), and was redundant. It was infolded and compressed by the surrounding hypertrophied muscular tissue.

We believe that these congenital pyloric stenosis cases can be divided into two classes:

1. A. Large tumors with almost complete compression of mucous membrane and complete obstruction.

B. Small amount of hypertrophy of muscularis, but with almost complete compression of the mucous membrane, and complete obstruction.

2. A. Large tumors, with only partial compression of the mucous membrane, and only partial obstruction.

---

[1] Lewis, Dean, and Grulee, C. G.: The Pylorus After Gastro-Enterostomy for Congenital Pyloric Stenosis, The Journal A. M. A., Jan. 30, 1915, p. 410.

B. Small amount of hypertrophy of muscularis, with only partial compression and only partial obstruction.

We believe that many of the so-called *pylorospasms* which are treated medically with good results, but show recurrence of symptoms from time to time even into adult life, belong to the class of hypertrophy, with partial obstruction. Such cases have been recorded by Marie, Russell and Landerer, and some of these have later come to operation.

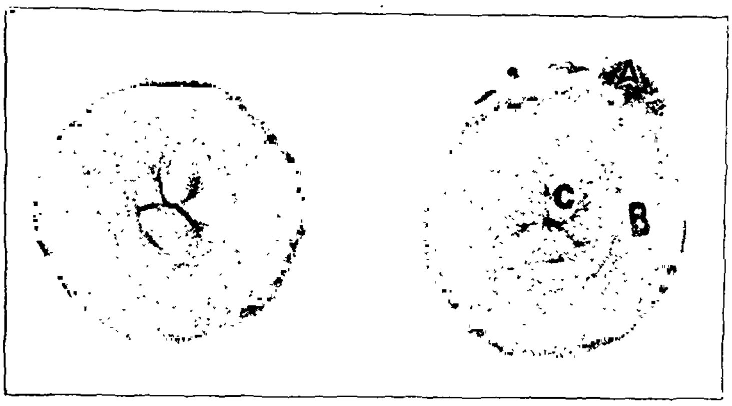

Fig. 3.—Cross section of pylorus; *A*, muscular ridge; *B*, circular hypertrophied muscle; *C*, the infolded membrane.

The new surgical procedures which we have devised are based, first, on the pathology described in the foregoing, and second, on the results from animal experiments.

Ramsteadt, who made a longitudinal incision through hypertrophied muscle, down to the mucosa, and Nicolls, who made a V-Y-shaped incision through the muscularis down to the mucosa, produced only a slight gaping of muscle and herniation of the mucosa at the site of the pylorus. Weber, who modified this slightly by suturing at right angles to the long axis, had not much success, since it was difficult to suture the hard, cartilage-like, hypertrophied muscle in the transverse direction and make it hold. It is evident from Figure 5 that the Ramsteadt, Nicolls and Weber operations produce a hernia on only one side of the pylorus. They do not reduce the infolded mucous membrane, and do not reduce the cartilage-like, hypertrophied musculature, so that the peristaltic waves can pass over the pylorus.

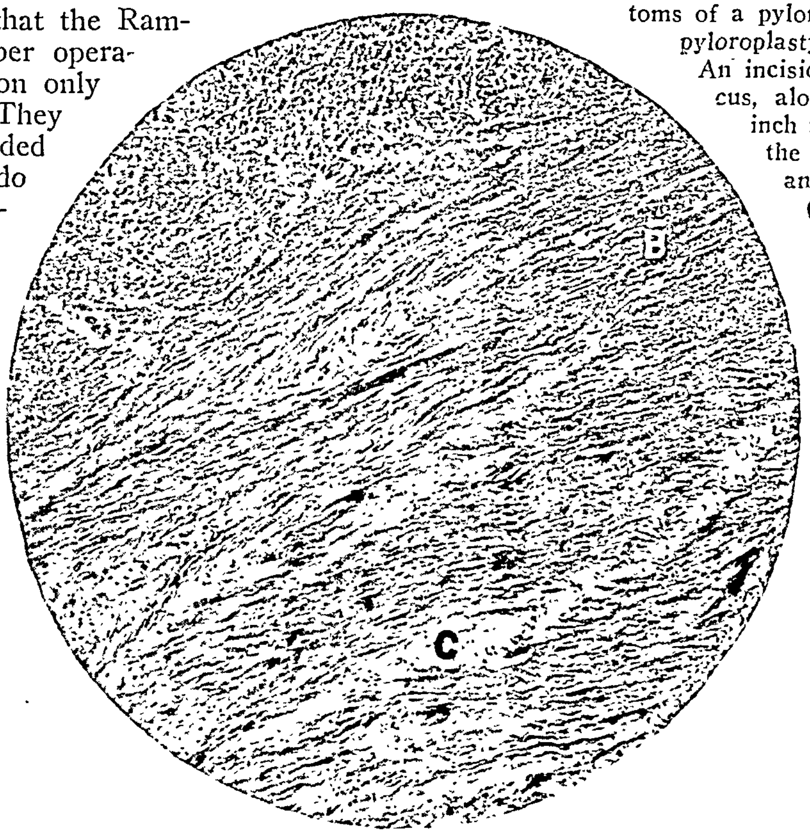

Fig. 4.—B, intermuscular connective tissue bundles; C, hypertrophied muscle.

I have demonstrated[2] how easily the mucous membrane can be shelled out by everting the muscularis. Since publishing the report of this work, I have performed fifty-six pyloric closures, with gastro-enterostomy by this method. By fluoroscoping these animals, we found by separating the mucosa from the muscularis that we would get a paresis of the pylorus, which would last from two to twelve weeks. On the other hand, in a series of animal experiments, a report of which will appear in print later on, in which we resected one half of the circumference, and one half of the length of the pylorus and pyloric antrum, we reconstructed the resected half by two superimposed free fascial transplants. No paresis occurred. To the contrary, this reconstructed pylorus, with its one-half normal intact mucous membrane and muscularis, and its other half of fascial transplants, showed on fluoroscopic examination a perfectly normally functioning pylorus. When the mucous membrane is separated from the muscle, we separate Meisner's from Auerbach's plexus, which probably accounts for the paresis of the pylorus. This is the first essential step in the pyloroplasty. By cutting down to the mucosa and shelling it out, we reduce the folds of the infolded mucous membrane (Fig. 5), and produce a paresis of the spastic pylorus. The second part is to reconstruct the hypertrophied musculature to its normal thickness. This can be performed by either cutting away the inner circular layer, or utilizing it as a plastic flap, as will be shown in the following steps in four cases operated on by this method.

1. TYPE A.

Case 3.—A baby, aged 3½ weeks, was admitted to Dr. Abt's clinic at the Michael Reese-Sarah Morris Hospital for Children, with all the typical signs and symptoms of a pyloric stenosis. Operation of a pyloroplasty was performed, as follows: An incision, 1 inch above the umbilicus, along the right rectus, and 1 inch in length, was made through the skin. This was retracted, and a slight curved incision (Fig. 6) was made through the anterior sheath of the rectus. This was carried through the abdominal wall to the peritoneum, and the peritoneum opened. A fine gauze sponge was placed immediately into the abdomen to prevent evisceration. A fine catheter was now passed by mouth into the stomach to allow the collapse of the enormously distended stomach. A small retractor was placed in the right side of the incision, and slow traction was made. With the index finger hooked into the lesser curvature near the pylorus, I was able to deliver the hypertrophied pylorus into the wound without bringing any other portion of the stomach or bowels into the wound. The pylorus was now grasped between the thumb and index finger (Fig. 7) and a longitudinal incision was made over the upper anterior quadrant of the pyloric tumor, and slightly beyond each end of it, down to the mucosa. If one should hesitate to use the sharp scalpel here, for fear of injuring the mucosa, he could make a superficial incision into the tumor and divide the deeper portions to the mucosa, with the handle of the scalpel. The hypertrophied musculature cannot be everted so easily as described in pyloric closure, but one side of the musculature can be grasped with fine gauze by the assistant, while the operator makes pressure with the thumb and index finger from below. Then a Kocher dissector, with the aid of the scalpel, was used to free the mucosa from each side of the divided muscularis until it was almost completely shelled out. The mucosa separates very easily; in fact, much easier than it does on the normal pylorus, either human or animal.

---

[2] Strauss, A. A.: Two New Methods of Closure of the Pylorus for Pyloric and Duodenal Ulcer, The Journal A. M. A., Oct. 31, 1914, p. 1525.

The muscularis was now everted as much as possible, and a very fine scalpel (Fig. 8) was used to divide the muscle tumor longitudinally into two layers of equal thickness, a deep and a superficial, and the incision thus made was carried lateralward by a specially constructed angle knife almost to the edge of the divided muscle tumor. This newly made flap was everted (Fig. 9). The opposite side was then treated in the same way. The everted edges were closed with No. 00 fine waxed *silk interrupted* sutures (Fig. 10). A small piece of free transplant from the great omentum was sutured with four interrupted waxed silk sutures over the pylorus to cover the raw surfaces (Fig. 10, inset).

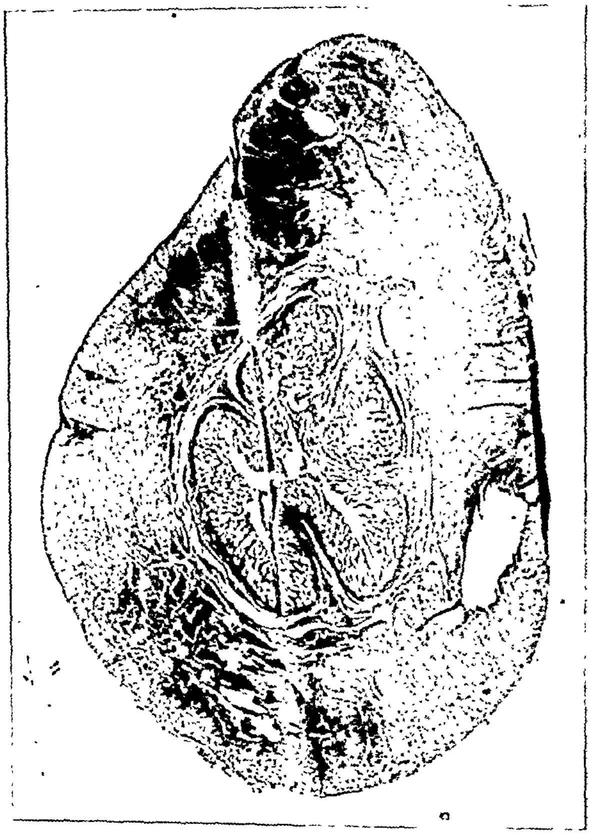

Fig. 5.—Photomicrograph; *A*, hypertrophied muscle; *C*, infolded membrane.

We now had a reconstructed pylorus, with about the normal thickness of muscle, and plenty of room for the unfolded mucosa. The entire operation did not take over ten minutes, and seemed to be devoid of shock. The abdomen was closed with a slight imbrication of the walls, as one would use in an inguinal hernia. Interrupted chromic catgut was used. Two *tension* sutures of heavy waxed silk also were used. I believe the imbrication will prevent hernia and evisceration. The patient was now turned over to Dr. Abt for the after-care. He made an uneventful recovery, was given water a few hours after the operation, and mother's milk in twelve hours. He quickly gained in weight. There was no vomiting, no gastric peristalic waves were to be seen, and the patient had normal bowel movements. The patient was fluoroscoped and roentgenographed at the end of twelve weeks. The pyloric function was normal, and the emptying time of the stomach was normal. The patient is now far beyond his normal weight for a baby of that age.

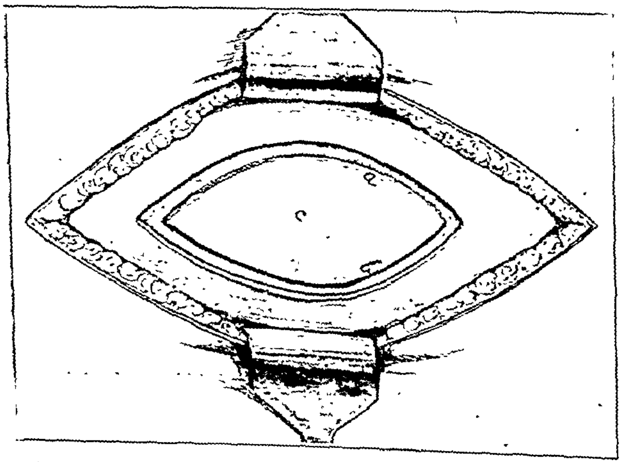

Fig. 6.—Incisions: *a*, first incision; *b*, second incision; *c*. sheath of rectus (anterior).

Case 4.—With my colleagues, Dr. George L. Davenport and Dr. Julius Hess, I saw a second case with all of the characteristic symptoms and signs of pyloric stenosis. I persuaded Dr. Davenport to try the above-described method. He very cheerfully permitted me to direct the steps of the operation. Local anesthesia was employed. The operation was performed by him with perfect ease in ten minutes. The patient was turned over to Dr. Julius Hess for the after-treatment, made an uneventful recovery, and is gaining weight rapidly. No gastric peristaltic waves could be seen following the operation.

Cases 5 and 6.—In a third and fourth case which came to Dr. Abt, operation was performed in the same way, and the patients were turned over to Dr. Abt for the after-treatment. Both have made uneventful recoveries.

1. TYPE B.

When the hypertrophy is very marked, we shell out the membrane, but instead of making a plastic flap of the tumor we remove the larger portion of the inner circular muscle. This procedure we have performed thus far only experimentally on dogs.

SECOND METHOD

When there is a small hypertrophy of the muscle tissue with almost complete compression of the mucous membrane, we make a second curved incision (Fig. 6 *b*) through the anterior sheaths of the rectus, and remove the oval flap with some of its muscle. After freeing the mucous membrane of the pylorus, we insert this free fascial transplant, as in Figure 11, which is covered with a free transplant from the great omentum with four interrupted fine silk sutures. This method has been performed on ten dogs, which were

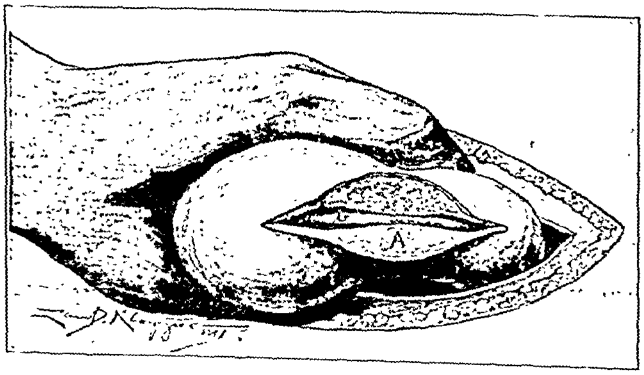

Fig. 7.—*A*, muscle tumor; *B*, the mucosa.

later fluoroscoped and roentgenographed, and killed at the end of six months. The pylorus was functionating normally, and the transplant organized without any cicatrization (Fig. 12). There seems to be a slight compensatory dilatation of the stomach wall opposite the transplants.

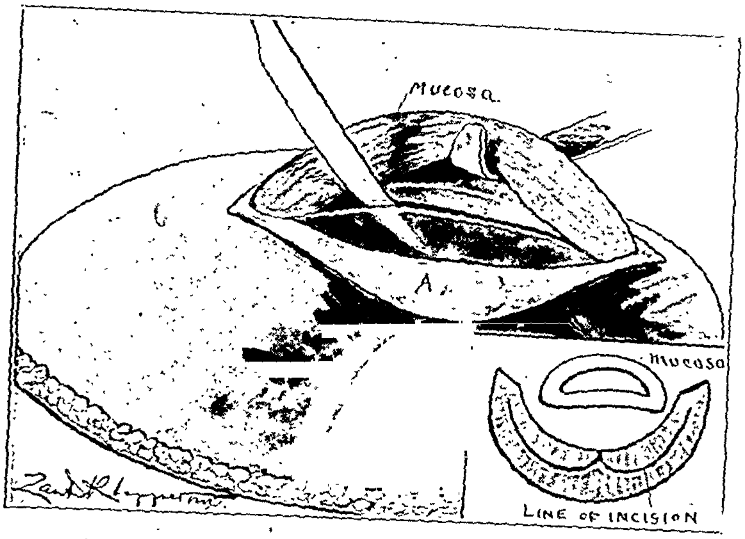

Fig. 8.—*A*, muscle tumor; *B*, internal layer of muscle; inset, transverse section.

ETIOLOGY

As regards the etiology of this condition, there are two views: first, that it is a congenital hypertrophy which later produces the spasm; and, second, that it is a physiologic hypertrophy, produced by the hypermotility and spasm of the musculature of the stomach. In order to answer this question, Dr. Abt and I are conducting some animal experiments at the Morris Institute for Medical Research of the Michael Reese Hospital. The basis on which we are working is as follows: If this condition is a physiologic hypertrophy produced by hypermotility and spasm, we ought to be able to reproduce it by producing spasm and hypermotility, and if this physiologic effect does not produce a hypertrophic tumor, such as we find in congenital stenosis, it would speak highly for the congenital origin of this condition. To prove this, the following experiments were performed:

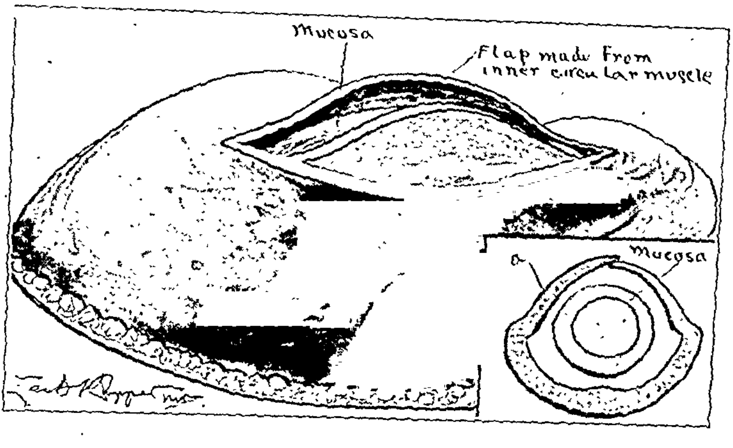

Fig. 9.—Muscular flaps turned out; inset, transverse section: *a*, muscularis.

Several groups or series of young dogs, from 6 to 10 days old, were used. The pylorus was exposed and the mucosa shelled out for half of its circumference. A fine free fascial transplant was sutured to the partially shelled out mucosa and sutured so as to produce the infolding, such as is seen in Figure 5. This infolding produced an obstruction which would barely allow a fine probe to pass through. In other words, we tried to reproduce the pathologic condition as found in congenital pyloric stenosis. The animal vomited, and had hypermotility and spasm, but no tumor developed.

On a second series of animals the foregoing experiment was performed, plus the cutting of the splanchnic nerves.

On a third series now being done the same experiment is being reproduced, plus stimulating the vagus nerves. This part of the experiment is accomplished by placing two fine insulated sterile wires around the vagus nerve and allowing them to come through the wound. In this way we are able to stimulate these nerves and produce a hypermotility as often as we care to do so.

On a fourth series of animals, after the stomach was opened, a foreign body was placed into the pylorus of sufficient size so it could not pass through but would allow a small amount of food to go through the pylorus. This foreign body was so sutured that it could not be regurgitated back into the stomach.

All of the experiments just mentioned are in addition to some others which will be described in detail in a later paper. They all produced hypermotility, vomiting and some spasm, but no hypertrophy of the pyloric muscles, such as is seen in congenital pyloric stenosis.

These experiments certainly speak highly for the congenital origin of this condition. Coutley, who found a pyloric stenosis in a 7-month premature infant, also speaks highly for this view.

Those authors who set forth the argument that, if it was congenital, the symptoms should start at birth, and not two or three weeks after birth, can be answered in the following hypothesis: The new-born infant for two or three days after birth gets but a few drops of colostrum, and a very small amount of milk. That the amount of milk in the first two or three weeks only gradually increases, we also know. We believe that like all other internal organs, and like other physiologic functions in the body, the stomach does not reach its full physiologic limit, especially as to motility, until that time. That is to say, the newly born infant has a very small amount of muscular activity, but this physiologic action is gradually developed and does not reach its full limit until two or three weeks after birth.

We are now carrying out some fluoroscopic examinations of newly born infants to prove this point. In a child born with a congenital hypertrophy, if such is the case, the slight opening left in the pylorus is sufficient to allow the undeveloped peristaltic waves of the first few weeks to force the food through, but the constant high tension to which the musculature of the

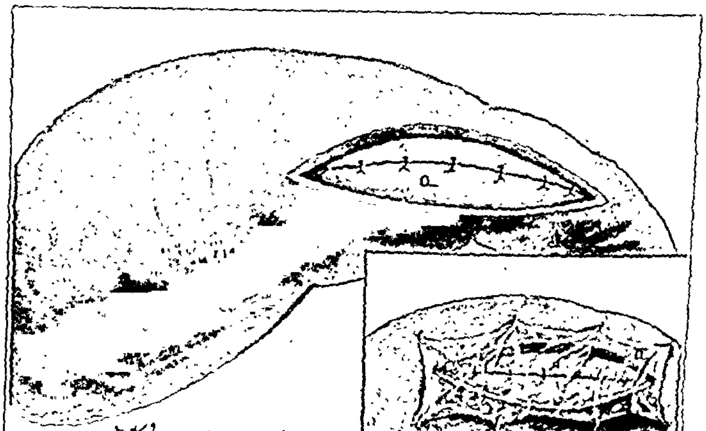

Fig. 10.—The newly made muscle flap sutured; inset, *a*, free transplant of great omentum covering field of operation.

stomach is forced finally throws it into a spasm which helps to close the pylorus, and produces all the subsequent characteristic symptoms.

We believe that one of the greatest arguments against the physiologic origin of this hypertrophy is that in a physiologic hypertrophy that portion of the stomach which undergoes the greatest muscular activity would show the greatest amount of hypertrophy. It is well known, from a mechanical standpoint, that there is less muscular motion immediately in the region of the pyloric ring where this tumor occurs than there is in the antrum of the pylorus, where the muscular movement of the peristaltic waves is greatest. If this is true, the tumor should appear in the antrum rather than at the place where it is found. It is also very hard to conceive that this tumor should not have a gradual ending on the antrum and on the duodenal side, if it is due to the physiologic hypermotility and spasm, whereas, as a matter of fact, it ends abruptly. It is also contrary to any knowledge we have of conditions in other parts of the body, and the rate of tissue growth, that such a tremendous amount of hypertrophy should be produced as we have seen in infants who were operated on at the end of one week after birth.

CONCLUSIONS

The advantages of the above-described methods of pyloroplasty over posterior gastro-enterostomy are:

1. The incision required is very small, in contradistinction to that necessary in performing posterior gastro-enterostomy — large enough to deliver the partially distended stomach, transverse colon, and then to find the right loop of jejunum.

2. Those who have performed gastro-enterostomies in these infants will appreciate the saving of a tremendous amount of shock thus secured.

3. The methods of operative procedure described cover every form of pathologic condition so far found in congenital pyloric stenosis.

4. The operations reconstruct a pathologic pylorus to a more normal pylorus, particularly as to its lumen and enormous thickness of musculature.

Finally, the normal anatomic relation of the stomach to bowel is preserved by the pylorus remaining the normal connecting tube between stomach and duodenum. The developing liver and pancreas in the infant, which we know from experiments in physiology are stimulated reflexly by food passing through the duodenum, must certainly be considered in a more normal condition here than with a closed-off pylorus, as occurs after a posterior gastro-enterostomy.

Moreover, the duration of the operation is one-third the time taken by posterior gastro-enterostomy.

The most important fact regarding this operative procedure is that these children come back from the operating room with no more shock than from the smallest minor operation. The projectile vomiting has ceased, no peristaltic waves are seen, they take their nourishment, and do not appear ill at all, as one would expect from an abdominal operation.

30 North Michigan Ave.

A Unique Work for Tuberculous Children.—The annual report of the North American Children's Sanitarium for 1914-1915 gives a history of the movement started in 1901 for the relief of poor children in Philadelphia during the hot months of summer. Since then this movement has been supported almost entirely by what has become a seasonal feature of Philadelphia life known as "porch parties." After a few years a seaside sanatorium for the treatment of tuberculous children was founded and much good has been done. The active and consulting staff of the sanatorium includes a large number of the more prominent surgeons and physicians of Philadelphia and Atlantic City, where the sanatorium is located. Prior to 1914, the sanatorium was supported wholly in the manner stated above with the assistance of the newspaper which founded it. In 1914, owing to the war, the income of the sanatorium fell off to such an extent that it was felt that it would have to be partially closed down, but an appeal made to the public by the newspaper, supplemented by the surgeons who compose the executive staff, resulted in very gratifying contributions which enabled the managers to keep the hospital open to its full capacity of thirty-six beds and even to increase it to forty-five. Substantial and commodious buildings completely equipped for treating particularly surgical tuberculous affections in children are owned by the sanatorium management. Since the sanatorium opened in 1910, 150 children suffering with tuberculosis of the bones and joints have been admitted. Of these, 114 have been discharged and thirty-six still remain.

OXYCEPHALIC EXOPHTHALMOS

WITH TRAUMATIC RUPTURE OF BOTH EYES *

RALPH A. FENTON, A.B., M.D.
PORTLAND, ORE.

Tower skull is so generally associated with mental deterioration that such patients are rarely studied by the ophthalmologist, but drag out a miserable institutional existence. The case herewith reported presents an unusual combination of unaffected mentality with the most excessive deformity, and the severest ocular complications.

A. L., white man, aged 47, parentage American for several generations, has had four brothers and four sisters; all relatives are long-lived, strong, healthy and of large frame. This man stands 6 feet 2 inches, and if his shambling, bowed posture were straightened he would be 2 or 3 inches taller. His hands are large and knotty from manual labor, his feet very large, splayed outward and flat. He has a characteristic "pituitary" slouch forward of the neck between the shoulders, and his gait and posture in walking are gorilla-like. He is unmarried, but considers his sexual powers normal; the sexual organs are of normal size and development.

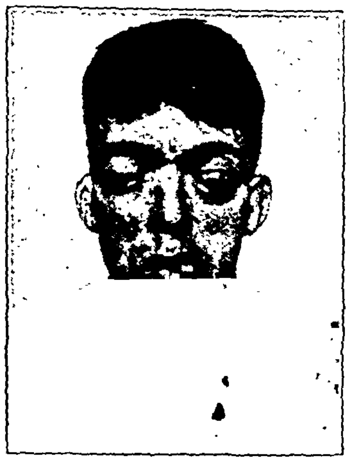

Fig. 1.—Front view, before rupture of left eye, after lid repair, December, 1914.

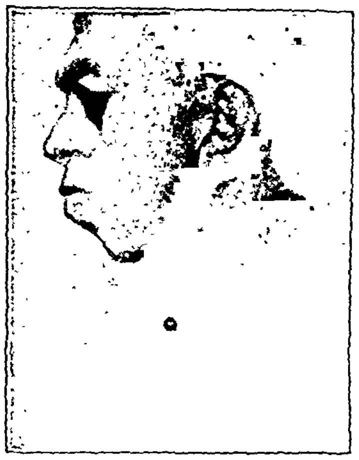

Fig. 2.—Side view, same time as in Figure 1.

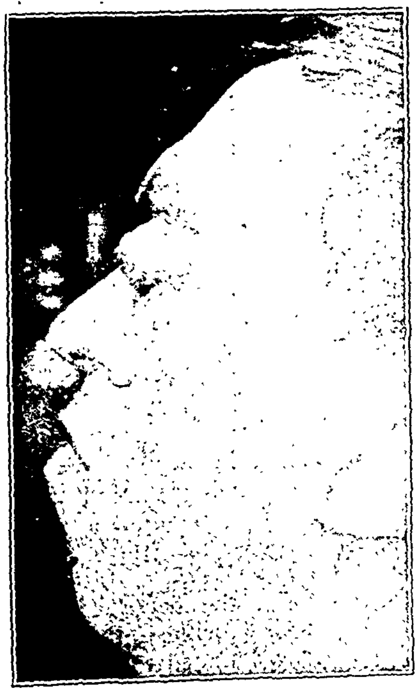

Fig. 3.—Side view, after rupture had healed, February, 1915.

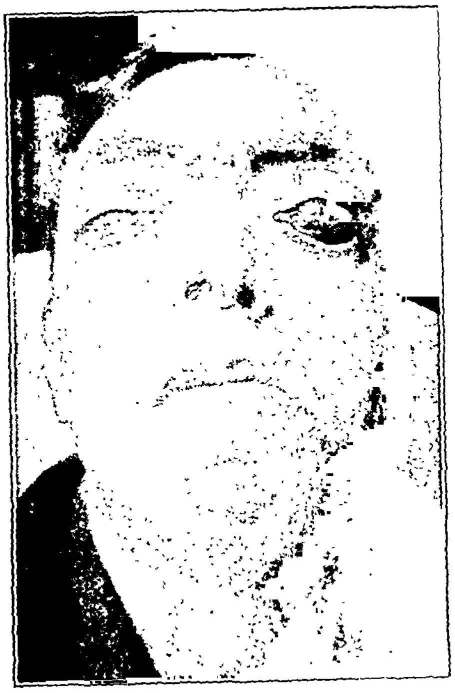

Fig. 4.—Front view, same time as in Figure 3.

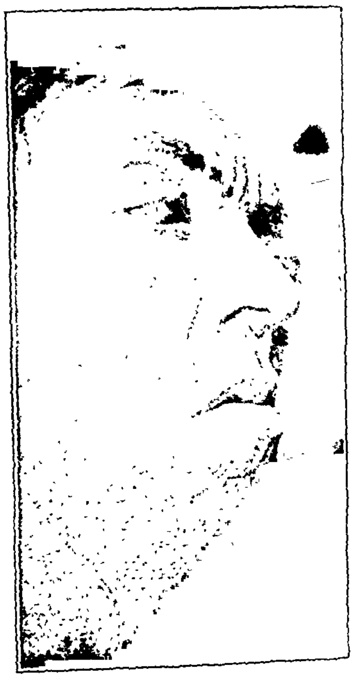

Fig. 5.—Three-quarters view, same time as in Figures 3 and 4; the left eye in this view projects as far as the nose.

His vision was somewhat defective in childhood, so that he did not go to school much; and his peculiar head and ugly face aroused cruel comment and made him rather shy and retiring. He was brought up on a farm, and since maturity has done various sorts of heavy work in lumber camps and in land clearing. When 39 his right eye was torn open and blinded by a flying fragment of a broken claw hammer. His general health has always been excellent, save for an attack of measles at 40, from which he was in bed for four days, and after which his sight failed somewhat. Previous to that time he had always been able to read newspapers in comfort, but within a few months his vision was reduced to the large headlines.

The remaining (left) eye seemed to protrude more and more after this attack of measles, and he had several severe corneal ulcers, which healed with much scarring and visual loss. The increasing exophthalmos, probably now due to the postfebrile softening of the sclerocorneal coat, and consequent lengthening of the globe, pushed the lower lid down more and more, and finally everted it altogether.

For this complete ectropion he came to us in November, 1914. The Ziegler cautery puncture was extensively made at one sitting under cocain, with rather pronounced reaction; the eye was kept open and filled with petrolatum, and after four weeks the scarring had restored the lid margin into contact with the globe. At this time refraction was attempted, and it was found that vision had improved with correction of the lagophthalmos from 2/200 to 5/200; — 7.00 sph. $\bigcirc$ — 3.00 cyl. ax. 180 degrees gave 12/200, but this was not prescribed at that time; he was cautioned to wear protecting goggles but neglected to obtain these.

January 10 he was brought in with the lids enormously swollen, conjunctiva chemotic and anterior chamber full of blood. The eye had been struck by a flying branch, rupturing the sclera subconjunctivally, just back of the limbus and in front of the internus insertion. Vision, light perception. He was put to bed, with iced compresses and atropin; a slow iritis was gradually controlled, and he went home in four weeks with about the same vision as before the accident. There is a slight increase in the photophobia which had annoyed him ever since his attack of measles.

---

* Read before the Section on Ophthalmology at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

The present condition, then, as shown in Figures 1, 2, 3, 4 and 5, is a total exophthalmos of both eyes, the globes lying outside the anterior margins of the orbit. The right eye is flattened, shrunken, small cornea, vision nil. Left eye, buphthalmos, conical cornea with transverse leukomas; conjunctiva thick and grayish, lids thickened and drooping, but not everted; pupil large, irregular, transversely oval, and disappearing behind the nasal limbus at the site of the recent scleral rupture; at this point lies an extruded patch of uveal pigment. There is divergent strabismus of about 10 degrees; all rotations are limited and difficult; he moves the head instead of the eye. The upper lid is held down voluntarily in the ptosis position to shade the pupil. Vision has come up to 10/100 and photophobia and conjunctivitis are much lessened since March, under —4.00 cyl. ax. 60 degrees, medium smoke tint, constantly worn.

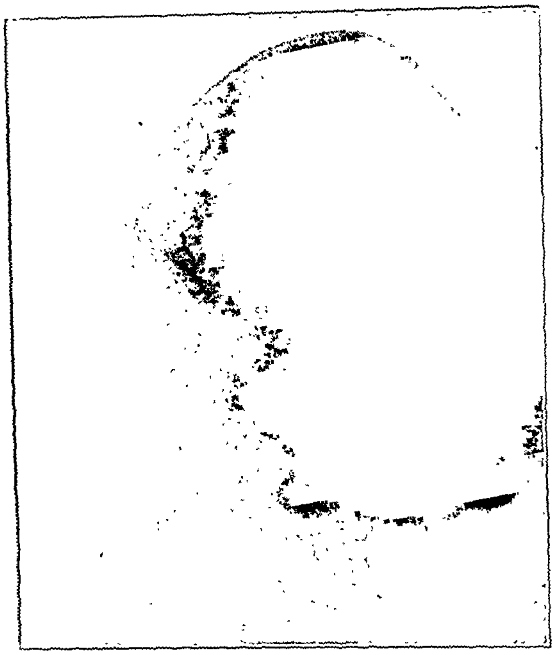

Fig. 6.—Lateral roentgenogram.

There is moderate septal deviation without obstruction, and no nasal discharge is present. The palatal arch is characteristically high, and the teeth in both jaws incline forward, occlude badly, and are much decayed.

The ears are large, but very thin, approaching the Morel type. Partial ossification of the lobular and meatal cartilages has taken place on both sides. Hearing is normal.

In Figures 6 and 7 we note especially the pointed vertex; the triangular form of the enormous skull; the grooves of the frontoparietal convolutions on the inner surfaces of those bones; the apparently normal sella impinging by a thin wall on large sphenoidal sinuses; the lowering and shoving forward of the orbital roof from a horizontal position to an angle of 45 degrees; the large open frontal sinuses, and the almost simian degree of prognathism.

With all this deformity we should expect mental deficiency, occasional motor pareses, or jacksonian attacks; but such things have never occurred. This man is heavily muscled and surefooted, a thorough and capable workingman within his visual limitations, well-informed beyond his opportunities, very fond of good music, kind and neighborly but very shrewd.

Generalization on a single case is fraught with fallacy; yet may it not justify us in revising a little the gloomy prognosis of clouded mind and useless life that attends the birth of such a child? The eye deformity suggests obvious measures of protection, and more than the usual caution should follow up the acute infectious diseases. Nor need we always assume the presence of hypophysial cysts or tumors. This man's large frame is common to all his family. Probably pressure has somewhat modified the activities of his chromaffin system, but he presents none of the dystrophy of the adiposogenital type and none of the cerebral hebetude which authorities lead us to expect.

I would ask the section's opinion whether early double subtemporal decompression might not save such cases from this gruesome catalog of complications. This would be worth the risks incurred, even if it could not, as here, save the alert mind of this unfortunate man from its lifelong incarceration behind so hideous a mask.

801 Stevens Building.

ABSTRACT OF DISCUSSION

Dr. Harold Gifford, Omaha: The photographs of this case give a fine representation of what Virchow called *Spitzkopf*. For some reason this term has been almost altogether displaced in Germany by *Thurmschädel*, our English equivalent being peaked or tower skull. A Greek term like oxycephaly is preferable to these expressions from the vernacular, which often call up an entirely erroneous picture, since it can be used entirely without prejudice as to its real meaning. The fact is there is a great deal of confusion as to the type of skull indicated by these terms. In Germany *Thurmschädel* is generally used to designate a skull which is flattened in front but which runs well out to the rear with a prominence at the site of the superior fontanel; this type being the result of the too early closing of the coronal suture. The typical *Spitzkopf*, such as is shown in the case of Dr. Fenton, is *probably* caused by the premature closure both of the coronal and the lambdoidal sutures with resultant flattening both in front and behind. Whether the [illegible] of the optic canal

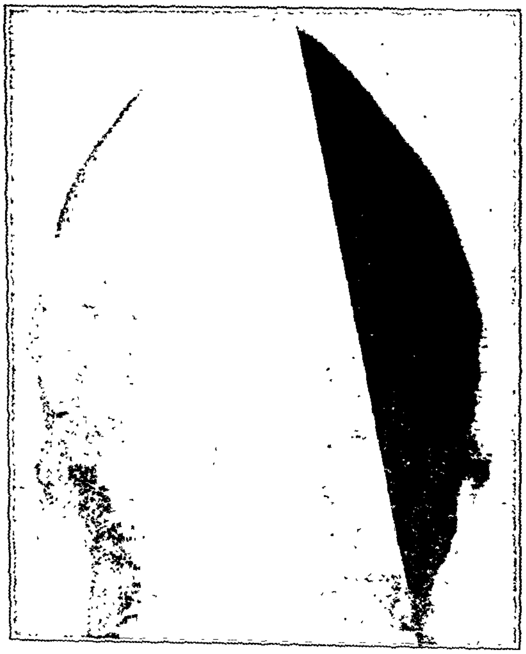

Fig. 7.—Frontal roentgenogram.

which was first observed in these cases by von Michel, is due to the pressing downward and forward of the superior orbital plate or whether the atrophy of the optic nerve is first caused by intracranial pressure, and the narrow optic canal is simply a lack of development corresponding to the small size of the nerve, is a matter of dispute. Following the idea that the displacement of the orbital plate is the main cause of the atrophy, Schloffer has opened the cranium, raised the frontal lobe and chiseled off the superior wall of the optic canal. In the two cases in which he has performed this operation, the visual results have been practically zero; and this is really what we should expect since the injury to the sight in these cases is nearly always produced in early childhood or infancy, and has generally reached the stationary point by the time that most of them are brought to the oculist for treatment. I believe that by keeping in mind the possibility of premature closure of the sutures as the cause of poor sight in infants and children, we might, by early decompression operations, do some good in many cases which hitherto have been allowed to go without treatment until it was too late. Luckily such exophthalmos with resultant corneal ulceration as is shown in Dr. Fenton's cases is very rare, as is the occurrence of ectropion; in fact the only other case of ectropion that I know from oxycephalic exophthalmos is one reported a few years ago by my colleague Dr. Patton. The excellent mental development which Dr. Fenton notes as remarkable in such an idiotic looking individual has been noted by other authors; in fact, but one in twenty of these unfortunate oxycephalics shows marked mental deficiency. This undoubtedly means, as Virchow pointed out, that peculiarities in the shape of the skull have much less influence on the development of the brain than is commonly supposed. An otherwise healthy brain adapts itself to the new conditions and finds room for its growth in other directions, while the poorly developed brain of the microcephalic idiot is the cause, not the result, of its peculiarly shaped skull.

Dr. **Edward Jackson**, Denver: Since tower skull or oxycephaly began to attract attention in connection with visual disturbance, I have looked for these cases, but I have seen no case of disturbance of vision with very marked skull deformity. I think these cases must be distinctly rare outside of some parts of Europe. Records have been based on a number of oxycephalics in a blind asylum. Dr. Gifford has brought out that the disturbance of vision comes very early in life. The stage of optic neuritis which precedes the optic atrophy is always in early childhood. There are practically no records of such cases except when children were brought into the asylum for the blind very early. As has been pointed out, many cases have shown marked narrowing of the optic foramen. It seems to me much more probable that the essential deformity, the original deformity, is rather in the bones at the base of the skull than in the union of the sutures of the vault. The thickening of the bone leads to the narrowing of the foramen. Trephining has been done too late in life to hope for any good results. We have more to hope for in these cases in the direction of internal secretions than we have from operative interference early enough to be of any benefit.

Dr. **Ralph A. Fenton**, Portland, Ore.: In regard to the protection of the eyes, this man found bandage pressure extremely painful. It was almost impossible to interfere with the upper lid of the eye in which he sees; so we have protected his eyes by keeping them filled with white vaselin. He does a good deal of work now out of doors where it is dusty. This man happens to be an exception to the general rule. His blindness is a result of ulcers instead of pressure on the optic nerves.

MALIGNANT TUMORS IN AND AROUND THE ORBIT

WITH REPORT OF STARVATION METHOD OF TREATMENT *

E. H. CARY, M.D.

Fellow of the American College of Surgeons

DALLAS, TEXAS

Since the starvation treatment of malignant growths of the upper neck and face has undoubted value, ranging from prolongation of life to a cure, depending on the nature of the case, amount of involvement, age of the patient, character of the operation, etc., I have been led to say a word on the subject and report the twenty-two cases in which operation was performed during the past nine years, two of which were nonmalignant tumors of special interest in which ligation seemed necessary. These cases follow Nos. 1 and 2, in which the patients were not operated on.

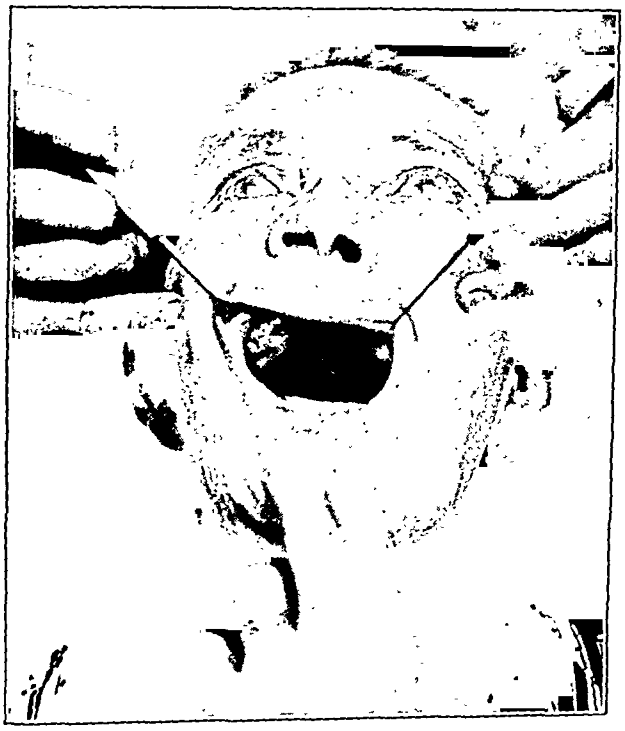

Fig. 1 (Case 3).—Sarcoma of the roof of the mouth. Picture taken May 8, 1908, operation April 20, 1907. At that time tumor was as large as an egg, the nose was closed and the cheeks swollen.

Robert H. Dawbarn of New York must be credited with the employment of the idea of starvation for malignant growths in the parts described, inasmuch as he has pointed out the numerous anastomoses of the external carotid artery, and suggested excision after tying each branch of the artery in an attempt to destroy permanently all such connections. He has further shown how futile is any attempt at starvation when the external carotid of the other side is permitted to remain.

My own experience has been so consistently in line with his that it seems worthless to report, unless it may serve to call attention to cases looked on as hopeless, yet not entirely so, and thereby enlist workers here to give that aid which can be given in many cases in which the patients are frequently encouraged to refuse any and all surgical attention.

HISTORICAL

It might be well here to go briefly into the history of ligation for malignant tumors and beg you to keep in mind the difference between ligation and excision.

In regard to the external carotid from the tables of Madelung and Lipps, it was tied for a tumor of any sort about 1830—it was not applied for outspoken malignancy until about 1854, at which period Maisonneuve endeavored to give the method a fair test. He performed unilateral and bilateral ligature collectively seven or eight times, securing no benefit from the procedure. The growths were all cancers of the buccal cavity, tongue and pharynx. Then follows a case of Lannelongue in 1873.

---

* Read before the Section on Ophthalmology at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

The next record of ligation of external carotid for starvation purposes was by Dr. Joseph D. Bryant,[1] in 1887. Tuffier, a French surgeon, in 1897 reported three cases; all of these were ligation, none attended by favorable result.

Following this came the masterly essay by Dawbarn, winning the Gross prize in 1902, reporting eighty-three operations of various surgeons on forty-eight patients, over a period of eight years, all practicing his operation of ligation on both sides of each branch of the external carotid with excision, with a tabulated list of cancer twenty-four, sarcoma twenty, no definite report, two, angioma two.

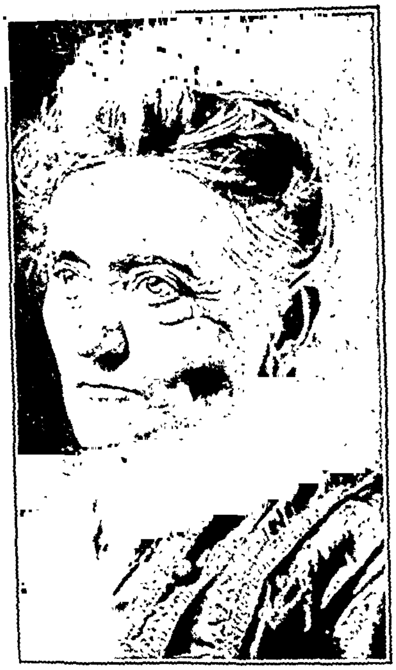

Fig. 2 (Case 5).—Sarcoma. Scar after removal of tumor, which displaced eye outward and upward.

In cases of cancer, life was prolonged for seemingly a short time; the tumors usually showing lack of activity for a few months. In the twenty sarcoma cases, the record was truly remarkable, especially when you understand that these cases were all hopelessly involved and rapidly approaching an end. Out of twenty cases—they being ward cases—only eleven could be traced; one of these was a tumor of the orbit, and the operation was supposed to be of no value, inasmuch as the blood supply is also derived from a branch of the internal carotid. Dawbarn had but two recurrences out of the remaining ten. Taking the three-year limit as a radical cure, he had four definite recoveries out of eight cases which survived the accidents of the first year, these being all far advanced and considered hopeless and ineradicable sarcomatous masses.

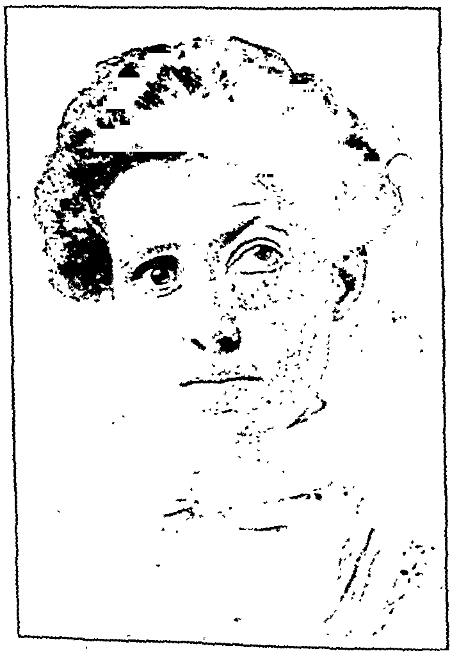

Fig. 3 (Case 7).—Melanosarcoma.

Dawbarn's cases are grouped into three classes in which the excision of the external carotid may be performed:

1. "Those where excision of both external carotid, and to avoid deformity, leave an operable tumor in place, thereafter depending on a closely and regularly maintained observation of growth for a period of years."

2. "Cases where the growth is operable and consequently excised."

3. The third class would comprise those whose cancer is already ineradicable, involving, for example, the base of the tongue, the floor of the mouth, and pharyngeal wall; here nothing is done to the growth, but all lymph nodes are removed in the path of the operation for excision.

First, I shall report two cases typical of others, occurring when the starvation treatment of excision was not practiced.

Case 1.—A sarcoma, involving the antrum on the left side, occurred eleven years ago in my practice. I have never forgotten this big, strong Norwegian, whose life was rapidly destroyed in spite of all that we did. The left side of his face became a tumor mass, sapping his life. The man died after an illness of only three months. The laboratory report showed small round-cell sarcoma. In this case ligation and excision were not practiced.

Case 2.—Another patient was sent to me from Mangum, Okla., ten years ago, with a history of eight years before having sustained a kick from a horse, which broke the nose, changing its relative position, markedly deviating the septum, and blocking the fossa of the right side so that it was impossible for the patient to breathe through the passage when suffering with the slightest cold. Two weeks before coming to me he had developed what seemed to be a maxillary sinusitis with swelling of the right side of the face with more or less discharge from the right nostril. The pain had been so acute that a dentist had extracted all of his teeth, thinking that this would relieve him. His physician was called in and recognized what appeared to be a polypus in his nose and advised him to come to me. I found an immense polypus growing from the ethmoidal membrane, filling the cavity of the nose and extending into and filling the postnasal space. It appeared benign and was promptly removed.

A day or two later an Ash operation, as practiced at that time, was done on the septum. It was straightened, complete drainage established and a favorable prognosis given. It was not long before I found my mistake, for from all surfaces there rapidly appeared new growths; even in the vault of the pharynx nodular masses appeared. A section of tissue was sent to a pathologist for examination, and the whole mass thoroughly removed. Microscopic examination confirmed the belief that it was sarcoma, and was of the round-cell variety. The ethmoid cells commenced to break down, and the right eye protruded and was pushed to the right side. Pain became intense and it was necessary to establish drainage through the inner canthus to the ethmoidal cavity.

Believing the most radical operation of no service, I advised the patient to return home. He went home and the next day, to St. Louis, where he was operated on, dying in two or three days. Ligation and excision were not performed.

These two cases are typical of others in and around the orbit observed by me, in which the disease invariably made rapid progress and the patients died early, regardless of the most complete removal of the tumor, wherever located.

---

[1] Bryant, J. D.: Med. News, 1887.

I shall now briefly discuss eleven cases of sarcoma occurring in various parts of the face and neck, with nine cases of carcinoma, along with two other cases, one being adenoma of the tongue and submaxillary space, and the other, a teratoma of the soft palate. I shall not go into details, for much of the history would be tedious and necessarily of little scientific value. In all of these twenty-two cases, ligation and excision were practiced.

SARCOMA CASES

Case 3.—Mrs. D., aged 62, had a sarcoma of three years' growth, involving both antrums. When I first saw her, both of her cheeks were markedly swollen, and she was unable to breathe through her nose. Her mouth being open, a tumor about the size of an egg could plainly be seen, involving the roof of the mouth. The patient had lost in flesh and strength, and it seemed that she could not survive a week. April 20, 1907, the external carotid and branches were ligated and excised on the right side, and two weeks later on the left side. The patient rapidly improved and the tumor diminished sufficiently for her to breathe through the nose. The hemorrhages ceased. The gums receded. The egg-shaped tumor in the roof of the mouth subsided, and the pain, which had been excruciating, disappeared. May 8, 1908, she was seen and we were unable to find pulsation in any of the arteries which had been excised. Figure 1 was taken on that date. The patient went to the county poor farm, and we have a record of her death, three years after the operation, from pneumonia, having lived with her tumors in a fairly comfortable manner, being given opiates for whatever pain she had. There was a pathologic report of the section, but the sarcomas were not disturbed.

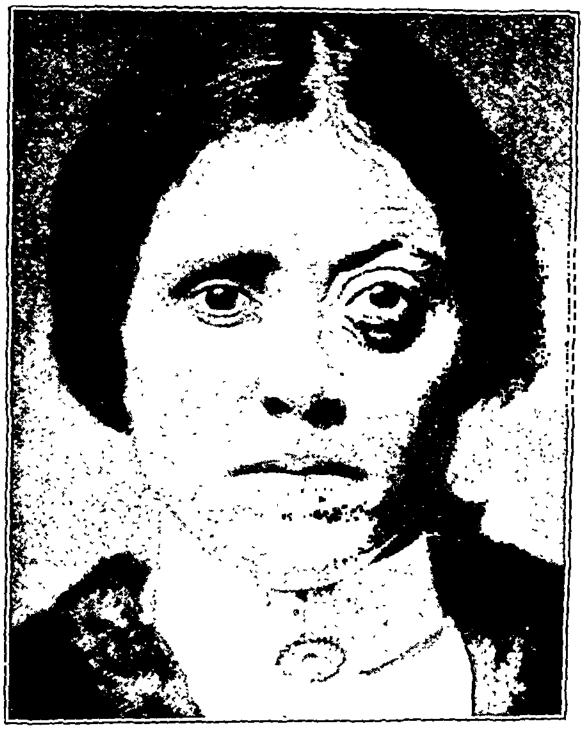

Fig. 4 (Case 7).—Later picture showing return of growth.

Case 4.—Mrs. D., aged 57, had a well-formed subperiosteal tumor lying over the superior maxillary and malar process near the antrum on the left side. There was history of a six months' growth, extremely painful on pressure; the patient said that there was constant pain, evidently due to pressure on the infra-orbital nerve. Oct. 18, 1907, ligation and excision of the carotid on the left side was done, with complete removal of the tumor, which was a large, spindle-cell fibrosarcoma. Two weeks later the opposite side was ligated and excised. After leaving for home the patient did not return for observation. She died eighteen months later, presumably from metastasis.

Case 5.—Mrs. M., aged 58, had a sarcoma involving the left antrum, extending into the orbit, and pressing the left eye far to the left. In December, 1907, ligation and excision were done on both sides, after which the tumor was removed and the eye replaced (Fig. 2). The patient regained strength, and the tumor area remained quiescent for about a year. This was followed by a slow ulcerating process involving the antrum and the orbital plate, causing the eye gradually to slough with some pain and no bleeding. The patient became addicted to morphin, which her family freely administered, and she died two years after the operation. There were no granulations. It looked as if lowered vitality due to morphinism intensified lack of vascularity to the parts, which slowly sloughed, and the patient died of the complications.

Case 6.—Mrs. C., aged 28, had a sarcoma growing from a perforated septum, closing both nares. It was further complicated by a seven months' pregnancy. One side was ligated and excised, Oct. 15, 1909. Two weeks later the opposite side was, and the tumor removed, the patient making an uneventful recovery. Five and one-half years later she was still living, having given birth to two children since the operation, and is now well.

Case 7.—Miss M., aged 20, had melanosarcoma of the orbit, complicated with hematoma, causing absorption of orbital fat and pushing the eyeball far out to the left. At this time, as the patient refused operation on the external carotids, the internal rectus muscle was divided and the eye was pulled further forward. A small tumor mass extending toward the optic foramen was removed without stretching the optic nerve unnecessarily. The orbital operation was facilitated by the absence of orbital fat, and the eye being pressed back into position, the muscle was stitched; drainage was then left for four days. The patient recovered binocular vision and seemed none the worse for her operation. This patient was operated on, Aug. 1, 1910 (Fig. 3). The pathologic report was a melanosarcoma.

Dec. 28, 1911, the patient returned (Fig. 4), accepting the ligation and excision operation, which was performed. The eye was pushed far out to the left with a tumor mass growing in the orbit. This tumor mass was all removed along with the eye; a circular incision was made near the margin of the palpebral fissure, and after the removal of contents of the orbit, the skin was pressed down into the orbit, covering most of it, allowing a small area of granulation to take place. The same method I have employed with excellent results, when one could leave the orbital fat, giving a smooth surface, as in Case 16, in which it had been removed on account of carcinoma of the conjunctiva. March 10, 1915, the physician reported Patient 7 well with a 22-months-old baby.

Case 8.—S., boy, aged 9, March 10, 1911, gave a history of having had a blow three years before over the inner canthus followed by swelling which lasted for days. In August, 1910, the swelling returned. A tumor involving the orbit, apparently originating in the ethmoidal cells, pressed the left eye outward. The tumor was fairly prominent and had been incised by an investigator for pus. I removed this tumor and cauterized the surface following the carotid operations on both sides. A year later there was a tendency to growth, but the eye was in good position and diplopia had not returned. The patient came to me, Jan. 1, 1914, nearly three years later, with a history of bleeding from the postnasal spaces, severe vomiting and headache. He was blind in the left eye, which protruded to the left side. He had lost his temporal field in the right eye, but retained his nasal field of vision.

Opthalmoscopically the left nerve was greatly inflamed, the eye being pushed well outward, with slight ability to rotate the ball. The right nerve showed the nasal side involved and apparently choked for 6 diopters with the temporal half of the nerve congested, but otherwise distinctly not involved, suggesting that the temporal half was sheathed, while the nasal half was bearing all the brunt of the tumor now involving the chiasm. The tumor had traveled back slowly through the orbital fossa following the nerve to the chiasm, and then the surrounding tissue of the brain. The boy died within the month (Fig. 5).

Case 9.—Boy, aged 2, had a sarcoma involving the left antrum and extending into the orbit. The eye was very prominent. Operation was performed on both sides, followed by removal of the tumor and with thorough cauterization of all the affected area. This was a desperate case. The child died four months later. The tumor mass had been growing perceptibly for six months.

Case 10.—G. G., boy, aged 19 years, had an exophthalmic and blind right eye. Vision in the left eye was 20/70. The papillomacular bundle of fibers was intact. An orbital sarcoma involved the optic nerve of the right side. The patient was operated on, May 16, 1912, following ligation and excision of the external carotids and branches of both sides. The orbital cavity was completely exenterated, following a circular skin incision near the margin of the lids, leaving the skin to be transplanted into the bony cavity. The patient made an excellent recovery from immediate operation. The tumor in this case had extended back to the chiasm, leaving only the nasal field of the left eye intact, showing how the function of the optic nerve to the right side and fibers going to the nasal side of the left eye had been destroyed, with their respective fields. Opthalmoscopically the right optic nerve was greatly inflamed from the growth. The left optic nerve on the nasal side was swollen and apparently choked. On the temporal side it was congested, but not swollen or choked, suggesting a separate sheath for each side. Report March 23, 1915; patient living, tumor has not returned, now blind in left eye, married in August, 1913, total loss of vision January, 1914. Is now strong but cannot see and is mentally confused under certain circumstances. I was surprised to learn that he is still living (Figs. 6 and 7).

Case 11. — Boy, aged 11, had an angioma of the cheek as well as a fibrosarcoma which extended down toward the supra-orbital notch and through disturbance of circulation had caused a subconjunctival hemorrhage into the conjunctival sac. March 2, 1912, both externals were ligated. The angioma was removed from the cheek. The tumor was removed from the brow. A letter March 7, 1915, stated that the patient was well and that there was no sign of return.

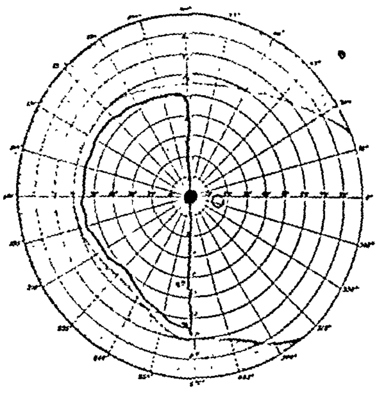

Fig. 5.—Field of right eye in Case 8.

Case 12.—S., a young woman, schoolteacher, with osteosarcoma, involving subperiosteally the alveolar process of the inferior maxilla, increasing the size of her chin to a marked deformity, complained, March 11, 1912, of pain radiating through her face and head. The growth involved both sides of the inferior maxillary bone to a point one-half inch back of the mental foramen. At the time of ligation and excision of external carotids, I made an incision, thinking I might remove some of the deformity, but decided on investigation to leave it with the hope of shrinkage. This has taken place perceptibly. Three years have passed. She is now living and states that though she has a prominent chin, she is without pain and feels well—better than one year before the operation.

Case 13.—Mrs. W. H. M. had sarcoma involving the left side of the orbit, beneath the frontal bone, with swelling due to edema extending over her left temple. Sept. 14, 1910, the orbital tumor was removed and examined, and found to be a sarcoma. The patient refused operation on the external carotids at this time, but on Aug. 18, 1911, she returned with edema over the temple from another mass in the orbit. She was now persuaded to have the external carotids and branches on both sides ligated and excised. The mass was not removed. She is at present living at Athens, Texas, and a recent letter states that she is now blind in that eye. Her vision was good when the carotid operation was performed (Fig. 8).

Case 14.—A boy, aged 12, November, 1910, had a large mass of adenomatous tissue growing on the surface of the tongue, principally the right side, about midway its length. In addition to this, he had a tumor the size of a pullet's egg growing in the submaxillary space of the same side. After ligation and excision of both sides the adenomatous tissue was removed and the base cauterized on the tongue. The tumor, which proved to be adenoma, was also removed and the wound closed. Healing was tardy and interrupted through infection, which yielded to antistreptococcic serum. The patient has been entirely well since.

Case 15.—Mrs. B., May, 1914, had a teratoma of the right side of the palate. She had had a fibroma removed from the uterus two years before. She had not noticed the least inconvenience from the mass growing between the muscles of the palate until a tonsillar infection was superimposed, when she had difficulty in swallowing and in breathing. Her physician, on inspection, discovered that the oropharynx was almost closed. When tonsillitis had subsided, she was sent to see me. On examination I found half of the oropharynx closed with a mass which pushed her tonsil down. It was smooth and gave no evidence, from appearance either anteriorly or posteriorly, that it was so large. To avoid hemorrhage and to enucleate the tumor, ligation and excision was done on both sides. A teratoma, 2 by 3 inches, kidney shaped, was removed through the separated muscular fibers, following an incision through the mucous membrane in the axis of the fibers. There was no bleeding, and dissection of the tumor was accomplished with the finger and blunt tonsillar dissector. The patient is living and well. The pathologist found connective tissue, cartilage, myxomatous tissue, some epithelial cells and some adenomatous tissue and classified it as a teratoma, not a dermoid.

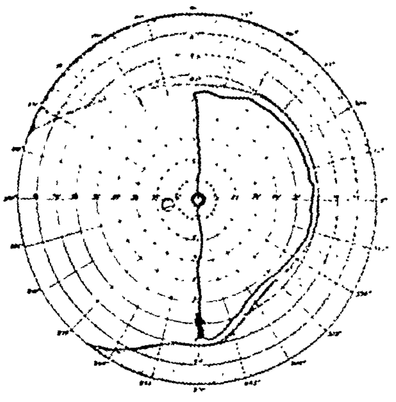

Fig. 6.—Field of left eye in Case 10.

CARCINOMA CASES

Case 16.—H., man, aged 60, underwent a double excision and ligation, in which a cancerous mass, far advanced, was removed, July 3, 1908, in the region of the superior carotid triangle, it being a metastastic tumor from an old carcinoma of the eye. A complete exenteration had been done fifteen months before. The patient improved for the first two months, holding his own for two months following, and then declined in strength and was advised to go home and was also told that he might expect the worst. Although his life was lengthened, he died some months after the operation.

Case 17.—T., man aged 61, had a carcinoma of the right side of the tongue which had increased in size and had been recognized for six months. May 15, 1908, the external carotid and branches on one side were ligated and excised, half of the tongue removed and all glands carefully dissected. The right hypoglossal nerve was sewed to the base of the tongue. The patient lost but little blood and slowly recovered from the effects of the operation. Two weeks later the external carotids in the left side with all glands were similarly treated. One year after the operation the patient was alive. Since that time, I have been unable to gain any information as to whether he is living or dead, but concede his death.

Case 18.—J. T. G., man, aged 35, Dec. 1, 1911, had a carcinoma involving the ethmoidal cells. I operated on both external carotids the same day. Some days later all of the ethmoidal cells were removed. The paient died in October, 1912.

Case 19.—B. T. C., aged 48, June 5, 1911, had carcinoma of the ear. The carotids of both sides were operated on, all glandular involvement and a hard carcinoma mass removed from back of the cartilage of the left ear. The ear was replaced and the patient slowly made a good recovery and was living when last heard from.

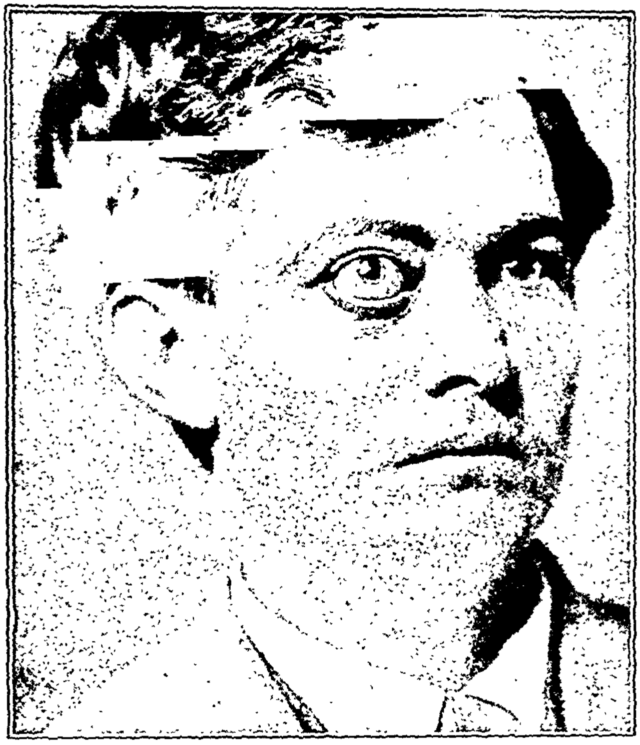

Fig. 7 (Case 10).—Orbital sarcoma.

Case 20.—J. S. G., man, aged 46, Dec. 16, 1911, was operated on for metastatic carcinoma of the lip involving the parotid gland of the right side. From pressure of this gland the patient had suffered excruciating pain throughout many branches of the trifacial nerve. The excision and ligation operation of both sides was followed by dissection of the involved parotid which had locked the jaws; the tumor extended well up beneath the lobe of the ear, and was dissected away from the internal carotid artery and jugular vein. This patient was made more comfortable, and died Oct. 1, 1912.

Case 21.—J. C. A., aged 52, June 22, 1912, had carcinoma of the lip. All branches of both carotids were excised, the cancer of the lip removed and all glands dissected. The patient was seen several months afterward and showed no evidence of return. I presume that the patient is now dead.

Case 22.—Mrs. S. A. G., aged 76, July 6, 1912, had epithelioma of the ear, left side, and epithelioma of the skin near the right inner canthus. Following carotid operation, the ear was removed and the cancer of the inner canthus dissected. The parts have healed and there is no evidence of return. She had double cataract as well. These were removed, and normal vision obtained. Recent report states that the patient is living.

Case 23.—Mrs. H., of Gilmer, Texas, was operated on, June, 1911, for carcinoma of the orbit, involving the eye and surrounding tissues. Ligation and excision of all branches was done, on both sides, and the tumor mass with the ulcerating eye removed. Several days later erysipelas developed and there was a serious infection which gradually subsided, the patient making apparently a good recovery. She was living at Gilmer in December, 1912. I have not been able to hear of her since.

Case 24.—C., man, aged 58, of Grand Saline, Texas, July, 1914, had a carcinoma involving the tongue wall on the left side, of six months' duration. Ligation and excision was done on both sides, all branches, and the glands dissected. One half of the tongue was removed to the base and the whole area closed with uninterrupted sutures without raw surface being left. The patient is now living but probably has metastasis in the neck. A letter states that there is swelling on that side.

CONCLUSIONS

1. (*a*) All branches of each external carotid must be tied.

(*b*) In the majority of cases both sides can be operated on without an interval of two weeks, and this without shock.

(*c*) Sarcoma offers the best results.

2. It may be noted that all the sarcomas occurred on the left side, except two. As the common carotid arises from the transverse portion of the aorta, a morbific tendency might find nourishment in excess from this circumstance.

3. Circulation from the ophthalmic branch of the internal carotid does not prevent the value of the operation in the orbit, as Dawbarn concluded.

4. In this group of cases, sarcoma occurs in all ages. In females it occurs most often beyond the age of 19, and in males, under this age.

5. Cancer occurs in this group oftener in males and only in one case under 46 years of age, which was the ethmoidal case of 28, coming under Case 6 (sarcoma).

6. I have not found in any of my cases an anomaly in the carotid distribution.

7. The results seem best when the tumor is not disturbed, suggesting traumatism at the sight, always an exciting factor.

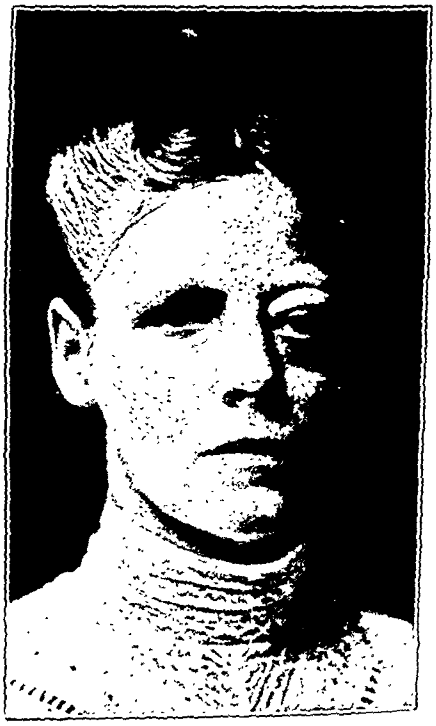

Fig. 8 (Case 13).—Sarcoma of orbit.

8. Though I have not practiced ligating uniformly the accompanying veins, it may be better to do so.

9. Although certain carcinoma cases were treated with the Roentgen ray, no good results were observed.

10. In two cases in which tumors involved the optic nerves — Case 9 secondarily and Case 10 primarily —both demonstrate that the optic tracts reach the chiasm and there decussate; when a nerve proceeds to its destination, the respective nasal half possibly, and the temporal half probably are separately sheathed, as is also the papillomacular bundle of fibers, which are intact and which may be disturbed but not destroyed.

These two cases suggest that, when the temporal sides leave the chiasm, these bundles become invested in a manner to permit an uninterrupted spread of an inflammatory process of either nerve to the nasal half of the other—this being limited as described in Cases 8 and 10.

I have known of the pia sending out trabeculae between fibers, splitting them up into bundles, each fiber having its own myelin sheath, but not a neurolemma as other nerves. A later report might demonstrate a distinct investment of the respective halves, but more likely the temporal side and not the nasal on account of anatomic developments.

One other explanation might account for the foregoing observation: the extension of the inflammatory process of the optic nerve might follow the nerve around on the side involved back of the chiasm, and in this manner cause complete destruction of the nasal half before they decussate, the choking of this part of the disk in the opposite eye taking place from that fact.

There of course is an excellent reason why the operation is of value in sarcoma and to a more limited extent in carcinoma. Our knowledge of metastasis is based on the morphology of these tumor masses, and we all know that the cells of the sarcoma variety make up the walls of the blood vessels, the cells themselves depending on this rich blood supply for their growth. When this is cut off, they necessarily shrink and cease to grow; whereas, in carcinoma, the blood vessels are not involved. The lymph channels remain and can easily carry off some of the infection to lymph nodes elsewhere, extending the progress regardless of the blood supply.

My observation has been that a distinct deterring influence is exerted in the carcinomatous growth, but that is the best that can be said. On the other hand, in sarcoma, your result can in a way be measured by the completeness of your operation in tying off and destroying all of the branches so that anastomoses will be controlled, whatver the cause of malignancy; the lack of nourishment influences the growth.

The technic of the operation as well as the things to avoid while operating will interest you only when a case presents itself. This information you can find without difficulty.

ABSTRACT OF DISCUSSION

Dr. C. G. Savage, Nashville: The subject presented by Dr. Cary is worthy of our deepest consideration. I have never had any ligations done.

One case I recall especially because of a second recurrence in a strange location. The cancer involved primarily the lower right lid, but later involved the right eye also. My first operation removed the entire lid and the globe. There was a recurrence in the orbit a few months later. In the second operation I removed the entire orbital contents. Without further manifestations in the orbit, a tumor formed on the corresponding side of the neck just below the ear, which was evidently malignant. It seemed to me that the man was doomed. I do not like to operate below the chin line, so I had one of our surgeons operate for the last malignant growth. The operation was done very thoroughly, the wound was left open and Roentgen-ray treatment instituted. Afterward I saw the patient frequently and I think I can safely say that at least a year after the operation there had been no recurrence. At that time the man was rejoicing because we had told him we could give him only temporary relief. The presentation of this subject ought to have a tendency to further nullify the recurrence of such tumors.

Dr. E. H. Cary, Dallas, Tex.: A question has been asked concerning a point which I did not bring out in the paper for the sake of brevity. In carcinomatous growths ligation could only effect a retardation of the growth. You really do not check it as much as you want to check it and the operation is not a success in carcinomatous growth. If there was some plan by which the lymphatic channels could be found and cut off, I think you could find a method of cutting off the spread of carcinomatous growth. In carcinomatous growth it is true that best results can be obtained if you can tie and cut off all the branches on each side and not disturb the main growth at all. One case of sarcoma involving the inferior maxillae, without much traumatism, I recall. This sarcoma receded and the woman has been teaching school for three years. I began operating with the idea of removing the growth, but when I saw it I knew it would remove almost the entire chin, so I proceeded as mentioned.

INTRATHECAL INTRACRANIAL INJECTION OF AUTONEOSALVARSANIZED SERUM FOR SYPHILITIC HEADACHE *

ALFRED GORDON, M.D.
PHILADELPHIA

Among the various methods devised for the use of salvarsan or neosalvarsan in the management of cases with involvement of the nervous system caused by recent or old syphilitic infection, the autosalvarsanized serum method appears to be the most successful. Such seems to be the view held by the majority of observers who are familiar with the subject. My experience in almost a hundred cases of syphilitic and parasyphilitic affections of the cerebrospinal axis is entirely in accord with that of others. Comparing this method with the intramuscular and intravenous, the results obtained are by far superior to those in the two latter procedures. The reason of it has been emphasized by Swift and Ellis, the originators of the method, and has been sustained by subsequent observers. Indeed the statement is a logical one that by subarachnoid injections a spirocheticidal substance is brought into direct contact and immediate relation with the nervous tissue and the spinal fluid, and consequently with the etiologic agent disseminated in both.

The introduction of salvarsanized serum may be accomplished in two ways: either intraspinal or intracranial. The intracranial method has been applied chiefly in cases of paresis, as it has been shown by a number of writers that only slight beneficial effect, or no effect at all, resulted from the intraspinal injections in this particular affection so far as mental symptoms are concerned, although some improvement has been obtained in the condition of the cerebrospinal fluid, particularly with reference to the cell count. In my experience with twenty-seven paretics, amelioration in the mental manifestations was observed in ten patients. Nevertheless, if a comparison is drawn between the syphilitic affections in which the brain symptoms predominate and those in which the cord symptoms are the most conspicuous, I may say that the autosalvarsanized serum, introduced through lumbar puncture, has given me, speaking generally, more favorable results in the latter than in the former cases.

It is therefore logical to presume, at least, that the circulation of the cerebrospinal fluid is such that it is not capable of transmitting the intraspinal injected specific remedy in an upward direction toward the upper portion of the cerebrospinal axis. At this juncture it is interesting to take notice of the important experimental work done with the object of verifying the above clinical observation.

---

* From the Neurological Department of Mount Sinai Hospital.

Harry Campbell[1] gives the following account of experimental work in the *British Medical Journal:*

> If trypan blue be injected through a trephine hole into the cranial subarachnoid space above the tentorium cerebelli, not only the cortex cerebri, but the entire cerebrospinal axis is found, postmortem, to be stained. If, on the other hand, the pigment be injected into the spinal subarachnoid space by means of a lumbar puncture, the cortex cerebri remains unstained, the staining in these cases being confined to the spinal cord and brain stem. It would appear that the cerebrospinal fluid flows from the cranium spinalward—probably a meager current—and also that some slight ebb and flow takes place between the fluid in the subarachnoid space at the base of the cranium and the spinal subarachnoid space, in accordance with variations in the quantity of intracranial blood.

More recently, William C. Woolsey[2] repeated Campbell's experiments with trypan blue and arrived at the same conclusion, namely, that when administered intraspinally its diffusion to the cranial cavity is less intense than in the cord. He could see that the meninges of the cord were stained a deep blue up to the level of the cervical enlargement from which point, by gradual gradations, the intensity of the color diminished to the foramen magnum. The periphery of the cord itself just under the pia was stained a distinct blue for a distance of from 0.5 to 1 mm. below the surface. No such invasion of the brain above the medulla could be distinguished.

Wardner[3] and Martland have made postmortem injections of carbolfuchsin into the spinal subarachnoid space on several cadavers. In no case, they say, even with the bodies placed head down and in almost erect position, has any staining of the structures beyond the posterior fossa been observed.

All these facts throw considerable light on the subject and explain fully the comparative failure in treatment of paresis or other syphilitic affections of the brain by the exclusive intraspinal introduction of salvarsanized serum.

The direct intracranial method has at this time quite a number of advocates. Levaditi, Marie and Martel, Neisser and Pollac, Marinesco and Minea, Berriel, Balance and Campbell are the earlier writers who almost simultaneously utilized salvarsanized serum for intracranial injections. All of them observed favorable results. Wardner, in a recent contribution,[3] reports six cases which he treated in collaboration with Martland, Eagleton and Beling by the intracranial method, from which he obtained some encouraging effect.

That the introduction of autosalvarsanized serum into the subdural space of the cranium may be a method *par excellence* in some select cases in which cerebral symptoms predominate; that the previously mentioned experimental work with regard to the current of the cerebrospinal fluid which is directed from the cranium spinalward, but not vice versa—both facts find their striking corroboration in the events of the following case, which seems to possess all the characteristics of a carefully carried out laboratory experiment.

J. K., tailor, aged 40, contracted syphilis at the age of 25. About two years ago he commenced to have pain in the upper cervical region. At first nocturnal, the pain gradually became continuous. The patient relates that the several physicians whom he consulted at first all agreed that in view of the history of syphilitic infection it was advisable to administer salvarsan, to which the patient consented.

The slight effect produced by the first injection necessitated repetition of the treatment and he received five injections, all intravenously. As the headache continued with greater severity, his last physician, Dr. Bellak, referred him to my service in the Mount Sinai Hospital. On examination the following condition was found. He suffered intense pain in the entire cervical and upper dorsal regions but especially in the occipital region and over the vertex on the left side. The pain was so severe that for nights he could not sleep. He was unable to eat, lost his appetite and began to lose in weight.

Physical examination showed: slight Romberg sign, markedly increased patellar tendon reflexes, but no other abnormal reflexes. He had frequent and sometimes imperative micturition and defecation. There was complete loss of sexual power. There were no changes in the objective sensibility. The mentality was fairly good.

The eye examination by Dr. LeFever showed a double primary optic atrophy well advanced; no response to light in either eye; accommodation and convergence were diminished; the visual fields symmetrically contracted; pupils unequal: right, 2.5 mm.; left, 3 mm.

A Wassermann test made on admission to the hospital by the pathologist, Dr. Rubenstone, proved to be strongly positive in the serum and spinal fluid.

Urinalysis showed traces of albumin. The thoracic and abdominal viscera were normal. The diagnosis was made of cerebrospinal syphilis.

In view of the previous intravenous injections of salvarsan which, according to his physician, gave no results, the intraspinal injections of autoneosalvarsanized serum were undertaken. The patient was given, intravenously, 0.9 gm. of neosalvarsan. About thirty minutes later 50 c.c. of blood were drawn from the median basilic vein. The blood was set aside for clotting and then centrifuged. It was then heated to 56 C. (132.8 F.) for half an hour and placed in the ice box over night. The next day the serum was diluted with a normal solution in freshly distilled water to make in all 30 c.c. A lumbar puncture was immediately made, 30 c.c. of spinal fluid were withdrawn and replaced by the 30 c.c. of the neosalvarsanized serum.

On the day following the treatment the pain in the head and in the neck was slightly improved, but very soon the same suffering returned. The condition of the sphincters began to improve rapidly; the tendon reflexes became less prompt. As the patient's suffering was unusually severe and he could not sleep, two weeks later another identical treatment was given and again without any effect on the headache. The withdrawn spinal fluid showed still a strongly positive Wassermann reaction and increased albumin content.

During a period of twenty-one weeks the patient received seven intraspinal injections of autoneosalvarsanized serum at two and three weeks' intervals. With the exception of the first, for each of the six other injections, 0.6 gm. of neosalvarsan was used. The Wassermann reaction remained positive. While the symptoms referable to the spinal cord have all disappeared, and the pain in the neck, probably due to a syphilitic cervical pachymeningitis, has greatly improved, nevertheless the headache remained unaltered in severity. It was particularly intense in the left parietal area. The insomnia was exhausting to the patient. The eyes were repeatedly examined and found in the same condition.

As the patient persistently pointed to the left parietal region as the seat of the intense pain, the thought occurred to me that we may deal here with a localized syphilitic thickening of the skull. He had been given, symptomatically, all coal-tar preparations, sedatives, mercurials and iodids, and there was no relief from the excruciating headache.

A decompressive operation was proposed to the patient and he promptly accepted it. Dr. N. Ginzburg removed a large flap of bone over the left parietal region. The skull was found decidedly thick. The membranes were seen covered with light gray patches of the size of a ten-cent piece, four in number, and quite a large number of very small patches irregularly distributed. The dura was not opened.

[3] Wardner, Drew M.: A Report of Five Cases of the Intracranial Injection of Auto-Sero-Salvarsan, Am. Jour. Insan., 1915, lxxi, 459.

On the day following the operation the patient felt some relief from the headache, but twenty-four hours later the pain returned with the usual severity. The wound healed up very promptly. The patient kept on suffering for the following two weeks. Insomnia, and anorexia were pronounced.

It was evident to me, in view of the fact that the cord symptoms were controlled by the intrathecal spinal injections of autoneosalvarsanized serum, that the latter did not reach the subarachnoid space of the cerebrum. Campbell's remarks[1] regarding the experimental work on the spinalward current of the cerebrospinal fluid appeared to me strongly applicable to the present case. An excellent opportunity presented itself here for injecting the cranial subarachnoid space. Accordingly the patient was given an intravenous injection of 0.6 gm. of neosalvarsan and serum was prepared by the pathologist in the adopted manner for the following day.

The patient was etherized; a lumbar puncture made, 30 c.c. of spinal fluid were withdrawn. The wound of the skull was reopened and 30 c.c. of the neosalvarsanized serum were injected carefully under the dura in close proximity to the large gray patches. On the day following the operation the patient began to feel better. The headache gradually subsided. He commenced to sleep at night, the appetite improved rapidly. The scalp wound healed up in ten days. The patient left the hospital two weeks later totally free from pain. He began to gain in weight and felt happy. Since then he has reported to the out-patient department regularly every week for a period of four months. No recurrence of pain has been observed. While the patient's general condition is, at present, normal, the condition of the eyes remains unaltered.

The present case appears to be of great importance from a therapeutic standpoint, also because of a clinical corroboration of the physiology of the movement of the cerebrospinal fluid.

The fact that seven injections of neosalvarsanized serum into the spinal subarachnoid space relieved and finally removed the cord symptoms alone and brought no relief whatever to the intracranial manifestations, points logically to a strict parallelism between this clinical observation and the experimental observation with trypan blue previously mentioned.

It is evident that had a good upward flow existed in the cerebrospinal fluid, the large amount of neosalvarsan injected in the spinal intrathecal space would have carried its spirillicidal effect to the neurons of the cortex cerebri. The rapid and remarkable effect produced on the brain tissue by direct contact with neosalvarsanized serum is undoubtedly equal if not superior to a direct laboratory experiment carried out with mathematical precision. My patient will perhaps require repeated intracranial injections, but the result obtained so far points strongly to the intracranial route as being the only one to be adopted in cases with conspicuous and persistent cerebral manifestations.

Paranoids and Brilliancy.—The paranoids are often supposed by an innocent public to be brilliant because they are frequently fluent talkers, plausible, and full of pseudologic, and the world, especially today, is prone to worship the god of verbosity. If I were breeding people as we breed horses, no man with a gift of gab, a different quality than gift of speech, would be permitted to come into my experiment station.—Charles W. Burr, M.D.

SPONTANEOUS EVOLUTION OF A TRANSVERSE PRESENTATION

WITH REPORT OF A CASE *

NATHANIEL G. PRICE, M.D.
Visiting Obstetrician, Newark Beth Israel Hospital
NEWARK, N. J.

A transverse presentation, if unaided by art, may have five possible terminations: 1. Impaction, with excessive retraction of the upper uterine fibers, rupture and death of mother and fetus from hemorrhage or exhaustion. This is by far the most common outcome of neglected shoulder presentations. 2. Spontaneous birth by a doubled body, the condition termed "evolutio conduplicato corporis" by Roderer, in which the head and thorax are jammed tightly into each other and are born together. 3. Spontaneous rectification, that is, under exceptional conditions the lower fetal pole may be pushed downward and finally become the presenting part. 4. Spontaneous version, in which, as the result of excessive unilateral contractions of the uterus, the upper fetal pole is pushed downward and actually presents at the vulva. 5. Spontaneous evolution, as described by Douglas of Dublin. In this favorable termination, the presentation remains unchanged, but the trunk and buttocks, impelled by powerful contractions, roll past the shoulder and extrude from the vulva before the presenting shoulder.

It was my good fortune to attend a case of labor with transverse presentation, which terminated with the interesting phenomena of this last form of natural delivery. Inasmuch as Prof. J. W. Williams of the Johns Hopkins University cites in his treatise but one instance of such an occurrence in his varied and extensive obstetric experience, the report of this case must prove at least of statistical value.

Mrs. B., a stocky young primipara, aged 20, height 4 feet 10 inches, weight 140 pounds, was admitted into the maternity ward of the Newark Beth Israel Hospital, July 12, at 5 a. m. in advancing labor. Her pelvimetric measurements were those of a slightly justomajor pelvis; interspinous 27, intercristal 30 and external conjugate 22 cm. The junior intern, Dr. Hirsch, examined her on admission and found the os dilated 4 fingers, but because of a tense and bulging bag of waters, he alleges, he was unable to make out the exact presentation; he could find no fetal heart sounds. At 7:30 the bag ruptured and the right arm prolapsed as also some coils of cord, which had no pulsation. He at once summoned me to the case. The diagnosis was apparently a left scapulo-anterior, so I ordered ether anesthesia in expectation of doing a version or decapitation if I found the former measure too hazardous. I might add that the patient was having terrific bearing-down pains.

Before she was fully under the anesthetic, to my great surprise, I observed the shoulder rotate forward under the pubic arch, sink downward and become visible at the vulva. With the next pain, which was unusually violent, the dorsum, laterally bent, appeared, then the buttocks, legs, posterior shoulder and arm. The head still remained in the pelvis; tilting the trunk toward the abdomen of the mother and making moderate traction effectually liberated it.

The fetus had some noteworthy characteristics; it was the size found in an 8-months' pregnancy and weighed 5½ pounds; it showed signs of commencing maceration, as evidenced by peeling of the skin, in several small areas; the neck was peculiarly elongated so that it had a diameter of 1½ inches; the head was of conical shape and terminated with a meningocele; all the cephalic bones were widely separated and the umbilical cord, more than a yard long, tapered almost to a point at its umbilical insertion.

---

* Presented before the Clinical Society of the Beth Israel Hospital, July 27, 1915.

Outside of a slight rise of temperature the first four days of the puerperium, which was probably sapremic, the patient made an uneventful recovery.

It can be readily understood that evolution is impossible unless three essential requirements are fulfilled, namely, a roomy pelvis, a small, easily compressible fetus and powerful bearing-down pains; all these factors were manifested in this case.

In the rather meager literature of this remarkable resourcefulness of nature, a few instances of living children have been reported. In the treatise on midwifery by Prof. William Thomson Lusk, my lamented teacher, mention is made that Kuhn cites a case in which a living child was born, weighing 4½ pounds, after the spontaneous evolution of a shoulder presentation. Also that Simon, according to Spiegelberg, collected 125 cases in which 14 infants were born living; three of the mothers had died.

The determination whether spontaneous delivery will be effected in a particular instance is extremely difficult and ordinarily we should waste no time in anticipation of such a favorable outcome; this is especially true if the diagnosis of transverse presentation is made early before the bag of waters has ruptured. But if the expectant mother is in good condition, if the fetus is premature, if excessive retraction has already taken place making internal version a dangerous procedure, and if evidence of beginning evolution is already present, we might for a reasonable time adopt the policy of "watchful waiting" rather than proceed at once to decapitation. Indeed, in favorable instances, if the pelvic floor is offering an unyielding obstacle to Nature's attempt at delivery, we might expedite matters by following the recommendation of Dr. Taylor and overcome the resistance, by making deep incisions into the distended perineum to the extent of 3 or 4 inches, at the vulva.

APPENDECTOMY THROUGH THE RIGHT INGUINAL CANAL

GEORGE DE TARNOWSKY, M.D.
CHICAGO

Removal of the appendix through the right internal inguinal ring is not a new procedure; it has probably been done, in a more or less unpremeditated manner, by many surgeons; but, so far as I can learn, the method has never been advocated as a justifiably integral part of a right inguinal herniotomy.

The now well-established custom of removing the appendix whenever the lower abdomen is opened led me to adopt the habit of carrying out the same prophylactic procedure during the performance of all right inguinal herniotomies, whether of the oblique or direct type. The femoral ring is usually too far removed for this purpose. I have performed the operation over fifty times with uniform good results. In no case has infection occurred, either within the peritoneal cavity or in the inguinal canal; the wounds have healed with normal rapidity and, so far, no relapses of the hernias have been reported. The patients have not complained of more pain than is habitually experienced in simple herniotomies; neither has nausea or meteorism been accentuated by the added intraperitoneal work.

The cecum lies in the right iliac fossa, directly on the iliac fascia. Its lower end is from 4 to 6 cm. from the internal ring, depending on whether it is in a distended or contracted condition. When it is full, the lower end lies just over the outer half of the inguinal ligament. The outer wall or outer right margin is in contact with the lateral abdominal wall. It is always sufficiently mobile so that it can be delivered through the ring, partially or in toto, depending on the size or distensibility of the latter. As for the appendix, the only practical point to remember is that it is given off directly from the mesial posterior wall of the cecum, behind and beneath the termination of the small intestine. Delivery of the cecum must be resorted to whenever the tip of the appendix is retrocecally located, its mesentery is abnormally short, or it is displaced by kinks or adhesions.

TECHNIC

1. The usual herniotomy incision is employed, opening the inguinal canal.
2. The sac is separated from the cord, the sac opened, and its contents—if any—dropped back into the peritoneal cavity.
3. The contents of the inguinal canal are protected by means of a gauze pad.
4. The index finger of the right hand is passed through the sac opening obliquely upward and outward, that is, continuing in the direction of the canal.
5. The finger is swept along the iliac fossa from without inwardly until the cecum is encountered. The appendix can often be recognized by the touch, and its relative position ascertained.
6. If the internal ring admits two fingers or can be readily stretched to admit them, I am in the habit of introducing both index and middle fingers, grasping the cecum between them, and delivering it. When the appendix is freely movable, it has often been possible to hook the index finger over its base and thus deliver it, only one finger being necessary for this maneuver. With a small, not readily distensible ring, by passing a straight intestinal forceps of the Barrett type alongside of the index finger, the cecum can be identified, grasped by the forceps and delivered. Finally, I have lately tried the expedient of putting on a surgical cotton glove over the rubber one in order to obtain a better grasp of the slippery cecum or appendix. The experiment is worth trying, but one must get accustomed to the clumsy thickness of the cotton glove.
7. The removal of the appendix itself presents no great difficulties. Only three points in technic need be emphasized:

(*a*) Having grasped the appendix or its mesentery by means of a suitable forceps, as much of the cecum as possible should be replaced into the peritoneal cavity before going any further. This will avoid any possible danger of strangulation.

(*b*) The purse-string suture is placed around the base of the appendix before it is amputated or its mesentery is tied off. This obviates the annoying possibility of the stump slipping out of sight before the operation is completed. In other words, it gives the operator something to hold on to.

(*c*) In the retrocecal type of appendix, with very short mesentery, it is much easier to amputate the appendix first at its base, between two clamps, dissecting it out from below upward and controlling the blood supply by means of a running suture of fine silk or catgut. These closely adherent retrocecal cases are the only difficult ones to remove. It is a waste of time to try and reach the tip of the appendix first; the tension is so great that either the mesentery or appendix will tear. Suture of the short meso-appendix must be done by means of a short full-curved needle; here again it has seemed easier to begin proximally, that is, at the stump of the appendix, and suture upward, using the glover's lock-stitch.

8. The hernial sac is closed, and the hernitomy completed. It seems puerile to state that no drainage should ever be used in the canal, but as I have on several occasions been asked this question, it has seemed best to lay emphasis on this particular point.

COMMENT

As technic and confidence in the procedure improved, the time element has been rapidly reduced. Anesthesia is now prolonged an average of five minutes, so that undue lengthening of the operation cannot be adduced as a contraindication. The alleged danger of infecting the inguinal canal with resultant recurrence of the hernia, which has made a number of clinicians hesitate to adopt the procedure, has proved to be nonexistent.

In my series of cases, 30 per cent. of the appendixes removed were found to be grossly pathologic; hence I feel convinced that inguinal apppendectomy is a rational procedure. Of course, I do not advocate the inguinal route in nonherniated patients; neither would I advise that an acute appendix be removed by this route, even in the presence of a coexistent right-sided hernia. I am of the opinion, however, that, in all right inguinal herniotomies, the removal of the appendix through the sac and ring is a legitimate, logical and comparatively easy procedure.

Should the necessity of drainage ever present itself, it is a simple matter to pass a curved forceps through the sac opening to the iliac crest and make a stab drain. This was done in Cases 528757 and 530288 of my Cook County series. The first case proved to be one of tuberculous peritonitis with a badly kinked retrocecal appendix; the second, wrongly diagnosed as a strangulated hernia, turned out to be a gangrenous appendix with abscess in the scrotum. Both cases healed satisfactorily.

A PLAGUE-LIKE DISEASE OF CALIFORNIA GROUND SQUIRRELS AFFECTING MAN IN OHIO

WITH A DEMONSTRATION OF SPECIMENS *

W. B. WHERRY, M.D.
CINCINNATI

SUMMARY

Following the discovery of a plague-like disease, due to *B. tularense*, by McCoy and Chapin in California, W. B. Wherry and B. H. Lamb described the occurrence of the same micro-organism in two cases of conjunctivitis in Ohio. Both cases were characterized by ulcerative conjunctivitis involving the palpebral conjunctivae, accompanied by lymphadenitis of the preauricular and cervical glands on the corresponding side, a high temperature and marked prostration.

These patients were under the care of Dr. Derrick T. Vail and Dr. Robert Sattler, respectively, and their clinical courses have been published in the *Ophthalmic Record* (1914) and the *Archives of Ophthalmology* (1915).

In searching for the probable source of infection in these two cases the following points were considered: Both patients were affected with the virus affecting rodents in California; both patients had handled rabbits previous to the onset of the disease; there were numerous rumors that wild rabbits in Ohio, Kentucky and Indiana were dying off in large numbers of some disease. With the kindly cooperation of Dr. J. H. Landis, health officer of Cincinnati, the same disease due to *B. tularense* was discovered in wild rabbits found dead in southeastern Indiana.

The virus (a small encapsulated rod) is extremely difficult to demonstrate and is best stained with anilin Hoffman's violet or gentian violet. It could not be grown on any medium except the coagulated egg-yolk recommended by McCoy and Chapin.

All the esential features of the disease as it occurred in man could be reproduced by placing a little of the virus in the eye of a rabbit or guinea-pig.

Infection also takes place, in rodents, through the gastro-intestinal tract, through the nasal mucous membrane, and, as shown by McCoy and Chapin, squirrel fleas (*Ceratophyllus acutus*) may successfully transfer the virus. As the recent experiments of Dr. Wayson show, the house fly and the stable fly (*Stomoxys calcitrans*) may also transmit the virus shortly after feeding on an infected animal.

It seems likely that this rodent disease is widely distributed and that through the watchfulness of health officers further cases will be discovered.

ABSTRACT OF DISCUSSION

Dr. G. W. McCoy, Honolulu: It is gratifying that what we thought was a problem of purely scientific interest should have turned out to be one of practical importance in preventive medicine. Apparently we have another disease to add to the list of those traced primarily to the lower animal and occasionally transmissible to man. I would like to emphasize that this is an example of a plague-like disease, but one not due to a pest-like bacillus. It is easy to get these things confused. The organism, as Dr. Wherry has said, is in no way similar to the plague bacillus, yet in practically all the animals with which we worked the symptoms and lesions were similar to those of plague. We thought we were fairly familiar with plague, but when the first case of the new infection came under observation we would have fallen into error but for the fact that we insisted on cultural verification of every case. We carried the infection on in animals, and soon found that we were dealing with a disease of rodents other than plague. A great similarity to the lesions of the plague was the most striking point about it. After we had had a great deal of experience with this disease to supplement our experience with plague, we could in a majority of cases differentiate the gross lesions; and of course a microscopic examination would practically always decide the matter at once, and a cultural investigation would invariably do so. Dr. Wherry spoke of the cultures losing their virulence. We found that to be the case with the cultures from squirrels. I do not recall now whether we had any culture that became entirely avirulent. There is one point of importance about the lesions produced by these avirulent cultures, and that is that they produce in guinea-pigs lesions which are practically indistinguishable from those of tuberculosis. I remember when we first observed these subacute or chronic lesions we thought there had been some error in our technic and that we had introduced tuberculosis. We found that this was not the case. I may say that we always kept in mind in our work the possibility of the occurrence of the plague-like disease in man.

Dr. N. E. Wayson, San Francisco: We have duplicated Dr. McCoy's methods of flea transmission of the disease, but were not so successful as he in our results. Healthy animals separated from those infected by wire netting of the same mesh as mosquito netting, with fleas as the only common carriers, remained well. Our experiments with fly transmission were positive. The stable-fly transmissions were made by allowing the fly, held captive in a vial covered with netting, to bite the infected animal, and transferring it to a normal animal, changing the gauze between bites to prevent possible contact infection of the shaved belly of the normal animal. The stomoxys experiments were successful in a small percentage of cases; but the house-fly experiments yielded nearly 100 per cent. of "takes." The house flies were allowed to feed on, and crawl over, infected viscera, and then crawl over a cocainized eye. This method was positive in transmission, even with a twenty-four-hour interval between the exposure to the infection and to the normal eye.

---

* Read before the Section on Preventive Medicine and Public Health at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

We have not been successful in transmitting the plague-like disease by the methods of the Indian Plague Commission, in which fleas known to be infected are individually fed, under observation, on normal animals. Our control experiments in plague with this method have also been negative; probably due to an insufficient degree of septicemia in the infected animal used as a host. The same criticism in the plague-like disease experiments will not hold.

Dr. Nathan Barlow, Cuyamel, S. Honduras: During the last fifteen months in Honduras we have frequently had outbreaks of a peculiar disease which resembled climatic bubo, and was reported by me as an epidemic of climatic bubo, but which resembled very closely the disease described by Dr. Wherry, with the exception that there were no conjunctival symptoms. The gland juice from this disease was found by ordinary cultural methods and by ordinary stains to be free from demonstrable micro-organisms, which agrees with the description of climatic bubo; but it seems to me not impossible that some diseases which are at present classed as climatic bubo may really be infections with the same or a similar organism to that described by Dr. Wherry.

I should also like to bring out the importance of making practitioners in subtropical countries more acquainted with this and all other plague-like diseases, because it has twice happened that my assistants have made the diagnosis of plague, and were ready to bring about measures which would have been sure to quarantine Honduras, and I was able to see the cases before these steps had been taken. By making the proper examinations we were able to demonstrate that the cases were not plague. The serious results of such a mistake would be greater in the case of the Central American countries than in the United States, because the health authorities cannot go so far with the people there as here; and after one such error it is very likely that if true plague were later found, the necessary quarantine measures would be very much delayed.

Dr. William B. Wherry, Cincinnati: I do not see any reason why this virus should not produce other types of disease in man besides conjunctivitis. It seems possible, judging from McCoy and Chapin's work, and our own work on animals, that human beings might be infected by way of the gastro-intestinal tract and through abrasions of the skin. The virus might give rise to some forms of rhinitis, sore throat, and tonsillitis. Those are the possibilities. I am not at all certain that the virus is virulent enough to produce septicemia in man. Unfortunately we did not avail ourselves of the opportunity that we had to test that. We should have drawn off some peripheral blood to see if the virus were circulating or not. In one case we took blood rather late, and the results were negative. It seems that the virulence of the virus is diminished by passage through man. Guinea-pigs inoculated directly from a human being died after six or seven days; and in three or four days when it came from another guinea-pig; so apparently the virulence is slightly diminished for rodents by passage through man.

Improving the Race.—Environment and education alone cannot make appreciable progress in the improvement of the race. But with favorable surroundings and the selection of the best types the field for improvement is limitless.—Luther Burbank.

New Instruments and Suggestions

PROTECTION OF STERILIZED DRESSINGS FOR SHIPPING ABROAD

Gordon G. Copeland, B.A., M.D., Toronto, Ontario

It may be of interest to report by what method surgical dressings have been sent abroad to the Red Cross or other organizations, insuring their arrival in perfect condition. A year ago I was impressed with the unsatisfactory methods of shipping sterile dressings, and devised some of the essential steps in the method I report. I explained the idea to the Canadian Red Cross, and other organizations here who have enthusiastically adopted the method, which has proved practical in actual operation.

Red Cross packing cases are 27 by 15 by 15 inches, outside measurements, with rope handles. These cases fit into transport wagons and are a standard size. They are 26 by 14 by 14 inches, inside measurements. I designed two tin boxes of equal size to exactly fit into the standard Red Cross case. They were first manufactured through the kindness of the Christy Brown Company, and the Macdonald Manufacturing Company is now making the boxes and selling them at the actual cost of material, about 25 cents. The box is according to the following description: 30.2 cm. (11$\frac{11}{16}$ inches) wide, 35.1 cm. (13$\frac{13}{16}$ inches) long, 34.7 cm. (13$\frac{11}{16}$ inches) deep, outside measurements. All edges are soldered. There is a rim or ledge turned in all around the open top, the ledge being 0.8 cm. ($\frac{5}{16}$ of an inch) wide. There are two lids: the first is of flat tin which is to be soldered to the top ledge when the dressings are in place. It is 29.6 cm. (11$\frac{11}{16}$ inches) wide, by 34.7 cm. (13$\frac{11}{16}$ inches) long. From one corner a triangle is cut off, 3 cm. (1$\frac{1}{4}$ inches) on two sides. On the under surface a wire ring is soldered, and under this another slightly larger triangle of tin is soldered to make the corner the same size as before it was cut. This ring is for tearing off the soldered lid when necessary. A top lid with a turn down of 1.8 cm. ($\frac{11}{16}$ of an inch) is put on over all.

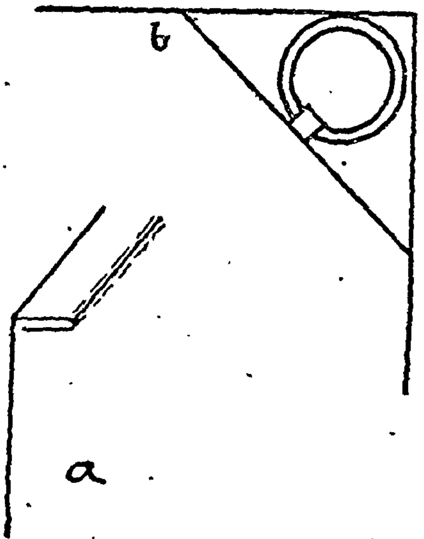

Diagram of construction of box for sterile dressings; *a*, ledge turned in around open top; *b*, ring for purpose of opening box.

The dressings are packed into Canton-flannel bags which exactly fit the tin boxes. In order to have the right shape, the bags are placed in the tin box first, and the dressings, such as gauze wipes, compresses or surgical pads made to the standard Red Cross sizes, are carefully packed into the Canton-flannel bags. When full, the bags are taken out of the tin boxes, and sewed up with a running or overcast stitch which can be easily undone. The bags are marked with a table of contents and the name of the society making them. They are then wrapped in sheets so as to be handled without soiling. The bags of dressings are then steam sterilized under high pressure on two occasions, and are absolutely sterile. The tin box is flame sterilized by pouring in methylated spirits and lighting it. The first tin lid is also flame sterilized at the same time. The boxes become nearly red hot, and absolutely sterile. A nurse, wearing sterile gloves, packs the sterilized unwrapped bags into the sterile tin boxes, and the sterile tin lid is put on with the ring up. This lid is then soldered all around and at this stage, every crack being hermetically sealed, the interior of the box and the contained dressings are and will remain sterile so long as the box is unopened. A list of contents is placed on the top of the first tin lid, the final lid is placed on top, the two boxes are placed in the wooden Red Cross case and the lid nailed on. These boxes may be sent to the ends of the earth, the contents being in perfect condition as regards dryness and sterility so long as they are unopened; and surgeons at the base hospitals, or at the firing line, can depend on the dressings arriving in as perfect condition as if they came from the sterilizer to the operating room in the best hospitals.

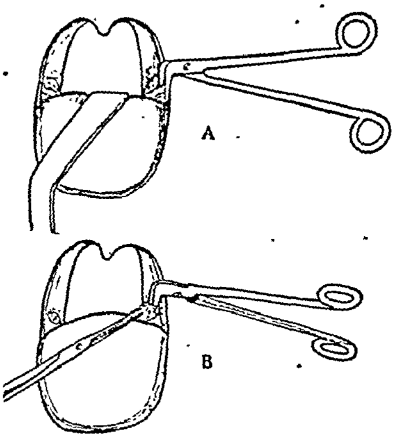
The majority of the guaranteed sterile dressings sent from Toronto have been sterilized and packed at the Toronto General Hospital under the conscientious supervision of Miss Gunn, the woman superintendent, and Miss Dunbar. The reports coming to us from abroad are that the dressings are a wonderful blessing to the surgeons and the wounded.

NEW INSTRUMENT AND TECHNIC FOR CIRCUMCISION OF THE TONSIL

Frank G. Murphy, M.D., Mason City, Iowa

In a previous article[1] attention has been called to a new operation for the relief of chronic tonsillar infection. This operation consists of the establishment of free drainage of the tonsillar and peritonsillar region, with subsequent atrophy of the tonsil, by separating the attachments around the tonsil instead of its enucleation. The method of procedure in this operation is as follows:

After the field of operation has been anesthetized, the forward blade of the scissors is inserted behind the plica between the anterior pillar and the tonsil, the incision being made as deep as possible, as at *A* in the illustration.



New instrument and technic for circumcision of the tonsil: *A*, incision; *B*, grasping of tonsil with forceps.

The tonsil is then grasped as at *B* with a pair of tonsil-forceps. As gentle traction is being made with the forceps, any attachments which there may be to the posterior pillar are severed. Adhesions in the supratonsillar fossa are then cut. The anterior fossa is then dissected farther back so that the tonsil, when the operation is completed, is attached only to the pericapsular tissue.

Irrigating Tip.—Below is a drawing of an improvised urethral and bladder irrigating tip which has served me well. The tip is the hard rubber portion of a discarded stethoscope or ear piece, into which is inserted a couple of inches of glass tubing, firmly held by the use of a little cement, and to which is attached the rubber tubing of the irrigator bottle.—J. A. Van der Hulse, M.D., Akron, Ohio.

The Child and the State.—When the state, for its own protection, compels a child to go to school, it pledges itself not to injure itself by injuring the child.—Dr. William H. Allen.

Therapeutics

PNEUMONIA

(*Continued from page 1461*)

TREATMENT

4. *The Bowels.*—The bowels should move daily. Constipation should be prevented, but a diarrhea is not desirable. A cathartic may be given in the beginning of the disease, the one preferred by the physician. Later, his preferred laxative, whether a compound aloin tablet, a cascara tablet, or some other combination, should be given, but, preferably, it should be a vegetable laxative. An occasional enema of glycerin and water, one ounce of each, will be found valuable. It will empty the colon and prevent the necessity of giving large doses of a laxative or a cathartic. Such treatment will aid in preventing tympanites.

A diarrhea will weaken the patient and add one more element to cause weakness of the heart. If it occurs, the bowels should be cleaned out with a laxative, castor oil if it can be taken, and then movements should be prevented by $\frac{1}{10}$ grain of morphin. Saline cathartics are likely to increase the amount of gas in the intestine, and hence are generally contraindicated. Bismuth is likely to remain too long in the bowels and promote the growth of germs and the absorption of toxins, which will add one more danger in the pneumonia toxemia that is constantly feared. Phenyl salicylate (salol) in 0.25 gm. doses, in capsules, may be given in these diarrheal conditions, four or five times in twenty-four hours, for a few days, and will often stop excessive fermentation.

5. *Care of the Skin and Mouth.*—It is rare, with the proper diet, the proper treatment of the bowels, and with plenty of fresh air, that the temperature in pneumonia is so high as to require sponging with cold water. Even when the temperature is very high, with a cerebral complication, tepid sponging in a warm room is as severe treatment as should be tried. Ordinarily, then, sponging once or twice a day with hot water is advisable, both for the comfort of the patient and to remove perspiration and keep the skin active. The temperature is more or less reduced by the warm sponging, the blood-vessels of the surface are slightly dilated, the circulation is equalized, and the normal activities of the skin, which are essential, are increased. Also, warm sponging tends to relieve the tension of blood in the head, and many times aids in promoting sleep. If the patient's temperature is low, hot-water sponging is certainly advisable, and hot-water bags should be used around the extremities and even around the body. Such a condition is often seen in pneumonia in alcoholics. Profuse, cold, clammy perspiration should never be allowed to remain on the patient's body. Warm alcohol sponging in such conditions is advisable, that is, sponging with pure alcohol. A dash of alcohol in a basin of water has no therapeutic or physiologic value and represents nothing but a fad.

Cleanliness of the mouth, teeth and tonsils is very important. The patient may have infected himself from his own tonsils or his own gums; such possibilities should be remembered, as well as the necessity of keeping the mouth as clean as possible during the illness. While alkaline mouth washes are cleansing and soothing, acids are more likely to kill the mouth germs; hence not only are orange juice and lemonade advisable for the salts that they contain and for stimulating the secretions of the mouth, but they may even have a germicidal value. There is no reason why a patient should not chew pieces of orange. The pulp, if swallowed, is perfectly harmless, and adds some bulk for the intestines to act on. Suppurating spots in the mouth should be touched with tincture of iodin or with Lugol's solution. Hydrogen peroxid solutions may be used in full strength for swabbing, or diluted for a mouth wash or throat gargle.

The sputum, being as likely to communicate disease as is that from tuberculous patients, or even more so, should receive the same antiseptic care as does that of tuberculosis. The patient's mouth, excretions from the nose, and the nurse's hands and contaminated clothing or gauze should be treated in the manner so well understood in tuberculosis.

GENERAL CONSIDERATIONS

Although pneumonia has been considered a self-limited disease tending to recovery, this can hardly now be said to be generally true. The sthenic type of pneumonia which does tend to recovery, with one or more lobes distinctly involved, is now not so frequent as a less circumscribed pneumonia, or an asthenic type with a low temperature and without much tendency to self-limitation and, as the statistics show, not a great tendency to recovery. The crisis which should introduce recovery means, according to Hektoen,[1] the destruction of the pneumococci in the lungs and blood. This, he says, is accomplished by phagocytosis and by extracellular digestive processes. Therefore, the greatest defense against pneumonia is a production of leukocytosis and of antibodies in the blood. Such patients as rapidly die of a toxemia have this blood defense in insufficient amount. When this defensive process has been produced in sufficient amount to destroy the pneumococci rapidly, the recovery is by crisis; when it is in sufficient amount to destroy them only slowly, the recovery is by lysis, and this latter form of recovery is the one which we now more frequently see.

If the patient does not die of the acute onslaught of the germ by incombatable toxemia, or by exhaustion from a later general toxemia, or from a migration of the pneumococci to the meninges, his survival or death depends on the ability of his heart to withstand the disease. Willson[2] states that his postmortem findings have shown, in every fatal case of pneumonia, a coincident attack on the heart muscle and a more or less destructive myocarditis; he thinks it likely that "every heart that weathers the pneumonic storm sustains similar lesions, of milder degree perhaps, yet from which it never fully recovers." This finding emphasizes the part that the heart plays in the disease of pneumonia.

Rohdenburg and Vander Veer[3] believe that pneumococci are not infrequently present in the spinal fluid in pneumonia, even when there are no distinct meningeal symptoms. It is quite possible that a slow-going pneumococcic meningitis without distinct meningeal symptoms may be the cause of some deaths that have been attributed to toxemia, that is, deaths of patients that have insomnia, delirium and high temperature without more distinct meningeal symptoms.

It has been shown by Dochez and Gillespie[4] and confirmed by Dochez and Avery[5] that lobar pneumonia may be divided into four groups by immunologic tests on animals. These latter investigators do not believe that the virulent types of pneumococci are often found in the mouths of healthy persons who have not been directly exposed to pneumonia. The germs frequently found in the mouth belong to the fourth group of pneumococci, those of low virulence, which are, however, responsible for about one fifth of the cases of pneumonia. In patients who have the more virulent type of pneumococcus the disease will be prolonged if this virulent type is found long in the mouth of the patient. Generally, after a certain number of days the virulent type of pneumococcus has disappeared and perhaps is replaced by a nonvirulent type. On the other hand, these observers often found in the mouths of the assistants and nurses the virulent type of pneumococci which they had acquired from their patients. Such nurses and attendants are certainly active carriers of this infection, and may infect others even if they develop sufficient immune bodies from such vaccination, which it really is, to prevent the occurrence of the disease in themselves. Pneumonia, therefore, seems to be, in 80 per cent. of the cases, a contact disease. Consequently, the necessity of making it a reportable disease and surrounding each case with all the preventive care that is used in other contagions is self-evident.

There is no specific treatment for pneumonia; no one treatment can be guaranteed either to abort or to shorten the disease. Some years ago veratrum viride, pushed to its cardiac depressant action, was thought to be of great benefit. More recently lauded treatments have been large doses of quinin, of salicylic acid, of potassium iodid, and of quinin and urea hydrochlorid; probably there are other drugs that have been stated to be of marked benefit. The success from these drugs must be considered more or less accidental, and but few followers of these treatments have been able to obtain the success of their founders.

That occasionally pneumonia may be aborted must be acknowledged, as the pneumococcus is found in the mouth without pneumonia occurring; hence the germ may enter the respiratory tract, causing congestion, and still the disease might abort. Doubtless many supposed aborted cases, however, were congestions of the lung in which the pneumococcus was not present.

That venesection was at one period of considerable value in pneumonia when the disease was constantly sthenic, the patient was sturdy and had a surplus of respiratory strength, is doubtless true. This treatment has apparently at times saved life. Occasionally, in an overpowering onslaught of this infection, in a strong, plethoric man, with rapid congestion and consolidation of one or both lungs, venesection may be valuable today. Such cases are becoming more and more rare.

Venesection, veratrum viride, aconite, and large doses of the coal-tar products are all more or less in disrepute on account of the almost assured heart weakness that a patient with pneumonia will develop sooner or later. Consequently, the physician dislikes to think that he may have hastened this heart failure by his treatment. The trend of the treatment of severe acute disease is the trend of civilization. The dire blood lettings, profuse vomitings, severe catharsis, then the cardiac depressants, then the coal-tar antipyretics, then the starvation, and lastly the use of alcohol to depression have all given way to the change in humanity due to civilization. The strenuous life that we lead has caused the heart and circulation to be less and less able to withstand disease and less and less able to stand severe radical treatment. Consequently, harsh methods tend to prostration and a fatal outcome in pneumonia. Conservation of energy is now the watchword in this disease.

(To be continued)

DOSAGE OF CALOMEL

Dr. Nathan B. Eddy, Standish, N. Y., writes:

> In The Journal (Oct. 2, 1915, p. 1183) in the department of Therapeutics under the heading, "Acute Diarrhea," it is said, "This foolish one-tenth-grain-dose-of-calomel-every-hour fad should be given a decent burial." Allow me to object.
>
> We have just been having here a *considerable* number of cases of acute diarrhea, apparently due to the defective water supply. The same general treatment was used as outlined in the article in question, except that calomel was given in divided doses, one-tenth grain in children, one-quarter grain in adults, usually at half-hour to one-hour intervals.
>
> The apparent result was that less calomel was needed for the desired effect, and, perhaps more important, where vomiting was present, the divided doses were better retained than larger single doses. Single doses were used in some cases.
>
> It seems to me there is still a place for divided doses of calomel, the article to the contrary.

There is probably no doubt that in selected cases divided doses of calomel may act satisfactorily, but it is rare that divided doses will act better than a single dose in amount carefully selected to fit the case. The criticism concerning the small-dose-of-calomel fad was aimed at the great frequency with which calomel is thus administered in hospitals in postoperative cases, without regard to the condition of the stomach or intestines, and to all young children who need a cathartic or have any disturbance whatever, and to most adults who have some intestinal disturbance. A frequent consequence of the administration of small doses of calomel, especially in postoperative cases, is nausea, vomiting, and also many times an irritation of the duodenum which lasts several days.

It takes many hours for calomel to cause purging. When it is time for the first two or three doses to cause such action, many other doses on the one-tenth-grain plan are on the way. If protracted looseness of the bowels is desired, this may be good treatment. On the other hand, even though it cannot be denied that calomel in small doses frequently repeated has a certain amount of antiseptic or germicidal action in the intestine, as is claimed, it still would seem that some other antiseptic, as phenyl salicylate (salol), would be better and safer.

The success of small doses of calomel recorded by the correspondent is not questioned. It is still urged, however, that such treatment can do harm, and it is to be deplored that calomel in divided doses is given thoughtlessly and as routine treatment without individualizing the patient and the object of treatment.

New and Nonofficial Remedies

The following additional articles have been accepted by the Council on Pharmacy and Chemistry of the American Medical Association. Their acceptance has been based largely on evidence supplied by the manufacturer or his agent and in part on investigation made by or under the direction of the Council. Criticisms and corrections are asked for to aid in the revision of the matter before publication in the book "New and Nonofficial Remedies."

The Council desires physicians to understand that the acceptance of an article does not necessarily mean a recommendation, but that, so far as known, it complies with the rules adopted by the Council.

W. A. Puckner, Secretary.

BETANAPHTHYL SALICYLATE. — Betanaphtholis Salicylas. — Betan. — $C_6H_4.OH.CO.O.(C_{10}H_7)$. — The salicylic acid ester of betanaphthol.

Actions and Uses.—Betanaphthyl salicylate undergoes no change in the stomach, but is split up into its original compounds when it reaches the intestinal tract by the pancreatic juice and intestinal secretions. It is believed to act as an intestinal antiseptic and, being excreted in the urine, to act in a similar way in the bladder. (See general article on Naphthol Compounds, N. N. R., 1915, p. 210.)

It has the antirheumatic properties of salicylic acid. It is said to be useful in intestinal fermentations, catarrh of the bladder, particularly gonorrheal cystitis, rheumatism, etc.

Dosage.—From 0.3 to 0.5 Gm. (4 to 8 grains) in cachets, milk or emulsion.

Non-proprietary preparation: Betanaphthyl Salicylate, M. C. W.—*Manufactured by the Mallinckrodt Chemical Works, St. Louis, Mo.*

Betanaphthyl salicylate is obtained by heating betanaphthyl-sodium and sodium salicylate with phosphorus oxychloride at from 120 to 130 C.

It is a white, shining crystalline powder, colorless and tasteless, melting at 93.2 C. It is insoluble in cold or hot water or glycerin, soluble with difficulty in cold alcohol or turpentine, easily soluble in boiling alcohol, in ether, in benzene, and in warm linseed oil. In the cold it is not changed by acids or alkalies of moderate concentration. When heated with alkalies it is decomposed into its constituents, which, if the solution be acidulated, will crystallize.

It is distinguished from salol by its higher melting-point and by the production of a brownish-green color, when a trace of nitric acid is added to its yellow colored solution in pure sulphuric acid. It burns on platinum foil, leaving no residue (absence of fixed mineral impurities). If 1 Gm. of betanaphthyl salicylate be shaken with 30 Gm. of boiling water and filtered through a moistened filter, the filtrate should not have an acid reaction (absence of salicylic, hydrochloric or phosphoric acid), nor should it after cooling show a crystalline deposit (salicylic acid or betanaphthol); nor should it become turbid on the addition of silver nitrate (chlorides or phosphates) or barium nitrate (absence of sulphate), nor should it give a violet color with solution of ferric chloride.

Proprietary Preparation:

BETOL.—A name applied to betanaphthyl salicylate.
Manufactured by Merck and Co., New York.

Classification of Tropical Diseases

Escomel publishes in the *Cronica Medica*, 1915, xxxii, 150, a study of blastomycosis in man in Peru and Bolivia. It is accompanied by eight illustrations of two typical cases, and he declares that there is unwarranted confusion in the nomenclature of tropical diseases, especially in Peru and Bolivia. Cases have been grouped as uta, espundia, buba, etc., when in reality all these tropical diseases of the skin and mucous membranes should be classified as leishmaniasis, with or without flagellates, syphilis, tuberculosis, pain, or blastomycosis, "the latter constituting," he remarks, "the most extensive and the cruellest chapter of pathology in our tropical region." The dictionaries define blastomycosis as saccharomycosis, that is, any disease condition due to a yeast-fungus. In his two cases the skin around the mouth and the mucosa of the upper air passages were mainly affected.

THE ANTIFERMENTS OF THE BLOOD

The Abderhalden test for the presence of specific enzymes in the blood, which has frequently been referred to,[1] has awakened interest not only in the possibilities of practical application which it represents but also in its relation to the underlying principles of immunity. Even a cursory review of the literature of the subject will indicate that Abderhalden's views have not gone unchallenged and his contentions have not remained without contradiction. The differences have ranged from the complete denial of the phenomena themselves to the mere expression of doubt as to the validity of their interpretation.

It will be recalled that according to Abderhalden the injection of foreign proteins of any kind into the blood leads to the prompt formation and appearance in the blood of enzymes which can digest proteins of the sort introduced, but not any other kinds. In the case of pregnancy, for example, it is postulated that placental protein finds its way into the maternal circulation. As a result, the blood serum of the pregnant woman or other mammal acquires the property of digesting proteins prepared from placental tissues. This fact has been applied to the detection of pregnancy. In a similar way a comparable serum test for the detection of cancer has been devised with protein derived from carcinomatous tissue. The underlying postulate in all these cases is that the body can generate new enzymes which will attack only certain native proteins.

Jobling[2] and his collaborators at the Vanderbilt University, Medical Department, in Nashville are among those who take exception to this assumption of the genesis of specific enzymes, and they seek to explain the phenomena in a quite different manner. It is known that the blood may contain not only proteolytic enzymes but also antienzymes. Protein-digesting ferments are frequently liberated from cells such as the white corpuscles of the blood, but their digestive capacity is inhibited by the presence of antiferments in the blood. Proteolytic enzymes are present in the blood under a variety of conditions, but they are not specific and they become evident only when the antienzyme has been removed. According to Jobling and others, normal human serum rarely contains strong proteolytic enzymes and therefore does not give a positive Abderhalden reaction. On the other hand, serums of pregnant women, of patients with pneumonia, or with cachexia due to certain causes do contain ferments and will give positive Abderhalden reactions. Such tests can be obtained with all human serums containing much proteolytic ferment, regardless of the disease from which the patient is suffering, not only with placental tissue but also by removal of the antitrypsin by suitable methods. In the case of the pregnancy test a positive reaction is due to the adsorption of the antienzyme by the placental tissue used or by the bacteria. The enzyme is merely permitted thus to act on the unprotected serum protein. The digestive reaction, as several investigators have insisted, is exerted, in all cases of positive test, on the serum itself, rather than on the foreign substance added.

Extensive investigations have shown that a variety of ether-soluble substances or products derived from them can act as ferment-inhibiting agents. This is particularly true of soaps of some of the fatty acids. Jobling and Petersen[3] have shown that they can be prepared from the tubercle bacilli and tuberculous caseous material. They suggest that the production of the latter in tuberculosis must be partly due to the presence of substances which inhibit the action of the enzymes set free as a result of the disintegration of the cells. Further experiments have shown that it is the fatty acids of the unsaturated type which are endowed with the antitryptic power. In caseous material from tuberculous lymph glands and from caseous pneumonia, ferment-inhibiting substances were also identified as compounds of unsaturated fatty acids.

The association of the unsaturated carbon bonds with the antitryptic power has been made even more likely by the fact that treatment with iodin or hydrogen peroxid, which changes the desaturation of the fatty acids, also destroys their antiferment activity. Jobling and Petersen relate these facts to the action of iodid in tuberculosis. Caseous areas often may be present in the lung, but unless they open into the air passages, tubercle bacilli may be absent from the sputum. If iodids are now given, the antiferments are destroyed, proteolysis can proceed, and the caseous matter begins to soften and is more likely to rupture into the bronchi so that bacilli are then discharged with the sputum.

With the establishment of the contention that the activity of fatty acid derivatives (soaps) as ferment-inhibiting agents is dependent on the degree of unsaturation and "iodin value" of their fatty acids, has come the attempt to discover whether all antitryptic agencies in the body are of this lipoidal character. It is now known that the antitryptic power of serum is almost entirely removed by extraction with an organic solvent such as chloroform or ether. Furthermore, serums become far more toxic when their antifermentative potency is thus destroyed, perhaps because the enzymes in them are then given full scope to produce poisonous digestion products from the unprotected serum proteins. Applications of the principle involved to other problems in immunology will suggest themselves.

CAMPHOR, NATURAL AND SYNTHETIC

It is reported that the first, and, so far, the only productive camphor plantation in the United States (that at Satsuma, Florida) distilled its second year's crop this spring.[1] The yield is said to be satisfactory. Smaller plantations in various parts of Florida will soon come into bearing. This is the result of a government campaign begun twelve years or so ago. It is expected that more and more land will be set out in camphor, and that this country may soon (perhaps within a decade) be independent of foreign camphor producers.

Before the camphor monopoly becomes a page of forgotten history, some writer with an eye for the romance of actuality should record its life-and-death struggle against the synthetic camphor industry. The camphor of commerce is now obtained chiefly from Japan and the island of Formosa, to both of which regions the camphor laurel (*Cinnamomum camphora*) is indigenous. After taking possession of Formosa, Japan gradually brought under control the fierce head-hunting tribes that had previously made camphor gathering almost impossible there, and in 1899 made the industry a government monopoly, which in 1903 was extended to Japanese camphor. The Japanese captured the world's camphor market, reaping, it is said, huge profits, which reached their climax in 1906-1907, when camphor brought as high as $80 per picul of 130 pounds.[2] Meanwhile, a rival industry was growing up in Germany. In 1870 it became known that synthetic camphor could be manufactured from oil of turpentine. This was converted: (1) into pinene hydrochlorid; (2) into camphene; (3) into isoborneol, and (4) into camphor.[3] In 1905, the growing importance of camphor in the production of celluloid and other substances stimulated the first important attempt to produce synthetic camphor for the market. The idea captivated the imagination of chemists, and the production of synthetic camphor became one of those crazes which blast hopes and wreck fortunes. Over two hundred patents were taken out; by 1908 the synthetic camphor industry, favored by temporary business conditions, was able to deal a serious blow at the Japanese natural camphor trade. The Japanese rallied, however, and, by underselling wherever their trade was threatened, regained control of the market. In 1909 the German synthetic camphor industry, though not killed, was so crippled (being also hampered by the fluctuations in the supply of turpentine oil) as no longer to endanger Japanese supremacy.[4] On account of our plentiful supply of turpentine oil, the manufacture of synthetic camphor has been regarded as a promising field for enterprise in this country. American turpentine oil ranks next after the French as a base for synthetic camphor, in the opinion of German manufacturers.

The chemical formula for natural and synthetic camphor is the same, $C_{10}H_{16}O$. The two substances are best distinguished by the polarized light test. Natural camphor from the camphor laurel[5] rotates polarized light to the right, whereas synthetic camphor, which is composed of dextrorotatory and levorotatory camphor, is optically inactive. This opposite rotation in two bodies identical in the number and kinds of atoms in the molecule is supposed to indicate a reverse arrangement of atoms or atomic groups, so that the two isomers correspond to each other like the right and left of a pair of gloves. In many instances this reverse structure is accompanied by an as yet inexplicable difference in medicinal activity. Thus, when synthetic epinephrin was first placed on the market, it was found to have but half the clinical activity of natural epinephrin. Natural epinephrin is levorotatory; the synthetic product then marketed was optically inactive, being a mixture of dextrorotatory (*d*) and levorotatory (*l*) epinephrin. When their attention was called to the differences between natural and synthetic epinephrin, the manufacturers of the latter were able to produce a satisfactory article by separating out and discarding the *d*-substance, which was only one fifteenth as powerful as the *l*-product in its effects on the blood pressure.

A similar gradation in the effects of levorotatory, inactive and dextrorotatory camphor has been reported,[6] *l*-camphor in massive doses strongly stimulating the central nervous system of frogs, the optically inactive (synthetic) camphor producing a less marked reaction, and the *d*-camphor (the natural product) a still weaker one. The *l*-camphor is said to be more toxic than *d*-camphor.[7] The present war, by cutting off from Germany the supply of Japanese camphor, has naturally stimulated among German clinicians an interest in the possibility of substituting artificial for natural camphor in medicinal use. The government therefore recently ordered clinical tests made. Synthetic camphor, used externally and in moderate doses internally, has been reported as having the same effects as natural camphor.[8] The published clinical reports, however, are few and the details are somewhat meager. The announcement of a manufacturer that synthetic camphor has been fully established as equal in medicinal value to natural camphor therefore appears premature. The substitution of synthetic camphor for the natural product in medicinal use seems unwarranted where no necessity exists, at any rate, until the discrepancies in the evidence have been cleared up. Even Levy and Wolff,[8] who report having found the former a satisfactory substitute for the latter product, warn against using more than 1 gm. in a single dose, on account of the greater toxicity of the artificial substance.

[3] Thorpe's Dictionary of Applied Chemistry, Vol. I, art. Camphors, p. 619.

[4] Report for 1909 of the Elder Merchants of Berlin, quoted in Camphor Industry in Foreign Countries (Note 2).

[5] A natural camphor is known which, though otherwise identical with ordinary camphor, rotates polarized light to the left. This *l*-camphor occurs in the volatile oil of feverfew (*Pyrethrum parthenium*) and in the oil obtained from the fresh twigs and leaves of *Artemisia nana*. (Thorpe's Dictionary of Applied Chemistry, Vol. I, art. Camphors, p. 620.)

[6] Langgaard, A., and Maass, T. A.: Therap. Monatsh., November, 1907, p. 573, quoted by Bachem, C.: Med. Klin., April 11, 1915, p. 425. Sassen (Inaug. Diss., *Bern*, 1909, *also* quoted by Bachem) was unable to confirm these observations. Langgaard and Maass found but slight differences in the effects of the different *forms of* camphor given in moderate doses; all the effects produced were on poisoned animals. Grove (Jour. Pharmacol. and Exper. Therap., January, 1910, *p. 445*), in experiments on frogs and white rats, found that the pharmacologic action of the three kinds of camphor differed not in kind, but merely in degree. Mammals were about three times as susceptible as frogs to the action of all forms of camphor.

The pharmacologic evidence with regard to camphor is confused and contradictory, and the clinical evidence is naturally still more so. On the subject of the clinical value of natural camphor there are many diametrically opposed opinions. While in Europe camphor is widely used for its circulatory actions, especially in threatened cardiac failure, certain English and American observers[9] have been unable to detect any action from camphor which would justify reliance on it as a cardiac stimulant. Further observations are much to be desired.

THE MANAGEMENT OF DIABETES

Last week's issue of The Journal[10] contained a brief historical survey of the purpose which has permeated some of the methods of dietotherapy in diabetes, particularly those which have involved the use of considerable amounts of carbohydrate-containing foods. As is so often the case in medicine, the intent of some of these procedures has been either misunderstood or not taken into consideration at all by those who have attempted to apply them to the human patient, and the results have frequently been unexpected failures. Many physicians have inaugurated the "oatmeal" treatment in the regimen of a diabetic without appreciating that its field of usefulness is admittedly limited, and that it represents, not a permanent sort of dietary, but a vigorously and intelligently instituted temporary mode of therapy intended to develop an increase of carbohydrate tolerance and to diminish a severe impending acidosis and ketonuria. None of the "cereal treatments" were originally intended to be permanent unvaried dietary procedures. A careful study of the recommendations of those who proposed them would have dispelled the false claims and irrational practices.

The warning to insist on an intelligent appreciation of the aim and method alike of any new procedure in therapy may not be amiss in relation to the treatment of diabetes by prolonged fasting—a method advocated by Dr. F. M. Allen,[11] now of the Rockefeller Institute of Medical Research. It is the more timely because a fundamental factor in the new plan consists in a larger share of education for the patient and a smaller element of nursing or hospital life.

A competent American student of diabetes has succinctly summarized the intent of the new procedure as follows: Fasting and a low diet have long been known, but it is only fair to give Allen the credit, first, of seeing the therapeutic significance of inanition in a severe case of diabetes; second, of proving on diabetic dogs that prolonged fasting would render them sugar-free, and, third, of having the courage of his convictions and applying this principle to human diabetics.[12] The ideal of treatment in this disease is a sugar-free and acid-free urine. Present experience indicates that the glucosuria in cases of even the severest type of diabetes may with advantage be cleared up by one initial fast. The necessary duration may sometimes be as long as eight or ten days. Under these conditions, contrary to the general impression, the severe acidosis of diabetes is markedly reduced. Allen has expressed the situation by saying that, broadly speaking, freedom from glucosuria seems attainable in all cases of uncomplicated human diabetes before there is danger of death from starvation.

Heretofore the fasting in cases of diabetes has been of brief duration. The loss of body weight has usually been feared as a dangerous depletion of reserve energy; and in the presence of severe acidosis, carbohydrates, though poorly tolerated, have been depended on to bring relief from this condition. In the milder types of diabetes the usual measures used in diabetic therapy, namely, restriction of carbohydrate or protein and brief fasting, if necessary, suffice to keep the patients sugar-free, and in good condition. Such measures notably fail in the severer types. The fundamental significance of Allen's treatment, involving a suitable initial fast, lies in the belief that if glucosuria and hyperglycemia are prevented, the damaged internal function of the pancreas, on which the utilization of sugar ultimately depends, is protected, and rest becomes possible. Structural losses cannot be repaired; but it is reasonable to assume that if there is a "functional" element in the etiology of human diabetes, a complete rest of the weakened function may both permit and facilitate recovery.

The policy of Allen's method involves "prompt and lasting freedom from glucosuria and acidosis" not only in mild and incipient cases but also in all diabetic patients, even the severest. This represents a far more radical treatment than any hitherto proposed. The avoidance of acidosis means the elimination of the necessity of administration of objectionable alkalies often given in very large doses. The danger of coma is correspondingly reduced. The subsequent carefully selected diet is intended to maintain the advantage of freedom from intoxication at any cost. Therefore, instead of attempting to increase the weight of the somewhat depleted patient and maintain it at the highest possible level, as has so often been attempted, the aim is to keep the weight low in the belief that the reduction is beneficial to the diabetic. Any gain which brings back glucosuria or ketonuria must be checked. From this point of view, it becomes necessary on the return to restricted diet to test the patient's tolerance not only to carbohydrate but equally well to fat and protein, and to keep within it. During the fasting periods, alcohol may be given until the ketonuria disappears. This is not absolutely essential, though alcohol appears to be valuable and does not produce glucosuria.

Although it is perhaps too early to grow unduly enthusiastic with respect to the success of the treatment by initial fasting, enough favorable reports have been recorded to designate the outlook as one of promise. Dangerously weak and emaciated patients have borne the fasting with apparent benefit, "giving the impression that they have been suffering more from intoxication than from lack of nutrition." Many of the dangers which suggested themselves have *not* arisen or have been successfully managed by those who have tested the method. After all, under any dietary plan the most important feature is to educate the patient so that he can carry out a dietary scheme with intelligence. Until the physician himself knows foods as well as he knows drugs, it is useless to expect dependable results from those in his care. Too often he is hopelessly bewildered when there is need of suggesting a "diet list." Green corn and celery, bananas and cucumbers are all in the same vegetable category in his mind. A radical treatment which removes polydipsia, secures relief from polyphagia and makes the patient feel better is always welcomed by the individual; but the treatment cannot be expected to succeed unless it can be intelligently prescribed.

Aside from the advantages of comfort and simplicity, the ultimate prognosis of diabetes on the basis of the new treatment must depend on the question whether diabetes is an inherently progressive disease or "the simple weakness of a metabolic function." Rest and restoration may succeed in one case; repair may fail in the other. Joslin has come to feel that coma no longer represents the culmination of diabetes, but that it is an avoidable accident. Whatever the ultimate outcome, Allen's treatment is believed, in his own words, to remove the glucosuria and acidosis more quickly and surely than has been the practice heretofore, and to enable patients to do better when these symptoms are removed than when they are allowed to continue. Any plan which holds out prospects like these for severe diabetes deserves to be studied carefully, to say the least.

LUMBAR PUNCTURE IN DELIRIUM TREMENS

The belief is becoming more or less general that the final factor in the production of delirium tremens is a marked increase in the pressure of the spinal fluid. Schottmüller and Schumm[1] found a marked elevation in the pressure of this fluid in 80 per cent. of the cases of acute alcoholism examined by them, and in one instance they drew as much as 100 c.c. with no unfavorable reaction. Steinebach[2] found a similar condition in 75 per cent. of patients with alcoholic delirium, and in the remainder there was a relative increase in the pressure of the fluid. That this increased pressure may be responsible for the delirium and is not merely a condition which accompanies chronic alcoholism is indicated by the fact that increased pressure is not found in alcoholics before or after an attack of delirium tremens, nor do habitual drinkers who are not suffering from acute alcoholism or who have not had delirium show an increased pressure. Further, in animals killed during a state of acute alcoholism, Braun[3] has demonstrated an internal hydrocephalus and an inflammatory infiltration of the pia. Finkelnburg[4] found, in dogs which had been given from 2.3 to 3.3 c.c. of alcohol per kilogram of weight, a maximum increase in the spinal fluid pressure of 72 per cent. This increase began from twenty to thirty minutes after the animal became intoxicated, reached its greatest height in from one and one half to three hours, and remained high for several hours. He believes that similar conditions obtain in acute alcoholism in man, and that the headache, hyperesthesia of the skin, dizziness and other nervous phenomena following a debauch are due to this increased pressure and to the internal hydrocephalus which accompanies it.

[3] Braun, cited by Bumke: Die exogenen Vergiftungen des Nervensystems, Handbuch der Neurologie von Lewandowsky, 1912, iii.

[4] Finkelnburg: Experimentelle Untersuchung über den Einfluss des Alkohols auf den Hirn-Rückenmarksdruck, Deutsch. Arch. f. klin. Med., 1904, lxxx, 130.

If delirium tremens is due to increased pressure, the lowering of the tension by lumbar puncture should cause an improvement in the patient's condition. In this regard Steinebach's results are to the point. In every case the delirium grew milder; frequently it ended entirely. The disorientation as to time and place usually remained for a while. In two instances the delirium returned. Following a second puncture, an increase in the pressure was again found and the delirium soon abated. In the total series of eighteen cases, the average duration of muscular unrest following lumbar puncture was from three to four hours, and of delirium, twenty-four hours. In thirty-three cases in which lumbar puncture was not done, the average of the restless days was four, and of the delirium, five days. Thus, through lumbar puncture the duration of delirium was shortened 60 per cent. and the restlessness 75 per cent. This series of cases was punctured during the first twenty-four hours of delirium. Of the cases that were punctured on the second day following the onset of the delirium, improvement occurred less rapidly. Here the average duration of restlessness was from six to seven hours, of mental confusion twenty-four hours, and of delirium, eighty hours.

The manner of action of lumbar puncture in delirium tremens has been thought to be the same as that described by Quincke for puncture in acute serous meningitis. If the interventricular pressure reaches a certain point, the usual channels of escape for the spinal fluid become occluded. Then, by lumbar puncture, the hypertension is released and healing begins. Certain facts, however, make another explanation necessary. First, lumbar puncture works equally well in cases which show only a relative increase in pressure. Second, Steinebach found that after the withdrawal of the spinal fluid in these cases, the reinjection of from 15 to 20 c.c. of physiologic salt solution gave even more beneficial results. These facts indicate that there is probably some toxic irritant present in the spinal fluid. Accepting this view, the best treatment of delirium tremens is a spinal puncture which releases the pressure and removes part of the toxic substance and a dilution of what remains by the injection of salt solution.

The nature of this toxic substance is not known. In approximately 80 per cent. of these studied cases, alcohol or one of its derivatives has been demonstrated in the spinal fluid by the iodoform crystal test. Finkelnburg has shown experimentally that alcohol reaches a higher concentration and remains for a longer time in the spinal fluid than in the blood. While this may play a rôle in the increased pressure associated with acute alcoholism, it does not in the production of delirium, because delirium frequently begins during a period of total abstinence, and in such cases no alcohol can be demonstrated in the spinal fluid. Alcohol is apparently one of the substances which has an affinity for nervous tissues. It is secreted by the choroid plexus into the cerebrospinal fluid, but its presence there is a result of large amounts of alcohol recently consumed and is not the final factor in the production of delirium.

The most important therapeutic effect of lumbar puncture in delirium is stopping restlessness and muscular exertion, since that minimizes the chances of cardiac failure. The best results seem to occur in pneumonia when early puncture is made, and here a sparing of exertion is, of course, essential.

THE KIDNEY AND SUGAR EXCRETION

The average normal sugar content of the blood may be expressed, in round numbers, as 0.1 per cent. of glucose. Although the kidney cells are continually bathed with a sugar solution of this concentration, none of the carbohydrate passes them so as to reach the urine. There are other substances which may enter the blood stream in minutest doses — in quantities far smaller than those represented by the circulating sugar — yet they promptly make their appearance in the kidney secretion. As soon as the glucose concentration in the blood is slightly raised to the point commonly designated as hyperglycemia, sugar is likely to appear in the urine. Here is a group of undoubted facts that are not easy to explain. If all readily diffusible substances that find their way into the circulation could be found in the renal secretion, as various inorganic salts and urea are, this feature would be easy of interpretation. If it could be demonstrated convincingly that certain substances fail ordinarily to get into the urine because the renal cells are impermeable to them as they seem to be for colloids like the proteins, this, too, could readily be understood. But the so-called threshold phenomenon — the fact that glucosuria is dependent on a more or less pronounced rise in the concentration of a substance ordinarily present in the blood at all times — has been a stumbling block for a diversity of physiologic hypotheses.

One of the first contributions from the newly equipped James Buchanan Brady Urological Institute of the Johns Hopkins University and Hospital[1] offers an explanation of the problem in what appears to be a tenable and demonstrable form. The authors, Peirce and Keith, remind us of two unquestioned facts, namely, that the kidney uses a relatively large amount of oxygen, and that glucose is one of the main sources of energy in the body. It is therefore very probable, they argue, that the kidney normally oxidizes a certain amount of glucose. Hence, even if the boundaries of the renal cells are permeable for this sugar, not all of the glucose that penetrates into the cell will reach the lumen of the glomerulus or kidney tubule. The assumption is accordingly made that sugar normally gains entrance into the kidney cells in proportion to its concentration in the blood. There is no contention that the cell boundaries are in any way impermeable or permeable with difficulty to sugar. During its passage through the cell, some of the glucose is oxidized, as we might expect, and if not too much has entered, it will be oxidized in its entirety and none will appear in the urine.

---

[1] Peirce, G., and Keith, A. M.: The Excretion of Sugars by the Kidney, Proc. Soc. Exper. Biol. and Med., 1915, xii, 210.

Are there any facts in corroboration of this hypothesis? We may cite a few instances contributed by Peirce and Keith: The hourly oxygen requirement of the kidneys has been determined approximately by physiologists. It is found to be of a sufficient magnitude to produce complete oxidation of all the sugar which the kidneys might be expected to excrete if they were completely permeable to sugar. Again, if the kidney cells are actually permeable to sugar, which they in turn burn up, then the sugar content of the renal vein should be lower than that of the arterial blood entering the kidney. This, likewise, is found to be true. Finally, Peirce and Keith are finding that only the sugars which are oxidized by the body will show the so-called threshold phenomenon. They venture the added statement that if the kidney is permeable for a sugar when and only when its concentration in the blood rises beyond a certain level, that sugar is oxidized by the kidney. Carried to its logical consequence, this may be interpreted to mean that any substance which finds its way through the kidneys into the urine, only when its concentration in the blood rises above a certain level, belongs to compounds metabolized by the renal tissue. We shall await further demonstration.

The Autonomic System.—In the average healthy individual there is maintained an equilibrium between these two systems, the autonomic and sympathetic, subject to all the physiologic variations and physical needs of the body. This balance is kept up through the constant stream of stimuli arriving by the nerve paths and also by the direct chemical actions on the system, of hormones from the internal glands, or elsewhere. The points of possible intervention are so innumerable and the variety of stimuli is so great that it seems hopeless ever to be able always to diagnose accurately either the point or nature of the intervention. In marked variations from the normal, one finds many cases which show a pronounced tendency to an over or under action of one or the other system; and by keeping in mind the symptoms of hypertonus or hypotonus of the sympathetic or the autonomic system one finds many individuals who may be classed either as having a vagotonic or autonomic constitution or a sympathicotonic constitution.—J. W. McIntosh, M.D., *Canad. Med. Assn. Jour.*, September, 1915.

Current Comment

OSTEOPATHS AND THE HARRISON LAW

As anticipated, the federal government is having much difficulty in the administration of the Harrison law, owing to the fact that there is no uniform standard as to what constitutes the practice of medicine in the different states. Not only the definitions and provisions of the statutes, but also the decisions of various courts of last resort differ widely on this point. In some states, osteopathy is included in the practice of medicine; in other states, it is legally distinct. The dilemma of the Treasury Department is apparent from its conflicting rulings. Treasury Decision 2232, recently issued, revokes Treasury Decision 2172 and substitutes the following ruling: "Osteopaths should be permitted to register and pay special tax under the provisions of the act of Dec. 17, 1914, provided they are registered as physicians or practitioners under the laws of the state and affidavit is made in application for registration on Form 678 as required by Treasury Decision 2215 of June 10, 1915." This form is the one used by all physicians, and contains a statement sworn to by the applicant that he is practicing medicine at the time of making application. The intent of the Treasury Department in this ruling is obvious. If the ruling had provided for the registration of osteopaths in those states in which they are legally recognized as physicians, there would be no ground for criticism. The inclusion of the term "or practitioners," however, leaves the entire question open to argument. What does the Treasury Department mean by "a practitioner?" This might include Christian Scientists, clairvoyants, seventh sons of seventh sons, and every other fad or form of quackery. But the decision is of slight importance, after all. Suppose osteopaths are allowed to register under the Harrison law. What of it? Such registration will not give them the right to practice medicine, unless they are given this right by the law of the state. Registration under the Harrison law will not confer any right to practice medicine not given by the statutes of the state.

THE DISCOVERY OF ETHER ANESTHESIA

In a recent review of the controversy over the priority of the discovery of ether for anesthetic purposes, Dr. Allen J. Smith[1] has presented, in facsimile, the documentary evidence bearing on Dr. Crawford W. Long's work. Altogether there are eleven pages of photographic reproductions of letters and attestations of various kinds, including particularly the page from Dr. Long's account with James Venable, a patient who permitted Dr. Long, March 30, 1842, to administer ether to him. This was done with the understanding that when Venable had become unconscious, the surgeon was to remove one of two small tumors (wens) on the back of his neck, which, because of apprehension of pain, he had declined to have removed previously. There was the further understanding that if the first tumor was removed without pain under ether anesthesia, then the surgeon was to remove the second. June 6, accordingly, the second operation was performed, permission to do it serving as a demonstration of the success of the first operation. The patient was charged $2 each for "extracting the tumor" and 25 cents each time for the ether. This item from Dr. Long's account book is certified under the hand and seal of P. F. Hinton, the clerk of the Superior Court of Jackson County, Ga., as being "a correct copy of an original entry made in his book for medical services for the year 1842 by Dr. Crawford Long." As C. F. Jackson of Boston, the only other person whose claims for the honor of the discovery of ether anesthesia merit consideration, did not communicate his ideas on the subject to any one until 1843, and then merely verbally to a number of medical friends, and did not suggest it until 1845 to Dr. W. T. G. Morton, who applied it successfully in 1846, the dates in the ether priority controversy are thus cleared up. The other question sometimes discussed, whether or not Dr. Long really appreciated his great discovery, and the assertions often made that he failed to make it known or abandoned the use of ether anesthesia, are all answered by these reproductions, which show very clearly that he continued to use it and to demonstrate its efficiency in spite of opposition on the part of members of the profession around him who could not bring themselves to recognize what a great discovery had been made. The originals of these documents are in the custody of Mrs. Taylor of Athens, Ga., a daughter of Dr. Long. The photographs are deposited in the archives of the University of Pennsylvania, School of Medicine, of which Dr. Long was a graduate. Dr. Smith's reproduction of them in his article[1] has made it possible for practically any one to consult the original documents in the case.

---

[1] Smith, Allen J.: Old Penn, Oct. 2, 1915.

SOCIAL INSURANCE IN CALIFORNIA

The appointment by the governor of California of a commission to study social insurance, and the appropriation of $20,000 for the purpose, is an evidence of the growing interest in this subject. The commission, consisting of five members, is not only directed to study social insurance systems at home and abroad, but is also empowered to recommend schemes for adoption by the state. California has just included occupational diseases within the scope of its workmen's compensation act, and the next logical step is the introduction of an insurance scheme to care for all sickness among wage earners. The more efficient medical care which a system of health insurance would provide for the workers of California is as greatly needed as it was in Great Britain. With the initiation of medical benefit under the British compulsory insurance system, many persons for the first time were able to afford the luxury of medical attention, and for the first time physicians were able to treat disease in its incipient stages among the industrial population. English physicians are expressing their surprise at the mass of suffering which previously was uncared for. The failure of many persons in this country at present to receive medical care constitutes the best argument for a change to the more effectual provision for medical attention offered by health insurance. At this time, when attention is being focused on these forms of insurance new to this country, the American Association for Labor Legislation, after three years of careful study, has prepared the draft of a health insurance bill which, it is announced, will be introduced into several legislatures next winter. This activity justifies the prophecy, previously made by The Journal, that the enactment of workmen's compensation laws would lead to new measures for both health and accident insurance.

DR. JAMES TAGGART PRIESTLEY—A FESTSCHRIFT

In commemoration of his forty years of practice, Dr. James Taggart Priestley, of Des Moines, has been honored by the issuance of a special number of the *Journal of the Iowa State Medical Society*, styled a "Festschrift." It has been done under the auspices of the Medical Library Club of Des Moines. Dr. Priestley well deserves this honor. As is said editorially in the Iowa journal, "the man who can live a generation or more in the sharpest competition, and retain the affection of his associates, is indeed entitled to expressions of the highest regard as distinctly his own. It is delightful to feel that honors gained by manly struggles for the rightness of things may come at a time of mental and physical well-being, and not after the recipient has passed to a state of indifference." Dr. W. L. Bierring gives a brief historical sketch of Dr. Priestley's illustrious great-great-grandfather, Joseph Priestley, the discoverer of oxygen, who, it will be remembered, spent the last ten years of his life at Northumberland, Pa., continuing the work in science which he had carried on in his native England. Dr. Priestley has well maintained the traditions of his family as a scientist, a man of character and strong individuality, and a leader in his sphere of action. In his long career as a practitioner in Des Moines, his impress has been for the uplift of the science and art of medicine, and for the betterment of fraternal relations in the profession itself. This number of the Iowa state society journal is a credit to those who conceived, as well as to those who carried out, the idea — and to the state society itself. It is splendid from a mechanical standpoint, and decidedly creditable in its contents.

HOSPITAL NOISES

The inhabitant of a large community who is without the experience of a temporary residence in one of its hospitals feels a sort of humanitarian pride in the now familiar signs, "Hospital Street — Make No Unnecessary Noise!" A brief stay in some of these institutions is sometimes sufficient to convince one, however, that the faults of others often seem more patent than our own which are nearer at hand. This applies all too often in particular to the subject of hospital noises, which, unfortunately, have not yet everywhere received the degree of consideration and correction which they demand. Few persons who have not given serious thought to the matter will realize the endless sources of noise, which is never soothing to a patient, and not infrequently is the occasion of intense psychic irritation to even the most docile inmate of a municipal health institution. Dr. Byam Hollings[1] of the Massachusetts General Hospital has recently pointed out some of the unappreciated noise factors, which will be recalled by the initiated through the mere mention of a word or two. Doors and elevators are rarely noiseless; windows and floors may creak and reverberate; chairs and ward utensils are famed for squeaks and rattles; the slam of dishes is rarely soothing, and the sound of bells and buzzers never reaches an immune auditor. To all of these and many other varied disturbances must be added the multitude of sounds and noises which are traceable to the human element—nurses, orderlies, porters, employees, visitors, physicians and patients themselves. Dr. Hollings reports that in a routine day more than 3,500 persons passed through a doorway in the main corridor of one of the buildings of the Boston hospital. It is thus easy to see how noise can be created. How to minimize it is a timely problem in every institution.

A LOSS TO THE PUBLIC HEALTH SERVICE

As mentioned in our news columns, Dr. John F. Anderson has resigned the position of director of the Hygienic Laboratory of the U. S. Public Health Service to accept that of director of a commercial biologic laboratory. The Public Health Service has sustained other similar losses recently: Dr. M. J. Rosenau, Anderson's predecessor, resigned to accept the professorship of preventive medicine and hygiene at Harvard; Drs. Reid Hunt and Worth Hale left the service to accept the positions of professor and assistant professor of pharmacology, respectively, at the same institution. It may seem discouraging that the Public Health Service should thus be deprived of the services of able men at the period of their greatest usefulness; at the same time, it is gratifying to realize that educational institutions, as well as some private manufacturing concerns, appreciate the value of such men. While occurrences like these must be discouraging to those who are interested in seeing the Public Health Service successful in its splendid scientific research work, it is a consolation to realize that the service is developing men whose work is appreciated.

TETRACHLORETHANE

Several months ago, attention was directed to the occurrence of an unusual illness among the workmen in some of the aeroplane factories of Great Britain.[2] As a rule, the varied symptoms included a general malaise and drowsiness, followed by more or less severe toxic jaundice. An investigation has revealed that this untoward condition is due to intoxication with tetrachlorethane or acetylene tetrachlorid ($CHCl_2 \cdot CHCl_2$). This substance is well known to industrial chemists, and also goes under the trade name of Cellon. Because of its solvent action on cellulose acetate, acetylene tetrachlorid is a constituent of the product used to coat the wings of aeroplanes. A study of its toxicology shows that it has a decidedly harmful influence on the liver and the kidneys. By ordering the proper ventilation of the workrooms and insuring the efficient removal of the toxic vapors, the dangers from this source can be eliminated.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST; SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ALABAMA

Personal.—Dr. Eugene D. Bondurant, formerly Dean of the University of Alabama, School of Medicine, Mobile, who was operated on last June for duodenal ulcer, has entirely recovered and has resumed practice in Mobile.——Dr. Abijah B. Bennett, Opelika, was struck by an automobile October 10, and sustained serious injuries.

GEORGIA

Drug Victims' Hospital to Close.—It is announced that the Atlanta City Hospital for Drug Victims will be closed November 1. During the existence of the institution, about 150 drug addicts have been treated and pronounced cured.

Personal.—Dr. James S. Greenleaf, Macon, fell from the second story window of his office, October 13, but was not seriously injured.——Dr. Mather M. McCord, Whigham, as the result of a competitive examination, has been appointed full time county health officer of Floyd County.

New Board Officers Elected.—At a meeting of the Georgia State Board of Medical Examiners held October 13, officers were elected as follows: Dr. Richard E. Hinman, Atlanta, president; Dr. Frederick D. Patterson, Cuthbert, vice president; Dr. Charles T. Nolan, Marietta, secretary treasurer.

IDAHO

Examination Required.—Word from the secretary of the Idaho State Board of Medical Examiners states that an examination is still required for the license to practice in that state. It appears that a report to the contrary has been published somewhere and several applicants have sent in their diplomas thinking that they could secure registration by so doing. An examination is essential.

New Officers for Idaho Society.—The twenty-third annual meeting of the Idaho State Medical Association was held at Lewiston, October 13 to 15, forming a part of the triennial joint meeting of the state medical associations of Idaho, Washington and Oregon, and the following officers were elected: president, Dr. Truman O. Boyd, Twin Falls; vice president, Dr. Oscar C. Carssow, Lewiston; secretary treasurer, Dr. Edward E. Maxey, Boise (reelected); and journal trustees, Drs. Robert L. Nourse, Boise, and John N. Alley, Lapwai. Twin Falls was selected as the next place of meeting.

ILLINOIS

Districting the State.—Secretary C. St. Clair Drake of the State Board of Health announces that Illinois will soon be divided into 2,600 districts with a registrar of vital statistics for each district, for the purpose of putting into operation the new state vital statistics law.

Personal.—Dr. Wilfred H. Gardner, Bloomington, is on duty in a British war hospital in London.——Dr. Louis J. Bechtold, Belleville, is ill with tetanus in St. Elizabeth's Hospital in that city.——Dr. John C. Helper, Benbow City, who has been suffering from anthrax, was reported out of danger. October 21.——Dr. Harmon E. Price, Clinton, is reported to have closed his office and discontinued the practice of medicine preparatory to leaving for California in November.——Dr. James A. Kleinsmid, Aledo, who was seriously injured in an automobile accident, October 5, is slowly improving.——Dr. Hugh A. Kelso, Paxton, was operated on in St. Luke's Hospital, September 29.

---

[2] Poisoning by Tetrachlorethane, Miscellany, THE JOURNAL A. M. A., Feb. 27, 1915, p. 766.

State Tuberculosis Society Elects Officers.—At the seventh annual meeting of the Illinois State Society for the Study and Prevention of Tuberculosis held in Danville, October 22 and 23, the following officers were elected: president, Dr. George T. Palmer, Springfield; vice presidents, Drs. Charles W. Lillie, East St. Louis, and Frank D. Rich, Joliet; treasurer, Mr. David R. Forgen, Chicago; and executive committee, Drs. James W. Pettit, Ottawa; Ethan A. Gray, Chicago; Theodore B. Sachs, Chicago; Lewis C. Taylor, Springfield; William A. Evans, Chicago; Mr. George W. Perkins, Chicago, and Mr. Herbert W. Mathews, Pekin.

Chicago

Hospital to Close.—It is announced that the Maimonides (Kosher) Hospital will close November 1, on account of lack of financial support. The hospital is said to have debts amounting to about $100,000.

Personal.—Dr. French S. Cary has been appointed assistant professor of urology and urological surgery, College of Medicine, University of Illinois.—Dr. William S. White, who was operated on at the Evanston Hospital for appendicitis and the removal of gallstones, recently, is reported to be doing well.——Dr. Jabez D. Hammond, who has been ill at his home for several weeks, is reported to be improving.——Dr. Oscar Dodd has been elected president of the Illinois Charitable Eye and Ear Infirmary.——Drs. Duro Guca and Leo M. Czaja have returned after a year in Serbia.

Memorial for Mrs. Preble.—Friends of Dr. and Mrs. Robert B. Preble have undertaken to form a memorial fund for a philanthropic purpose yet to be determined, to express their sorrow over the death of Mrs. Preble, and their sympathy for Dr. Preble and his family. Mrs. Preble had been actively interested in the work of raising funds for the Chicago Collegiate Bureau of Occupations, a bureau which has for its object the securing of positions for women with college training and was also interested in the philanthropic work of the Chicago Women's Club. Any wishing to assist in this work are invited to send checks or inquiries to Mrs. Charles L. Meeks, 5321 Greenwood Terrace.

INDIANA

Dispensary Charges Small Fee.—The Indianapolis City Dispensary, presumably a free dispensary for the indigent, has now decided to charge a fee of 10 cents each for bottles or containers supplied with medicine in the drug department, to those who are able to pay. The fee is entirely voluntary and medicine will not be refused individuals who produce satisfactory evidence of their inability to pay this fee.

Personal.—Dr. Claude C. Crum, Jeffersonville, has been appointed surgeon to the Jeffersonville plant of the American Car and Foundry Company.——Dr. Stephen L. Egart, roentgenologist at the Indianapolis City Hospital, has resigned to take effect, December 15.——Dr. Albert J. Irwin, Goshen, who has been ill for two weeks, has recovered and resumed practice.

Centennial Committeemen Selected.—The following new centennial celebration committees have been announced by the Indiana Historical Commission: committee on medicine, Drs. General W. H. Kemper, Muncie, chairman; William R. Davidson, Evansville; John G. Jones, Vincennes; Joseph D. Heitger, Bedford; William H. Stemm, North Vernon; Joseph H. Weinstein, Terre Haute; Oliver J. Gronendyke, Newcastle; W. Burrette Kitchen, Indianapolis; Frederick A. Tucker, Noblesville; Otis B. Nesbit, Valparaiso; Godlove G. Eckhart, Marion; Elmer E. Morgan, Fort Wayne, and Angus C. McDonald, Warsaw. Committee on hygiene and public health: Drs. William F. King, chairman, Indianapolis; Charles S. Bosenbury, South Bend; Charles A. Zinn, Frankfort; Eric A. Crull, Fort Wayne; Herman G. Morgan, Indianapolis; W. D. Thurber, Indianapolis; Porter H. Linthicum, Evansville; Henry B. Shacklett, New Albany; Charles C. Wert, Covington; Harry J. Thompson, Laporte, and Prof. J. C. Sanders, Columbia City.

IOWA

Tuberculosis Foes Organize.—The Iowa Association for the Prevention of Tuberculosis was organized in Des Moines, October 4, and the following officers were elected: president, Dr. William W. Pearson, Des Moines; vice presidents, Gov. Charles W. Clark, Dr. Walter L. Bierring, Des Moines, and Mrs. Charles Saunders, Council Bluffs; secretary, Dr. John H. Peck, Des Moines; treasurer, C. H. Stevenson, Des Moines, and assistant secretary treasurer, Dr. Herbert V. Scarborough, Oakdale.

Hospital Notes.—Mine workers of Iowa have purchased the old building of the Drake University Medical School, Des Moines, and will use it for a hospital for sick and injured miners and also will use it as a headquarters for their first aid teams.——Marengo is attempting to raise $20,000 for the building of a municipal hospital.——The Cedar Valley and May hospitals, Charles City, have incorporated under the name of the Cedar Valley Hospital. The institution is to be opened with equal rights to all physicians and surgeons of Floyd County.

Distinguished Visitors to Fort Madison.—At the meeting of the Fort Madison Medical Society, October 8, the guests of honor were Dr. William J. Mayo, Rochester, Minn., who spoke on "Surgery of the Spleen"; Dr. Victor C. Vaughan, University of Michigan, Ann Arbor, who delivered an address on "Infection and Immunity"; Dr. Richard H. Harte, Philadelphia, who spoke of "Typhoid Perforation"; and Dr. Donald C. Balfour, Rochester, Minn., who read a paper on "Gastric Ulcers." A reception and banquet were held in the Masonic Hall during the afternoon.

Personal.—Dr. Ernest T. Kegel, Iowa City, county physician of Johnson County, fractured his left leg below the knee while cranking his automobile, recently.——Dr. George L. Day, Lone Tree, is reported to be critically ill at a hospital in Iowa City.——Dr. Henry Matthey, Davenport, has been appointed surgeon in chief of the Military Hospital at Brounsberg, East Prussia.——Dr. Ella Blackburn, physician in charge of the women patients at the Iowa Hospital for the Insane, Mount Pleasant, is said to have been dismissed by the State Board of Control, October 5, as the result of an investigation made by the board of charges filed against the institution by Dr. Amelia A. Dickinson, Iola, Kan., a former intern.——Dr. Wilton W. McCarthy, Des Moines, who was seriously injured in an automobile accident several weeks ago, has returned to his home convalescent from the Methodist Hospital.——Dr. Clara B. Whitmore, Sioux City, started for Shanghai, China, October 4. to take up her new work as surgeon and gynecologist to the Margaret Williams Hospital, Shanghai.——Dr. Walter A. Matthey, Davenport, is under treatment in the Mercy Hospital for streptococcus infection of the left hand contracted recently during an operation.——Dr. Charles H. Cogswell, Cedar Rapids, after a sojourn in Egypt, has decided to return to France and enter the hospital service of the French army.——Dr. Edward R. Ames, Morrice, was seriously injured recently in a collision between his automobile and another motor car.——Dr. Mark F. Boyd, Iowa City, has succeeded Dr. Charles S. Woods, Iowa City, resigned, as state epidemiologist and superintendent of the department of preventive medicine in the medical department of the University of Iowa.

MARYLAND

Civic Club Formed.—A meeting of physicians of Baltimore was held at the Medical Library, October 8, to organize a physicians' civic club, the idea of which is to familiarize physicians with the newer forms of city government.

Memorial Scholarship Fund.—The friends of the late Prof. David Streett, Baltimore, have suggested the establishment of a memorial scholarship in his name at the University of Maryland School of Medicine, for worthy but indigent medical students.

Health Officials Visit Sydenham.—Health Commissioner John D. Blake and Dr. William T. Howard, Jr., the new assistant commissioner, made their first visit of inspection to Sydenham Hospital, the municipal hospital for infectious diseases, to acquaint themselves with the workings of the institution.

Insane Negroes to be Transferred.—The authorities at the Crownsville State Hospital, Dr. Robert P. Winterode, superintendent, have notified the supervisors of city charities that they will transfer about 200 negroes from the insane department at Bay View Asylum to the Crownsville State Hospital, the transfer to take place on or about October 28-29. This means that practically all the negro insane will be removed from this institution and cared for at a state hospital.

Personal.—After a year spent in France caring for the wounded, Dr. Roades Fayerweather has returned to Baltimore. In response to a request of the French officials, Dr.

Fayerweather talked little of conditions in France, but told of the hospital at Pau, where he spent most of his time as the head of the American Red Cross unit.——Dr. John F. Spearman, who has been stationed at the Red Cross Hospital at Glewitz, Germany, has returned to Baltimore.——Dr. Richard P. Strong, director of the International Sanitary Commission in Serbia, reached New York, October 4, on the *Duca degli Abruzzi*. He reports that more than 100,000 deaths from typhus occurred during the present outbreak.——Dr. Frank J. Powers has succeeded Dr. George L. Wilkins, Baltimore, who had been for more than fifteen years physician to the city jail.——Dr. James A. Nydegger has been appointed a member of the Board of Visitors and Governors of St. John's College, Baltimore.

MASSACHUSETTS

Ether Day.—The sixty-ninth anniversary of Ether Day was observed October 16 at the Massachusetts General Hospital. Dr. William Williams Keene, Philadelphia, delivered an address on "The Dangers of Anesthesia" and during the day demonstrations were carried out at the hospital from 10 a. m. to 1 p. m.

Personal.—Dr. Benjamin H. Metcalf, Winthrop, has arrived home after an automobile trip from Winthrop to the Panama Pacific Exposition, San Francisco, in which his machine carried five passengers, baggage and equipment.——Dr. Edward H. Nichols, who recently returned from France, delivered an address before the metropolitan district branch of the Massachusetts Dentists' Society, October 11, on "War Surgery in France."——Dr. Timothy J. Sullivan, Somerville, has been appointed medical attendant for the employees in the postal service.

Changes in Harvard Faculty.—Dr. Martin J. English has resigned as fellow in pediatrics; Dr. Raymond B. Parker as alumni assistant in obstetrics; Dr. Cyrus H. Fiske as assistant in biological chemistry; Dr. Clarence C. Little as research fellow in gynetrics, and Dr. Thomas Ordway as instructor in medicine in Harvard Medical School.——The board of overseers of Harvard College has appointed Dr. Marshall Fabian assistant professor of pathology in the medical school; Dr. Edward A. Doisy assistant in biological chemistry, and Dr. Samuel E. Chiu, Austin, teaching fellow in biological chemistry.

Question of Cures Ruled Immaterial.—In the trial of Francis F. Davies and George J. La Plant, chiropractors, in the supreme court at Springfield, for practicing medicine without a license, attempts were made by the defense to introduce evidence to show that "cures" had been *effected.* These questions were ruled out as immaterial. Judge Irwin stated that the question of cures was not at issue and it made no difference if the men performed miracles. He declared the question at issue was whether or not the men had engaged in the illegal practice of medicine as charged. The defendants were fined $500 each. This trial is thought to establish definitely the legal status of chiropractic in Massachusetts. The supreme court in the Zimmerman case decided a few months ago that chiropractic was the practice of medicine and the present case has decided that it is not simply massage. Its followers, therefore, are subject to the requirements of the medical practice act.

MINNESOTA

Physicians' Building Planned.—Plans have been prepared on Second Avenue, Minneapolis, between Sixth and Seventh streets, for a twelve-story building to be used by physicians. The building will cost about $1,000,000.

Dermatologists Organize.—The Minnesota Dermatological Society was organized at a meeting held in Minneapolis, October 19, members being present from Minneapolis, St. Paul, Duluth and Rochester. Regular meetings will be held four times a year alternately in St. Paul and Minneapolis.

Personal.—Dr. Bert R. Karn, Ortonville, was operated on for appendicitis, October 11, at the Grand View Hospital, Ortonville.——Dr. Louis S. B. Robinson has resigned as assistant superintendent of the Minnesota State Sanatorium for Consumptives and will return to his practice in St. Paul in November.——Dr. Joseph Nicholson, Brainerd, was operated on for appendicitis, recently.——Dr. Owen J. Evans, Minneapolis, was operated on at Hill Crest Hospital, October 9, for osteomyelitis of the left femur.

MISSOURI

Petition for Quarantine of Syphilitic.—Probably a unique instance in the campaign against venereal diseases is the issuing of an injunction in Springfield to quarantine a woman afflicted with syphilis. The health commissioner submitted a petition to the court for such an injunction, and the court, of which the judge is the Hon. Arch A. Johnson, granted his petition and the woman was placed in a hospital and compelled to take treatment. The text of the petition follows:

IN THE CIRCUIT COURT OF GREENE COUNTY, MISSOURI.
DIVISION NO. 2, SEPTEMBER TERM, 1915.

Edwin F. James, City Health Commissioner, Plaintiff
vs.
Margaret Dale, Defendant

Plaintiff states that he is the Public Health Commissioner of the City of Springfield and as such is charged with the care and responsibility of the health of the citizens of said city.

Plaintiff states that the defendant is an unmarried female of the age of about twenty years and is a resident of said City of Springfield, Missouri.

Plaintiff states that the defendant Margaret Dale is now infected and has for sometime past been infected with a venereal disease, to-wit, with the disease commonly known as syphilis.

Plaintiff states that defendant is a woman of bad repute and plies her vocation of a common bawd and habitually offers herself and her body for sexual commerce in the said City of Springfield and at other points in Greene County, Missouri, and is now exposing herself in said county on the banks of James River for sexual commerce, and as plaintiff is informed and believes, is now engaging in such sexual commerce with divers persons to plaintiff unknown.

Plaintiff states that by reason of the premises the defendant is a menace to the health and morals of the community and her unrestrained freedom and acts of sexual commerce constitute her a public nuisance and a menace to the people of said county and City of Springfield.

That by virtue of the laws creating the office now held by plaintiff, he is in law charged with the maintenance of good health and is charged with the duty of keeping said City free and clear of contagious and infectious diseases and is charged with the duty of safe-guarding said City and its inhabitants from disease and death.

Plaintiff states that unless his prayer herein be granted he is remediless at law and no action in law will afford plaintiff an adequate or full and complete remedy at law.

Plaintiff states that for the safe-guarding of the health of the community defendant should be quarantined for said disease and should be restrained from plying her vocation and should be restrained and placed under such charge as will prevent the spread of such disease.

WHEREFORE, Plaintiff prays that a temporary writ of injunction issue commanding that she be limited to her movements to a certain specified quarter and that she be placed under the care of a competent physician until she be purified and cleansed of such disease.

EDWIN F. JAMES, Plaintiff.
By T. J. DELANEY & PERRY T. ALLEN, his attorneys.

NEW YORK

Insane Hospital Changes.—Dr. John C. Feltz, assistant to the medical director of the State Hospital for the Insane at Schenectady, N. Y., has resigned and will make his home at Gettysburg, Pa., and has been succeeded by Dr. Edgar B. Funkhouser.——Dr. Hibbert R. Roberts, Rochester, N. Y., has been appointed assistant physician to the Dannemora State Hospital for the Insane.

No Danger of Anthrax Epidemic.—The State Industrial Commission has contradicted the rumors that there is danger of an epidemic of anthrax in this state. According to the records of the agricultural department anthrax was reported in animals in fifteen counties in 1913, in sixteen counties in 1914, and in ten counties thus far in 1915. Aside from the cases reported in the three metropolitan districts, six cases with two deaths have been reported from other counties.

Lay Cornerstone at Letchworth Village.—The laying of the cornerstone of the new attendants' home at Letchworth village for the feebleminded, October 19, marks another step in the progress of this institution. On this occasion the president of the board of directors, Frank A. Vanderlip, announced that $750,000 had thus far been expended on permanent improvements for the village and that the total cost would be about $3,500,000. Governor Whitman laid the cornerstone and in his address announced his policy of dealing with the increasing number of insane persons in this state. He recommended the establishment of five new dispensaries as an aid to the home treatment of incipient insanity in connection with the hospitals for the insane at Buffalo, Binghamton, Middletown, Utica and Willard. In the hospitals already having dispensaries, he unfolded plans for an extension of that line of work. Through special efforts of the hospital commission last year the number of patients on parole was increased by 439. Each patient cared for at home represents a saving of $208 for the state.

New York City

Memorial to Dr. Flint.—At a meeting of the faculty of Cornell University Medical College October 15, a memorial to Dr. Austin Flint was read and adopted. This memorial sets forth the achievements of Dr. Flint as a scientist, teacher and orator.

Society for Care of the Aged.—The New York Geriatric Society was recently organized with the object of studying diseases of advancing years. Dr. Robert Abrahams was elected president; Dr. Edward P. Swift, vice president, and Dr. Ignatz L. Nascher, secretary.

Greater New York Medical Association.—At the meeting of the Medical Association of the Greater City of New York held in DuBois Hall of the New York Academy of Medicine, October 18, Dr. E. Bosworth McCready, Pittsburgh, read a paper entitled "Paedology and Its Possibilities; the Study, Treatment and Education of Children Who Require Special Attention," illustrated by lantern slides.

Personal.—Dr. Vernon O. Heddens sailed for France as assistant surgeon with a hospital unit, October 16.——Dr. Merrill N. Foot, Richmond Hill, returned October 5 on the *Rochambeau*, after several months on duty with Mrs. Harry Payne Whitney's Hospital at Juilly.——Dr. Mary M. Crawford, Brooklyn, has returned after nearly a year of service with the American Ambulance Hospital near Paris.

Cornell Medical College Opening.—Cornell University Medical College entered on its eighteenth year with an excellent enrollment. Dr. John A. Hartwell, president of the Cornell Medical Society, presided at the opening exercises, at which addresses were made by Mr. Arthur F. Cratzer, representative of the senior class, and Dean William M. Polk, who spoke on the "Advance in Modern Medicine."

No More Horse Ambulances.—All horse drawn ambulances used in the service of the city hospitals in Manhattan and the Bronx, including Bellevue, Gouverneur, Harlem and Fordham hospitals, have been withdrawn from service and replaced by motor ambulances. Some of the horses just retired have been in the service twenty years and will be transferred to the city's inebriate farm at Warwick, N. Y. Both efficiency and economy will result from this change.

Request for Census Granted.—It has just been announced that Mayor Mitchell has granted the request of Commissioner Sigismund S. Goldwater for a census of Manhattan to be taken by the police following the election. This step has resulted from the failure of the state census board to furnish the department with any satisfactory figures from the state census of last spring. The department's calculations, hitherto generally accurate, have shown 600,000 more persons in the city than the number indicated by the state census board. If a large discrepancy is found between the figures obtained and those of the state census board, a census of the other boroughs will also be taken.

Report on Laboratory of Health Department.—At the special request of Commissioner Sigismund S. Goldwater, the medical societies of the counties of New York and Kings appointed a committee last May for the purpose of investigating the diagnostic laboratories of the department of health. A report based on this investigation has just been submitted to the health department. It states that containers and supplies are sometimes lacking at the different stations; that specimens are not collected after 4 p. m. and that transportation facilities to and from the department are slow and often burdensome. The investigating committee mentions the need of additions to the present staff, and advises that incubators be operated in certain boroughs for diphtheria cultures and a collection made at a later hour than is now customary. It suggests further the operation of several automobiles for the purpose of collecting specimens and carrying supplies.

NORTH CAROLINA

Personal.—Dr. Robert Crawford, Rock Hill, has returned after a service of about one year in Germany with the Red Cross.——Dr. Benjamin F. Royal, Morehead City, has been appointed a member of the board of directors of the Eastern Hospital for the Insane, Goldsboro, succeeding Dr. W. E. Headen, Morehead City, resigned on account of ill health.

Hospital Notes.—The contract for the Edgecombe Central Hospital has been awarded by the county commissioners to a firm of contractors in Sanford for $10,693.——Drs. Byrd Charles Willis and Edmund Simpson Boyce announced that they have taken over the management of the Parkview Hospital, Rocky Mount. Drs. J. P. Whitehead, Ivan P. Battle, Richard H. Speight, Jr., Emil B. Quillian and Joe P. Speight will continue their connection with the hospital as before and Drs. George Ben Johnston and A. Murat Willis, Richmond, Va., will continue as consulting surgeons on the staff. ——The Baby Hospital in the Bear Annex to the James Walker Memorial Hospital, Wilmington, closed September 29 after a very successful season in which fourteen babies were under treatment, ten of whom were returned to their parents recovered, two died and two were still under treatment at the time of the closing of the institution. The management hopes to have a building of its own by May 1 of next year.

PENNSYLVANIA

Personal.—Dr. William S. Wheeling, Spangler, is ill in the Spangler Hospital with appendicitis.——Dr. David H. Bemis, West Middletown, is reported to be ill with bronchitis.——Dr. John G. Thomas, Newton Square, is reported to be critically ill as the result of a bite of a poisonous insect. ——Dr. Warren E. Forsythe has been placed in charge of the health service of the Pennsylvania State College.——Dr. Daniel P. Maddox, Chester, has been reappointed a member of the Medical Bureau of Medical Education and Licensure.

Philadelphia

Funds for Negro Hospital.—More than 200 workers started October 19, on a ten-day campaign to raise $150,000 for the Lincoln Memorial Hospital for negroes.

Lip-Reading Clinic Opened.—The first lip-reading clinic was held at the Polyclinic Hospital, October 12, under the instruction of Dr. G. Hudson Makuen. Clinics will be held at the hospital every Tuesday, Thursday and Saturday afternoon, from 2 to 3 o'clock.

Reception to Surgeon-Generals.—A reception was given October 15 by the Medical Club of Philadelphia at the Bellevue-Stratford, in honor of Rear Admiral William C. Braisted, Surgeon-General, U. S. Navy, and Surgeon-General Rupert Blue, U. S. P. H. S.

Personal.—Dr. William G. Spiller, assistant professor of neurology in the University of Pennsylvania, was elected professor of neurology, October 18, succeeding Dr. Charles K. Mills, resigned, and elected emeritus professor of neurology.——Dr. Eileen Giles has been appointed physician in charge of the Alto Pass (N. C.) Hospital.——Dr. Melvin M. Franklin has been elected orthopedic surgeon to the Philadelphia General Hospital, to succeed Dr. Gwilym G. Davis, resigned after fourteen years' service.——Dr. J. Torrance Rugh has been elected professor of orthopedic surgery in the Woman's Medical College.——Dr. John W. West was recently elected president of the Ohio Society.——Dr. Michael G. Wohl has resigned as pathologist to the Howard and Samaritan hospitals to take charge of the pathological laboratory of the Nicholas Senn Hospital, Omaha.——Dr. John M. Baldy has been reappointed a member of the State Bureau of Medical Education and Medical Licensure by Governor Brumbaugh.——Dr. Henry A. Strecker has been appointed chief medical inspector of the Bureau of Health, to succeed Dr. Charles A. Groff, resigned.——Dr. Florence C. Child has been appointed medical inspector of the organization of Child Hygiene.

TEXAS

Hospital Opened.—The joint City and County Hospital, Wichita Falls and Wichita County, was opened to patients, October 15.

Upholds Vaccination Law.—After two years of litigation the supreme court of Texas has upheld the right of school boards to compel the vaccination of children before they will be allowed to enter the public schools. This decision was rendered in the case of Dr. A. D. Zucht against the San Antonio School Board, mention of which was made in The Journal at the time the action was begun.

CANADA

Hospital News.—The offer made several months ago by Dalhousie University, Halifax, N. S., to supply a hospital for overseas service has been accepted by the Canadian Militia Department. The following have offered to man that hospital: Drs. John Stewart, J. G. MacDougall, George M.

Campbell, J. R. Corston, L. M. Murray, E. V. Hogan and A. G. Nicholls. It is possible that the hospital will go to Alexandria, Egypt.——No. 6 Stationary Hospital supplied by Laval University is now up to full strength. It may leave for the front any day. The commanding officer is Lieut.-Col. G. E. Beauchamp; Majors J. O. D. LaCroix, J. P. Décarie and Georges Bourgeois; Capt. J. A. Lussier; Lieuts. J. U. Gariepy; J. de G. Joubert, J. E. Lorrain, L. D. Collin, Henri M. DuHamel.

Ontario Medical Commission.—The University of Toronto and the Ontario Medical Association presented their views to the Ontario Medical Commission during the past week. For the university, President R. A. Falconer was the chief speaker. He stated that every man who wants to practice the art of healing should have the proper medical training. If he wants to improve on that and become an osteopath, or chiropractor, well and good. President Falconer believed the university had a duty to perform to the public in preparing doctors for the world and was emphatic in his views regarding the danger of allowing men unlearned in medicine to practice at will. He pointed out that any modern school for medical practitioners was kept up at great expense to the community, and it was worth it, because, once prepared, a doctor gave long service to the community.——Replying to a question of the commissioner, Dr. Clarke, superintendent of the Toronto General Hospital, stated he did not favor osteopaths and chiropractors being allowed the privilege of treating patients in the hospitals, under existing conditions. He pointed out that all the medical students of the University of Toronto finish their training in the hospitals and only those can be allowed in who have proper medical training.——Dr. Harry B. Anderson, president of the Ontario Medical Association; Dr. R. A. Reeve, Toronto; Dr. Charles Sheard, Toronto; Dr. Howitt and McKinnon of Guelph, and others spoke for the Ontario Medical Association.——The chiropractors were also given a hearing.——Next week the commissioner announced he would take evidence under oath. The Academy of Medicine, Toronto, will be represented by several speakers or witnesses, who will deal with military surgery and sanitary science, life insurance examinations, surgery, bacteriology, etc.

Personals.—Word comes from England that Lieut.-Col. Walter McKeown, M.D., Toronto, stationed at Folkstone, England, has been appointed president of the Medical Pension Board. It is likely this refers to Canadian soldiers, although it is understood that the University of Toronto Base [illegible] Dr. McKeown was attached had gone [illegible] and was stationed *in Sicily* and would most probably be used in connection with the campaign in Serbia.——Dr. John M. Robb, Blind River, Ontario, has been selected as the conservative candidate for the Ontario legislature for Algoma.——Dr. Hugh A. Farris, Lake Edward, Que., has been appointed medical superintendent of the St. John County (N. B.) Sanatorium.——Dr. Joseph A. Leduc, Montreal, has been appointed head physician of the Foundling Hospital of the Grey Nunnery, in succession to the late Dr. Isiäe Cormier.——Capt. George R. Philip and Reginald S. Pentecost, Toronto, have been gazetted to the rank of majors.——Lieut.-Cols. Geo. S. Rennie, Hamilton, and Lorne Drum, Ottawa, have been promoted to temporary colonels. Both are serving abroad.——Dr. William Mann, Winnipeg, is temporary medical officer of the twenty-third reserve battalion, at present in England.——Col. Robert J. Blanchard, Winnipeg, is the president of the permanent board at Moore Barracks Hospital.——Dr. A. C. Scott, Indian Head, Sask., has been appointed to the medical staff of the Canadian forces in England.——Drs. George A. Ings and Frank H. Newburn, Calgary, Alta., have been gazetted majors in the Royal Army Medical Corps.——Dr. James W. Richardson, formerly of Calgary, has been appointed surgeon-specialist in the Imperial Army.——Major Charles A. Peters, M.D., Montreal, has been gazetted lieutenant-colonel.——Lieut.-Col. Archibald E. Ross, Sutherland, Sask., has been appointed assistant director of medical services of the first Canadian division.

GENERAL

Southern Medical Association to Meet.—The annual meeting of the Southern Medical Association will be held in Dallas, Texas, November 8 to 10. The general convention meetings will be held in the City Hall auditorium.

Ohio Valley Physicians to Meet.—The seventeenth annual convention of the Ohio Valley Medical Association will be held in Evansville, Ind., November 3 and 4, under the presidency of Dr. E. Otis Smith, Cincinnati. The headquarters of the association will be at the hall of the Evansville Business Association.

Pediatrists Organize.—The Central States Pediatric Society was organized in Chicago, October 15, and the following officers were elected: president, Dr. Borden S. Veeder, St. Louis; vice president, Dr. Olin W. Rowe, Duluth, Minn.; and secretary-treasurer, Dr. Clifford G. Grulee, Chicago. The next meeting will be held in St. Louis.

Alumni Election.—On October 16 the Massachusetts General Hospital Alumni Association held its annual meeting and banquet in Boston and the following officers were elected: president, Dr. Elbridge G. Cutler, Boston; vice presidents, Drs. Walter Channing, Brookline; George K. Sabine, Brookline, and William S. Thayer, Baltimore; and secretary-treasurer, Dr. Byam Hollings, Boston.

Return from Typhus-Stricken Serbia.—Four American physicians who have played a prominent part in combating typhus fever in Serbia, arrived in Boston on the *Cretic* last week. They include Dr. Louise Taylor Jones, Boston; Dr. Thomas W. Jackson, Washington, D. C., who succeeded Dr. Richard P. Strong as head of the American Sanitary Commission in Serbia; Dr. Joseph R. Thompson, Cleveland, and Dr. George W. Mellon, Beaver, Pa.

First Aid Treatment for Workmen.—At the convention of the National Association of Industrial Accident Boards and Commissions, held in Seattle, September 30 to October 2, quicker and more adequate medical treatment for injured workmen was vigorously advocated. Dr. Raphael Lewy, New York City, declared that of the 6,000 cases of injury he had examined in the past year 18½ per cent. had developed infection as the result of the lack of timely and expert treatment.

Railway Surgeons Meet.—At the annual meeting of the American Association of Railway Surgeons held in Chicago, October 12 to 15, *the following officers* were elected: president, Dr. Frank T. Fort, Louisville, Ky.; vice presidents, Drs. John M. Dodd, Ashland, Wis.; Edward H. Griswold, Peru, Ind., and Charles P. Frantz, Burlington, Iowa; and treasurer, Dr. Henry B. Jennings, Council Bluffs, Iowa. Asst. Surg.-Gen. William Colby Rucker, U. S. P. H. S., read a paper before the association on "Intent and Purpose of the Interstate Quarantine Regulation."

Convention of Southwestern Physicians.—The Medical Association of the Southwest held its tenth annual meeting at Oklahoma City, October 11 to 13, under the presidency of Dr. Jefferson D. Griffith, Kansas City, Mo. Fort Smith, Ark., was selected as the meeting place for 1916, and the following officers were elected: president, Dr. Joseph D. Becton, Greenville, Texas; vice president, Dr. Edward H. Martin, Hot Springs, Ark., and secretary-treasurer, Dr. Fred H. Clark, El Reno, Okla. (reelected).

Mississippi Valley Medical Association Meeting.—The forty-first annual meeting of the Mississippi Valley Medical Association was held in Lexington, Ky., October 19 to 21, under the presidency of Dr. Hugh Cabot, Boston. Indianapolis was selected as the next place of meeting and the following officers were elected: president, Dr. Willard J. Stone, Toledo, Ohio; vice presidents, Drs. Channing W. Barrett, Chicago, and Carl Lewis Wheeler, Lexington, Ky.; secretary, Dr. Henry Enos Tuley, Louisville, Ky. (reelected); and treasurer, Dr. Samuel C. Stanton, Chicago (reelected).

Conservation of Life.—The keynote of the Safety First Federation of America in Detroit, October 19 and 20, was the conservation of life, limb, health and property. Among the means to this end recommended by the association, are, the enactment of laws prohibiting the sale of dangerous weapons and explosives; the supply of free antitetanus serum by state and municipal authorities to be so placed that it can be conveniently and quickly obtained; the prohibition of the sale of firearms; the prohibition of common drinking cups and roller towels, and of spitting in public places and on sidewalks; the establishment of public baths in cities and the medical and dental inspection of school-children.

Bequests and Donations.—The following bequests and donations have recently been announced:

Children's Seaside Home of Atlantic City, N. J., $1,000; St. Timothy's Hospital, Philadelphia, $15,000, to endow three free beds in memory of Samuel L. Robeson, Sr., and Hannah W. Robeson, Samuel L. Robeson, Jr., and Louise Robeson, and Thomas A. Bradley and Mary A. Bradley, respectively, and $5,000 to the Home for Incurables, Philadelphia, for the endowment of a free bed in memory of Samuel L. Robeson, Jr., and Louise E. Robeson, by the will of Sarah J. Robeson.

Kansas University School of Medicine, $30,000, by the will of Dr. Joseph L. Porter, Paola, Kan.

Boston Floating Hospital, $25,000, to be known as the Nellie Ingalls Hodges fund, by the will of Walter William Hodges, Brookline, Mass.

Pennsylvania Hospital, Philadelphia, about $50,000, for the endowment of three beds in memory of her son Robert Hane Pile, by the will of Elizabeth Pile.

Polyclinic Hospital, Philadelphia, for a free bed as a memorial to Charles Baeder; St. Luke's Hospital and Northern Home for Friendless Children, Philadelphia, each $5,000, by the will of Julia Baeder.

Alvarenga Prize.—The College of Physicians of Philadelphia announces that the Alvarenga prize for 1915 has been awarded Dr. Joshua E. Sweet, Philadelphia, for his essay entitled "The Surgery of the Pancreas," and that the next award of the prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about $250, will be made July 14, 1916, provided that an essay, deemed by the committee of awards to be worthy of the prize, shall have been offered. Essays may be on any subject, but must not have been published. They must be typewritten and if in any language other than English, it must be accompanied by an English translation, and must be received by Dr. Francis R. Packard, secretary of the college, 19 South Twenty-Second Street, Philadelphia, on or before May 1, 1916. Each essay must be unsigned, but must be plainly marked with a motto, and be accompanied by a sealed envelope bearing outside the motto of the paper, and within, the name and address of the author. The successful essay, or a copy of it, is to remain in the possession of the college and other essays are to be returned on application within three months after the award of the prize.

LONDON LETTER

London, Oct. 8, 1915.

The War

THE OPENING OF THE MEDICAL SCHOOLS

The medical schools are opened this session under very unusual circumstances. The war has not only depleted the staffs and the students already in the schools, but has also limited the number of entries. The only London school which is able to record an increase in the number of students entering this year is the London School of Medicine for Women, where the increase is a record one, in consequence of the great demand for women physicians brought about by the shortage of men resulting from the demand of the army. In many of the schools the usual opening address was dispensed with. At Charing Cross Hospital, Dr. R. M. Burrows, principal of Kings College, said that the colleges and hospitals of London had done yeoman service in putting their students and their apparatus entirely at the service of the government and the nation during the war. At King's College a class for the training of munition workers was started, and it had proved the model for other classes instituted in the London County Council Polytechnics. Universities, colleges and hospitals in London and throughout the kingdom had placed the brains of their scientists at the service of the special problems of the moment. It was for the universities to show that they could make their education flexible. While they should welcome every opportunity to do definite war work, they had also to lay stress on the general principle that no nation went under except through a lack of brain power, and that financial and military successes were, after all, as much dependent on education as literature or science.

At the Leeds medical school the opening address, on "Science and War," was delivered by Sir William Osler, who treated the subject in his usual historical and literary manner. The following is a picture given by him of a huge British hospital camp "somewhere in France" containing thousands of beds: "The inner lining of the tents was of a colored Cawnpore material with attractive patterns. More beautiful wards cannot be imagined, so rich and varied in coloring. And to the call of country and humanity are men and women from all parts of the English-speaking world, seasoned old veterans of the Army Medical Corps, consultants from London and Edinburgh, specialists of distinction, general practitioners, men from Australia and Canada looking after their special hospitals, with units of our brothers from Harvard University and from Chicago. Some of these groups; as that from McGill University, Montreal, have brought over a complete staff, with nurses and orderlies and all the necessary apparatus for a 1,040-bed hospital. Other Canadian university units have come from Toronto, Kingston, Laval and Dalhousie. At home the members of these staffs are busy teachers and practitioners. The nurses have come from all parts of the empire, and two groups from the United States." Dealing with the subject of the war and international science, he said that to one who is by temperament and education a follower of Sir Thomas Browne and free from the "common antipathies" and "national repugnances," one sad sequel of the war will be, for this generation at least, the death of international science. "An impassable intellectual gulf yawns between the Allies and Germany, whose ways are not our ways and whose thoughts are not our thoughts."

At the London School of Medicine for Women, Dr. Florence E. Willey said that the lack of labor which is being increasingly felt on all hands has opened the doors of various industrial pursuits to women who had long desired such an outlet for their energies, and has come as a call to service to others who had never before awakened to any need to use their talents for the common weal. The summons to women to fill up the ranks has come from all kinds of professions and trades, but in none perhaps is the demand more urgent than in the medical profession, and that for many reasons, immediate and future. The ever-increasing number of medical men and women employed in military service abroad, together with the number employed in either whole or part time military service at home, has taxed the resources of the medical profession to the utmost, for in these ways the war has directly absorbed the services of many thousands of physicians. But in more indirect ways the war is creating a future need which threatens to be very serious indeed. Young men who would now be entering on a training for some professional career are enlisting for naval or military service, and thus the supply of medical students in the men's schools is seriously diminished, and this means for years to come decreasing numbers of men in the profession of medicine. If men are to answer the call of their country at this crisis they cannot make good this deficiency; hence women must; and that they are willing to do so is made clear by the doubling of the usual entry to the London School of Medicine.

BERLIN LETTER

Berlin, Sept. 28, 1915.

Personal

September 23, Professor Waldeyer celebrated his fiftieth professorial jubilee. At the time of his appointment he was a professor of pathologic anatomy in Breslau, and not until 1872, when he was called to Strassburg, was he appointed professor of normal anatomy. October 6 he will celebrate his seventy-ninth birthday.

Prof. Ernst Neumann, formerly director of the pathologic institute in Königsberg, and a well-known authority on diseases of the blood, celebrated the sixtieth anniversary of his doctorate, September 24. On the same day Professor Knauff of Heidelberg, formerly ordinary professor of hygiene and medical jurisprudence, celebrated his eightieth birthday.

Professor Neufeld, division chief at the Institute for Infectious Diseases at Berlin, has been appointed Geheimer Medizinalrat. Since Löffler's death he has been acting director of the institute, a position he will probably fill until after the war, as there is no probability of securing a successor to Löffler's position at this time. All the hygienists and sanitarians are in the field and cannot be persuaded to return to civil work at this time. Furthermore, there is not much choice, because of the scarcity of men from whom a selection may be made. Naturally, one would have to consider Professor Kolle, ordinary professor in Bern, and Professor Uhlenhuth, ordinary professor in Strassburg. Professor Pfeiffer of Breslau and Professor von Wassermann, the two most prominent bacteriologists to be considered for this position, are disinclined to accept the appointment. Wassermann must also be considered a probable successor to Ehrlich, although I do not believe that he will leave his position at the Institute for Experimental Therapy in Berlin.

Professor Schmidt-Rimpler, formerly ordinary professor of ophthalmology died at Halle, September 23, aged 77. While a student, he was a favorite of Albrecht von Graefe, and in 1863, when he completed his examination, he was made assistant at von Graefe's private clinic. In 1864 he took part in the war against Denmark; later he entered general practice and was appointed on the staff of the medical division of the Charité, and in 1866 he again took the field against Austria. When Graefe established his own service in the Charité in 1868, Schmidt-Rimpler was appointed his assistant. Von Graefe died in 1870, and Schmidt-Rimpler conducted the clinic until a successor was appointed, as he himself had received a call to Marburg. He remained at Marburg until 1891, then went to Göttingen, and in 1901 was called to Halle. He remained in active service until last year, and took an active part always in the development of ophthalmology, contributing many hundreds of articles on the subject. These appeared in current literature and also as a part of collaborated works. His best-known publication was a textbook on diseases of the eye and ophthalmoscopy, which was published in English, Italian, Russian and Japanese. He was also very much interested in the question of shortsightedness among schoolchildren.

The Commandments Governing the Relations of the Public with the Doctor

The medical society of Frankfort has elaborated ten commandments or rules to govern the relations of the public to the doctor. These rules have been printed and the doctors are asked to distribute them among their patients and to post them in their waiting rooms. The rules are as follows:

1. Do not call the doctor unnecessarily for trivial illness, and do not wait too long in the case of serious illness or until the illness has reached such a stage of severity that it is imperative to call the doctor. Much valuable time may be lost by delay in securing medical assistance.

2. If your condition permits, consult the doctor during his office hours and do not ask him to come to you. Some examinations can be made only in the doctor's office, where certain instruments which cannot easily be transported are kept.

3. If you have decided that you will call the doctor, inform him to that effect before he leaves his home to make his calls; that is, before 9 o'clock in the morning. The doctor must lay his plans for the day's work ahead of time, and if you wish to assure yourself of an early visit, send in an early call.

4. Do not ask the doctor to call at a certain hour, but leave the time for making a visit to him, if your case is not urgent or not an emergency case which demands an immediate response to your call. The doctor is never master of his time, and it is very difficult for him to make a visit at a certain time. The business man should not expect his doctor to time his call at the noon hour when the former can leave his business and be at home. If he cannot consult the doctor during office hours, he should go home and remain there until the doctor can come to see him.

5. Do not ask the doctor to come immediately when it is not necessary. Such a visit, being an emergency visit, is combined with great inconvenience and loss of much time, as it interferes with other work. At the same time, other patients who should be visited first are slighted thereby.

6. Never call the doctor at night except in an emergency case. The doctor is human, and like every other man must have his rest. A tired, worried and overworked doctor, one who is frequently disturbed in his sleep, naturally cannot render such efficient service to his patient as he could if his rest were not broken so much.

7. On Sunday the doctor should be allowed to rest. No demand should be made on his time, except when his services are absolutely needed.

8. If a doctor is needed to answer an emergency call, please do not notify more than one man at the same time. If, in the confusion of the moment, more than one doctor has been called, countermand multiple calls as soon as possible.

9. When the doctor is expected, please have everything ready for him so that time will not be lost. Above all things, do not expect the doctor to wait to see you, but have your room and yourself in readiness to receive him. Have water, soap and towel in readiness for him, likewise pen and ink and anything else that might be needed by him, to avoid delay.

10. Do not detain the doctor unnecessarily during his office hours. Other patients are waiting to see him, each in his turn, and lost time may be a valuable item for them. Furthermore, other patients are awaiting the doctor at their homes. Female patients should be prepared to submit to any examination with as little loss of time as possible, and be so dressed that they can leave the office quickly and without the assistance of a maid.

PARIS LETTER

PARIS, Oct. 7, 1915.

The War

THE OPERATION OF THE MEDICAL SERVICE DURING THE RECENT BATTLES

M. Justin Godart, assistant secretary of the medical service in the war department, has gone to inspect the working of the measures adopted to assure the rapid transportation and the suitable distribution of the wounded after the recent battles of Champagne and Artois. In an interview he said that on the battlefield automobiles have been multiplied and have come up to the first aid posts whenever this was possible. The sojourn of the wounded on the field has been reduced to the minimum. By agreement with the railway companies, the average speed of the medical service trains has been from 30 to 45 kilometers (from about 18½ to about 28½ miles). Moreover, these trains have not remained more than an hour at the stations. The wounded have arrived in Brittany twenty-four hours after the receipt of their wounds; in Paris fourteen hours after; in Fontainebleau sixteen hours.

M. Godart declared that many operations had been performed in surgical automobile ambulances under excellent conditions. As things are, however, it seems that these ambulances play an ill-defined rôle. When kept moving too exclusively, they do not render sufficient service; when left in one spot they merely duplicate the service of the fixed ambulance units. Something else is required: operation and sterilization rooms, without surgical staff, coming to the aid of incumbered units.

The assistant secretary finds the general hygienic conditions excellent. Tetanus has almost disappeared. Gaseous gangrene has greatly diminished. The hygienic condition of the troops is equally good. Strict orders have been given for the removal of filth and refuse and its incineration, for the disinfection of buildings and for the suppression of flies. Soldiers in camp do not sleep directly on the ground, but always on raised beds of brush. The medical officers of the regiments are directed to obtain the cooperation of the municipalities for strict sanitation within municipal limits at all costs. Laundry wagons with driers permit the perfect cleansing of the soldiers' linen. Thanks to these measures, diseases which were so destructive in previous wars at present play an insignificant rôle.

SCHOOL BUILDINGS UTILIZED AS HOSPITALS

An arrangement has been concluded between the minister of public instruction and the assistant secretary of the medical service by which a certain number of school buildings, utilized up to the present as hospitals, have been or soon will be restored to their use as schools. All these changes are being made with the sole design of reconciling the demands of the national defense and the welfare of the wounded with the interests of education. In no region has the number of beds for the use of the wounded been diminished, the restoration of the school buildings having been made possible by the substitution of other buildings, the creation of new hospitals or the expansion of existing hospitals. The minister of public instruction has given specially definite orders for the disinfection of the buildings thus returned to normal use, so that the pupils may find them in perfect hygienic condition.

THE REPORT OF THE AMERICAN RELIEF CLEARING HOUSE

The semi-annual report of the American Relief Clearing House, of which I have mentioned the activities in previous letters (THE JOURNAL, Aug. 28, 1915, p. 213 and Sept. 18, 1915, p. 1042), has just been published.

The total number of boxes received by the central committee of the American relief, coming from all parts of the United States, exceeds 15,000. Of these, 1,500 are from the American Red Cross, of which the central American committee is the official representative in France. Among the other American organizations which have contributed are the Lafayette Committee of New York, which gave 750 boxes and bales, containing 25,000 outfits, or a total of 505,000 useful articles for the soldiers at the front; the American Girls' Aid Society, which gave 2,000 boxes, containing more than 100,000 pieces of clothing for the refugees; the American Commission of Aid for Belgium (the Hoover Commission) which gave 1,000 boxes of clothing; the War Relief Committee, which contributed 6,000 boxes and bales; the Vacation War Relief, which gave about 900 boxes; and so on without mentioning a large number of private donors. All these supplies have been transported from New York to France without expense, thanks to the courtesy and generosity of the Compagnie générale transatlantique. The gifts, composed of the greatest variety of objects, represent an estimated value of 10,000,000 francs ($2,000,000). The supplies have been distributed directly by the central committee, with the aid of the French government, to more than 600 hospitals and medical institutions; to about 500 workshops and aid organizations of all kinds situated in all parts of France; also to the soldiers at the front. During one of the particularly active months of summer, there were sent to about fifty prefects about 62,000 pieces of clothing for the civilian population of their respective departments.

The American Central Committee, admirably seconded and counseled by its adjunct French, Belgian, Russian, Italian and Serbo-Montenegrin committees, whose members are the official representatives of their respective governments, foresees numerous and urgent needs springing from the coming winter campaign, and, with its correspondent organization at New York (The War Relief Clearing House for France and Her Allies), is preparing to send numerous new gifts and subscriptions from all parts of the United States.

INCREASE IN THE PRICE OF MILK

The report has lately been published in several journals that the milk supply of Paris is about to be cut off. This is not quite correct. Paris is still being supplied, but on certain days the milk arrives late, for the milk trains have had to yield the right of way to military trains. But, although milk is not going to be lacking in Paris, the price is without doubt going to rise. To supply a city the size of Paris, whose daily consumption amounts to about a million liters (over 250,000 gallons) of milk, a very complicated organization is required. Moreover, the scarcity of labor in the country, the increase in the price of fodder, the sale of a large number of cattle for slaughter, the high price at which they sell and the fact that the dairy regions of the north are invaded—all this has tended to reduce the production and to increase the price of milk.

PERMANENT MISSION OF PROPHYLAXIS

By a decree of the minister of war, a permanent mission of prophylaxis in the zone of the interior has been created under the presidency of the assistant secretary of the medical service for the duration of the war. It comprises: Dr. Baillard, the medical inspector general; Dr. E. Roux, director of the Pasteur institute; Dr. Laveran of the Pasteur institute; M. Brissac, director of Public Charities and Hygiene in the interior department; Dr. Simonin, professor in the Ecole d'application de médecine et de pharmacie militaires du Val-de-Grâce; Dr. Pottevin, member of the Conseil supérieur d'hygiène publique de France.

DISTURBANCES OF THE ARTERIAL CIRCULATION IN RELATION TO WAR

At a recent session of the Académie des sciences, Dr. Moutier read an interesting paper on this subject. All persons whom Moutier has been able to observe after return from the battlefield since the beginning of the campaign present a radial hypotension. In all, the radial tension falls rapidly from the normal 15, to a very inferior figure, which generally varies between 7 and 10. In subjects who before their departure present generalized hypertension, the return of the radial tension to normal is observed, or even, more frequently, a lowering to below normal. This radial hypotension is the consequence of a peripheral vasodilatation, dependent on and compensatory to an internal vasoconstriction. By applications of d'Arsonval high frequency currents locally applied at the abdomen, the arterial circulation is regularized and the radial tension becomes normal again.

Disturbances of arterial circulation are frequently observed at the region of a limb which has sustained a traumatism of war, when they are not observed in the limb on the opposite side. This is manifest when the lesion is in an arm. In the latter case in the injured limb one finds a tension different from that in the uninjured limb; sometimes the tension is higher, but more frequently it is lower; the radial pulse in certain cases may even be imperceptible. A return to normal is observed not only as a result of a local abdominal application, but also after a local high-frequency application at the level of the junction of the limb.

Moutier believes that these disturbances of arterial circulation may have considerable influence on the course and perhaps even on the production of many diseases and complications observed in victims of war (frozen feet, certain atrophies, and retardation of cicatrization or of osseous consolidation).

Marriages

Charles Alexander Balkwill, M.D., Grafton, Wis., to Miss Emma Marie Pinkham of Hillsdale, Mich., October 12.

Lucius Boardman Morse, M.D., to Mrs. Margaret Shepperd Kemper, both of Hendersonville, N. C., October 7.

Eben Wesley White, M.D., Castle Rock, Wash., to Miss Elinor Mae Hibbard of Walla Walla, Wash., October 5.

Alan Richard Welch, M.D., Smithfield, Ill., to Miss Mabel Lee Hinckle of Hinckle, Va., at Cuba, Ill., October 11.

John George Breslin, M.D., Charlestown, Boston, to Miss May Evelyn Taber of Dorchester, Boston, October 6.

Wallace William Smith, M.D., Springfield, Mo., to Carlie Bell Souter, M.D., of Chicago, October 14.

William Gilliam Kennon, M.D., to Miss Elizabeth Thompson, both of Nashville, Tenn., October 12.

Wilbur Paul Rickert, M.D., East Millville, N. J., to Miss Bertha Watkins of Vineland, N. J., recently.

Simon Eugene Driskell, M.D., Alachua, Fla., to Miss Ethel Jones of Jones' Mill, Ala., June 17.

John Hamilton Taylor, M.D., to Miss Jessie Schucraft, both of Chattanooga, Tenn., October 12.

Albert Abrams, M.D., to Mrs. Blanche Schwabacher, both of San Francisco, September 28.

Frederick Johnson Corey, M.D., to Miss Ethel Henninger, both of Havana, Ill., October 6.

Theodore B. Templin, M.D., Gary, Ind., to Miss Gladys Ohbano of Chicago, October 2.

Percy Raymond Pierson, M.D., Readstown, Wis., to Miss Madge E. Starr, September 27.

Curtis Clyde Eves, M.D., to Miss Glodean Smith, both of Philadelphia, October 16.

Horace Gray, M.D., Boston, to Miss Katherine Meeker of Chicago, October 16.

Deaths

John C. Price, M.D. University of Pennsylvania, Philadelphia, 1893; aged 44; a Fellow of the American Medical Association; formerly roentgenologist to the State Hospital, Northern Anthracite Coal Region and Moses Taylor Hospital, Scranton, Pa.; chief medical inspector of the Division of Hygiene and Engineering of the Department of Labor and Industry of the State of Pennsylvania, Harrisburg; a specialist on vocational diseases; died at his home in Camp Hill, Harrisburg, October 13, from nephritis.

James Benjamin Shepherd, M.D. Jefferson Medical College, 1855; aged 81; surgeon of the Fifth Virginia Cavalry, C. S. A., during the Civil War; since 1870, a resident of Texas; physician and surgeon to the Texas Military Institute, Austin; and later assistant superintendent to the State Insane Hospital in that city; for thirty-four years a resident of San Antonio; died at his home in Alamo Heights, San Antonio, October 11.

Wallace Ernest Parkman, M.D. University of California, San Francisco, 1896; aged 41; of San Jose, Calif.; a member of the Association of Military Surgeons of the United States; for ten years acting assistant surgeon, U. S. Army, with service in the Philippine Islands, during which he was a member of the squad which captured Luis Aguinaldo; died at the Garden City Sanitarium, San Jose, October 5, from chronic nephritis.

William Noyes, M.D. Harvard University Medical School, 1885; aged 58; a member of the Massachusetts Medical Society, American Neurological Association and American Medico-Psychological Association; formerly superintendent of the Boston Insane Hospital and clinical instructor in mental diseases in Harvard Medical School; died at his home in Jamaica Plains, Boston, October 20.

Elmer Ellsworth Ferguson, M.D. Rush Medical College, 1897; from 1900 to 1912 proprietor and chief surgeon of The Dalles Hospital, but for two years a resident of Hood River, Ore.; died at his summer home, October 11, from a gunshot wound of the heart, self-inflicted, it is believed, with suicidal intent while suffering from melancholia.

Samuel Gordon Todd, M.D. Trinity Medical College, Toronto; Queen's University, Kingston, Ont., 1890; aged 46; a Fellow of the American Medical Association and American Academy of Ophthalmology and Oto-Laryngology; of Oshkosh, Wis.; a well-known specialist on diseases of the eye, ear, nose and throat; died at his home in Oshkosh, October 13, from pneumonia.

Andrew J. Smith, M.D. Central College of Physicians and Surgeons, Indianapolis, 1886; aged 83; who served in the United States Navy during the historic trip of Commodore Perry to Japan and was later an assistant surgeon in the Army with Civil War service; a practitioner for more than half a century; died at his home in Indianapolis, October 15, from cerebral hemorrhage.

George W. Daniels, M.D. Kentucky School of Medicine, Louisville, 1877; aged 67; a member of the Indiana State Medical Association; a veteran of the Civil War, and president of the Regimental Association of the One Hundred and Twenty-Third Indiana Volunteer Infantry; until two years ago a resident of Sweetsers, Ind.; died at his home in Marion, Ind., October 8.

Ethbert B. Emory, M.D. Homeopathic Hospital College, Cleveland, 1881; aged 66; a Fellow of the American Medical Association and an esteemed practitioner of Winfield, Kan.; died in his sanatorium in that city, October 13, from the effects of an incised wound of the throat, self-inflicted, it is believed, with suicidal intent, while despondent and of unsound mind.

Lewis Attwood, M.D. Kansas Medical College, Topeka, 1904; aged 36; of Topeka, Kan.; a specialist on diseases of the eye, ear, nose and throat; formerly a practitioner and druggist of Meriden, Kan.; was instantly killed October 16, when a Union Pacific motor car on the Blue Valley branch plunged through a bridge into a flooded creek near Randolph.

Adolph Kessler, M.D. University of Berlin, Germany, 1855; aged 82; a member of the Medical Society of the State of New York; formerly a member of the board of coroners of New York County and assistant sanitary superintendent of the Board of Health of the Bronx; died at his home in New York City, October 19, from senile debility.

Homer G. Newton, M.D. New York University, New York City, 1863; aged 79; one of the founders of the Brooklyn Eye and Ear Hospital, and an early ophthalmologist and otologist of Brooklyn; surgeon of U. S. Volunteers during the Civil War; died at his home in Shelburne, N. Y., October 11.

John Leon Parker, M.D. University of Michigan, Ann Arbor, 1899; aged 44; consulting surgeon to the Charles City (Iowa) Hospital; local surgeon of the Illinois Central Railroad and a member of the board of Education of Charles City; died suddenly in his office in Charles City, October 14.

John Marshall Kellogg, M.D. College of Physicians and Surgeons in the City of New York, 1868; aged 75; for many years a practitioner of Orange, N. J., but later connected with a preparatory school in New York; died at his home in East Orange, N. J., October 18, from cerebral hemorrhage.

Warren David Kleppinger, M.D. Medico-Chirurgical College of Philadelphia, 1913; aged 26; a Fellow of the American Medical Association; chief of the house staff and pathologist of the Allentown (Pa.) Hospital; died in that institution, October 9, from carcinoma of the pancreas.

Calvin Brice McKeown, M.D. Medical College of the State of South Carolina, Charleston, 1878; aged 63; a member of the South Carolina Medical Association; until three years ago a practitioner of Fort Lawn, S. C.; died at his home in Chester, S. C., October 11.

John D. Jordan, M.D. University of Louisville, Ky., 1872; aged 69; a member of the Arkansas Medical Society; formerly president of the board of education and a well-known physician and druggist of Eureka Springs, Ark.; died at his home in Antlers, Okla., October 7.

Herbert Augustine Morse, M.D. University of Michigan, Ann Arbor, 1866; aged 70; formerly a Fellow of the American Medical Association; for many years a practitioner and druggist of Batavia, N. Y.; died at his home in that city, October 15, from angina pectoris.

James P. Frame (license, Missouri, 1883), aged 78; formerly president of the Lewis County (Mo.) Medical Society and president of the Bank of Ewing, Mo.; a veteran of the Civil War; died at his home in Ewing, October 2, from diabetic gangrene.

Stanislas Alcide St. Amour, M.D. Ecole de Médecine et de Chirurgie, Montreal, 1886; aged 52; of Cheboygan, Mich.; a member of the Michigan State Medical Society; died in St. Luke's Hospital, Chicago, October 19, from cerebral hemorrhage.

Edmond G. Scruggs, M.D. Medical College of Georgia, Augusta, 1858; aged 84; formerly a member of the Medical Association of Georgia; a practitioner and druggist of Warrenton, Ga.; died at his home in that place, August 15, from nephritis.

Benjamin F. Hall, M.D. Louisville (Ky.) Medical College, 1877; aged 62; of Rock Island, Ill., and Davenport, Iowa; a specialist on diseases of the eye, ear, nose and throat; died in the Augustana Hospital, Chicago, October 17.

George Haner, M.D. New York University, New York City, 1877; aged 67; formerly a member of the Medical Society of the State of New York; died at his home in Farmersville, N. Y., July 2, from cerebral hemorrhage.

William Miller Baird, M.D. Bellevue Hospital Medical College, 1877; aged 66; of Atlanta, Ga.; formerly a member and speaker of the house of representatives of New Jersey; died at the home of his son in Baltimore, October 10.

Nathaniel Cope Miller, M.D. University of Pennsylvania, Philadelphia, 1870; aged 67; a Fellow of the American Medical Association; died suddenly at his home in Stroudsburg, Pa., about October 10, from disease of the kidney.

George W. James, M.D. University of Nashville, Tenn., 1867; aged 74; a Confederate veteran, for many years a practitioner of Humboldt, Tenn.; died while making a professional call in that place, October 14.

William John McNaul, M.D. Jefferson Medical College, 1894; formerly a Fellow of the American Medical Association; for twenty years a practitioner of Kensington, Philadelphia; died at his home, October 15.

George W. Crosby, M.D. Missouri Medical College, St. Louis, 1870; aged 69; formerly a member of the Arkansas Legislature and a practitioner of Heber Springs; died at his home in that place, about October 14.

Samuel W. Craig, M.D. Cincinnati College of Medicine and Surgery, 1869; aged 74; a veteran of the Civil War; for thirty years a druggist of Cincinnati; died at his home in Mt. Auburn, Cincinnati, October 4.

John W. Williams, M.D. University of Louisville, Ky., 1887; aged 62; a member of the Kentucky State Medical Association; died at his home in Clay City, Ky., October 13, from carcinoma of the stomach.

Thomas Jefferson Box, M.D. Tulane University, New Orleans, 1891; aged 59; formerly a Fellow of the American Medical Association; died at his home in Torras, La., July 4, from heart disease.

David Henry Van Nuys, M.D. Jefferson Medical College, 1864; aged 81; for fifty-one years a practitioner of Falmouth, Ind.; died at his home in Anderson, Ind., October 15, from bronchial pneumonia.

Gentry Guy Fisher, M.D. University of Nashville, Tenn., 1909; aged 27; formerly of Dibrell, Tenn.; of Bokchito, Okla.; died at his home in that place, October 10, from typhoid fever.

Lawrence Orr McCalla, M.D. College of Physicians and Surgeons, Baltimore, 1893; aged 52; a retired practitioner of Starr, S. C.; was shot and killed by his wife's nephew, October 9.

Simeon King Fisher, M.D. University of Louisville, Ky., 1884; aged 61; a member of the Kentucky State Medical Association; died at his home in Milton, Ky., June 25, from diabetes.

Edouard Tourigny, M.D. Laval University, Quebec, 1904; aged 42; of Aurora, Kan.; died at St. Albert, Warwick Parish, Quebec, Canada, July 13, from pulmonary tuberculosis.

John David Shepherd, M.D. College of Physicians and Surgeons, Keokuk, Iowa, 1887; aged 67; died at his home in Meadville, Mo., August 11, from general nervous breakdown.

Willard Knowlton Dyer (license, Massachusetts, years of practice, 1894), aged 64; a practitioner of Boston for thirty-two years; died in a hospital in Boston, October 18.

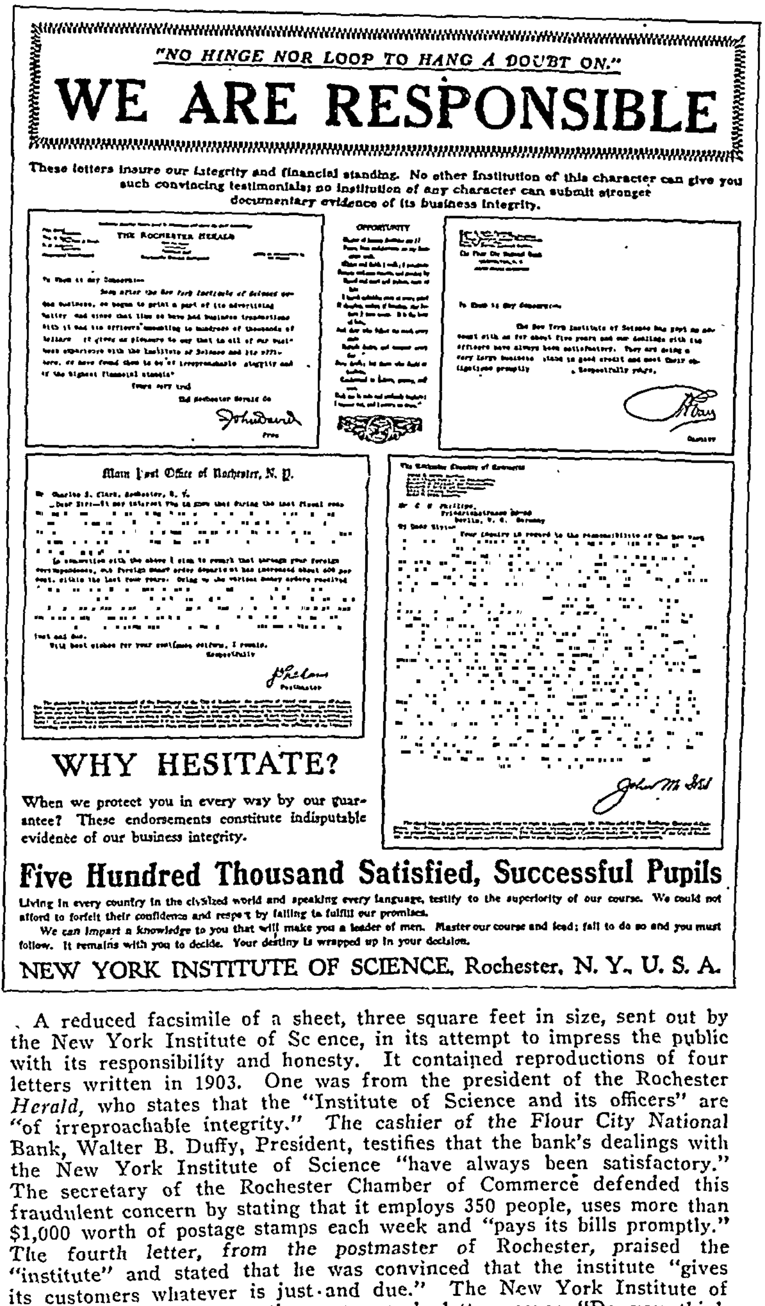
William Beatty, M.D. University of Toronto, Ont., 1880; aged 65; for nearly thirty-five years a practitioner of Dunlap, Iowa; died at his home in Omaha, October 13.

The Propaganda for Reform

IN THIS DEPARTMENT APPEAR REPORTS OF THE COUNCIL ON PHARMACY AND CHEMISTRY AND OF THE ASSOCIATION LABORATORY, TOGETHER WITH OTHER MATTER TENDING TO AID INTELLIGENT PRESCRIBING AND TO OPPOSE MEDICAL FRAUD ON THE PUBLIC AND ON THE PROFESSION

"LOCAL INDUSTRIES AND THE SOFT PEDAL"

The following letter from Mr. Roland B. Woodward, Secretary of the Rochester (N. Y.) Chamber of Commerce, reached THE JOURNAL office October 14. It was dated September 15, but bore the Rochester postmark of October 13. Mr. Woodward, in answer to an inquiry, hopes that THE JOURNAL will "find it worthy of publication."



"NO HINGE NOR LOOP TO HANG A DOUBT ON."

WE ARE RESPONSIBLE

These letters insure our integrity and financial standing. No other institution of this character can give you such convincing testimonials; no institution of any character can submit stronger documentary evidence of its business integrity.

WHY HESITATE?

When we protect you in every way by our guarantee? These endorsements constitute indisputable evidence of our business integrity.

Five Hundred Thousand Satisfied, Successful Pupils

Living in every country in the civilized world and speaking every language, testify to the superiority of our course. We could not afford to forfeit their confidence and respect by failing to fulfill our promises.

We can impart a knowledge to you that will make you a leader of men. Master our course and lead; fail to do so and you must follow. It remains with you to decide. Your destiny is wrapped up in your decision.

NEW YORK INSTITUTE OF SCIENCE, Rochester, N. Y., U. S. A.

A reduced facsimile of a sheet, three square feet in size, sent out by the New York Institute of Science, in its attempt to impress the public with its responsibility and honesty. It contained reproductions of four letters written in 1903. One was from the president of the Rochester *Herald,* who states that the "Institute of Science and its officers" are "of irreproachable integrity." The cashier of the Flour City National Bank, Walter B. Duffy, President, testifies that the bank's dealings with the New York Institute of Science "have always been satisfactory." The secretary of the Rochester Chamber of Commerce defended this fraudulent concern by stating that it employs 350 people, uses more than $1,000 worth of postage stamps each week and "pays its bills promptly." The fourth letter, *from the postmaster* of Rochester, praised the "institute" and stated that he was convinced that the institute "gives its customers whatever is just and due." The New York Institute of Science, commenting on the postmaster's letter, says: "Do you think that a postmaster, whose business it is to investigate postal affairs and prosecute frauds, would express his satisfaction concerning our business if it were conducted on a fraudulent basis and there existed the least doubt concerning the reliability of the institute?"

> *"To the Editor:*—In 'Medical News,' Volume LXV, Number 11, page 961, top of the page and second column, you have an editorial comment on an incident connected with an address on 'Patent Medicine Frauds,' before the meeting of the American Public Health Association in Rochester.
>
> "It seems to me that the article is in bad taste and is thoroughly unfair in its suggestion. You say: 'Doubtless it was this spirit that a few years ago inspired the Secretary of the Chamber of Commerce of Rochester,' *et cetera.* You do not say *how many* years ago; neither do you name the Secretary of the Chamber of Commerce of Rochester; neither do you point out that the letter written by John M. Ives, who was (then) the Secretary, although written on the Chamber of Commerce letter-head, was signed by him as an *individual* and not as Secretary of the Chamber.
>
> "I have served as Secretary of the Rochester Chamber for nearly seven years — which is more than 'a few years.' The inference to be drawn from your comment is that the *present* Secretary of the Chamber of Commerce of Rochester wrote the testimonial representing the Chamber, in order to not 'hurt local industries, no matter how fraudulent, how subversive of the public good, how dangerous to the public health, so long as the industry brings money to the town.' You evidently don't know the Rochester Chamber of Commerce nor the City of Rochester.
>
> "What I have said concerning the Secretary of the Chamber of Commerce may apply equally to the 'Postmaster of Rochester,' and, so far as I know, to 'the *President of the Rochester* Herald Company.'
>
> "It is such editorials as yours, expressing half-truths, permitting of wrong inferences and endeavoring to slander an entire community, which make honest men hesitate to align themselves with an association or organization that, in its *opposition* to what it deems an evil, loses its sense of fairness and sanity."

The editorial comment to which Mr. Woodward refers appeared in THE JOURNAL for September 11 under the title "Local Industries and the Soft Pedal." It is to be regretted that this comment strikes Mr. Woodward as "in bad taste" and "thoroughly unfair in its suggestion." After going over the matter with a good deal of care and giving due weight to Mr. Woodward's criticism, THE JOURNAL still remains unconvinced that it has done either the City of Rochester, the Rochester Chamber of Commerce, or its secretary any injustice. One statement in Mr. Woodward's letter is, evidently, based on a *misconception of the facts:*

> ". . . neither do you point out that the letter written by John M. Ives, who was (then) the Secretary, although written on the Chamber of Commerce letter-head, was signed by him as an *individual* and not as Secretary of the Chamber."

The facts: Mr. Ives' letter was written to a Mr. Phillips in reply to a question which Mr. Phillips *asked, not of Mr. Ives, but of the Rochester Chamber of Commerce,* about the fraudulent "New York Institute of Science." The "*New York Institute of Science*" not only reprinted Mr. Ives' letter as an endorsement, but emphasized the fact that this letter represented the views of the Chamber of Commerce rather than the views of a private individual by adding:

> "The Rochester Chamber of Commerce looks after the interests of the City of Rochester, and its Secretary would not prepare such a letter in favor of any firm engaged in a business questionable in any sense."

In view of the above facts, THE JOURNAL was certainly justified in assuming that a letter written by the Secretary of the Chamber of Commerce, on the stationery of the Chamber of Commerce, in answer to an inquiry addressed to the Chamber of Commerce, represented the views of the Secretary of the Chamber of Commerce. Mr. Woodward says further that what he has mentioned regarding the Secretary of the Chamber of Commerce may apply equally to the "Postmaster of Rochester," and, so far as he knows, also to the "President of the Rochester Herald Company." Once more, the facts: The letter reproduced by the "New York Institute of Science" was written on the stationery of the "Main Post Office of Rochester, N. Y.," and was signed "J. S. Graham, Postmaster." Likewise the letter from the President of the Rochester Herald Company *that the* "institute" reproduced in its advertising was written on the stationery of the *Rochester Herald* and signed "The Rochester Herald Co., John David, Pres."

Mr. Woodward's statement that we "evidently do not know the Rochester Chamber of Commerce nor the City of Rochester" may be true. We do know, however, that for years two of the most widely exploited and fraudulently advertised "patent medicines" in the country have emanated from the City of Rochester, and we understand that the fortunes amassed from the sale of these products are, today, invested extensively in other Rochester projects. We know, further, that for many years Rochester has been the headquarters of a syndicate of fraudulent mail-order concerns that have fleeced people not only of the United States, but all over the world. Fraud after fraud has been started by this syndicate, flourished rankly and has gone out of existence only when the accumulated experience of the public has nullified the power of its advertising or when the United States Post Office Department has issued a fraud order against it and denied it the use of the mails. What has Rochester done about it?

LAIRD'S RHEUMATISM FORMULA

During the past week or two, physicians in various parts of the country received a circular letter from one Madison R. Laird, Des Moines, Iowa. Mr. Laird's specialty, as indicated by his letterhead, is "Investments." Possibly Mr. Laird may have found the medical profession somewhat susceptible to inducements that are sometimes held out by those in his line of business. At any rate, he came to the profession, *via* the circular letter, with an offer to sell a prescription for "rheumatism" that was "really amazing" in the "prompt results" to be obtained:

> "*Dear Doctor:*—HAVE YOU A PRESCRIPTION THAT REALLY DOES GIVE RELIEF FOR YOUR CASES OF RHEUMATISM?
>
> "If you have not, please read this carefully.
>
> "For some time I have known of a prescription that is particularly efficient and reliable for the treatment of rheumatic ailments, being especially effective and prompt in rheumatic fever. . . ."

And much more to the same effect. Mr. Laird claimed that he had used it himself "for rheumatism and lumbago" and obtained "complete and almost immediate relief." Also, he confided, some of his relatives "have found it equally effective." In spite of his firm faith in the power of his remedy and his apparent belief that the medical profession had nothing as good to offer suffering humanity, Mr. Laird was, it seemed, unwilling to give the public the benefit of his "secret" but was perfectly willing that physicians should give the public the benefit of it—after Laird had been paid for it!

> "Believing this valuable prescription should be known to every doctor, I have decided to sell it to as many as care to send for it.
>
> "I will send you this prescription, with full directions, for $2.00."

One of the physicians who received the Laird circular and sent it in to THE JOURNAL was Dr. W. L. Wilson of Hinsdale, Ill. Dr. Wilson was asked to cooperate with THE JOURNAL in giving the profession and the public the benefit of Madison R. Laird's marvelous prescription to the extent of sending Laird his check for $2.00, for which THE JOURNAL would reimburse him. This Dr. Wilson did and in due time sent both the "prescription" and a letter he received from Laird to the Propaganda Department generously stating that he is "glad to contribute the $2.00 to the cause of advancing the department's work." The "rheumatism formula" was a typewritten affair and disclosed a typical, old-time, shotgun prescription of the polypharmacy period; probably the old prescription-files of half the drug stores in the country contain similar monstrosities. Here it is:

Compound Syrup Sarsaparilla	2 ounces
Wine of Colchicum Seed	1 ounce
Tincture Guaiac	1 ounce
Potassium iodid	1 ounce
Sodium Salicylate	120 grains
Rochelle Salts	60 grains
Water	1 ounce
	4 ounces

COMPOUNDING.—Dissolve the dry ingredients in the water. Mix liquids separately, adding Tincture Guaiac last. Combine the two mixtures, shaking well together.

DIRECTIONS.—Shake well before taking. One teaspoonful in half glass of water three times daily, before or after meals.

Accompanying this marvelous "formula" was a letter to Dr. Wilson in which Laird said:

> "I wish to thank you for your letter; it is one of a very few I have received. [A compliment on the profession's intelligence.—ED.] Several of the others have been 'roasts' of a sarcastic or amusing character. Some of these learned men have actually been insulted to receive such a proposal from a 'layman.'"

Laird further said that for years he had "been an interested reader of medical subjects, and for a layman have a very good knowledge of medicine." He also modestly acknowledged that his "long service as a civil engineer and contractor" had made him "a very good first aid surgeon." The letter closed with a description of the marvelous results obtained from the use of this formula in a case of tabes.

> "Six months ago this man was almost helpless from Locomotor Ataxia, could hardly walk, did not dare raise his eyes above the level and was entirely lost in the dark, could not find his way home after nightfall."

After using Laird's "rheumatism" medicine:

> ". . . he reported that he could go anywhere he pleased day or night without getting lost and the dizzy symptom had entirely disappeared. He has wonderfully improved mentally and bodily and is entirely another man."

The lesson this anecdote conveys to Mr. Laird is, "We sometimes stumble on facts that surprise us and this is one of them." How true! Equally axiomatic it is that we sometimes stumble on fancies that amuse us—and this is one of them.

Correspondence

The Proper Preparation of Food, and the Proposed Founding of Training Schools for Cooks in Connection with Established Medical Colleges

To the Editor:—A letter written by me to a medical journal, dated May 4 last, which discussed the question of human alimentation and proper food preparation in public places, brings up a question of vital concern and therefore appropriate for careful consideration in the ultimate hope that there may be brought forth a generation of cooks fitly prepared by scientific training for their important work. The suggestion was made that the training schools for nurses, and the revolution thus wrought in that line of work, furnished a fair parallel to what was possible in the dietary and culinary service rendered to the public in hotels, clubs, restaurants and the like, and that adequately equipped medical colleges should undertake to provide this educational and dietetic service.

The contention in the letter named was that the physical aspect of people, as seen in city streets, supports the view that there is something wrong in the general manner of food preparation by public caterers, and a single paragraph of this letter will be quoted in illustration:

> Stated generally, the appearance of the crowd in the street tends to confirm this view, not one in five looking either healthy or happy. The facial complexions of persons of all ages and conditions—anemic, chlorotic, icteric, cachectic, in many forms and every degree—would be shocking if not so common as scarcely to arouse comment, and seem to point to a deeply rooted cause or causes operating adversely at the very basis of nutrition and producing effects that are ultimately recognizable by observing medical men in profound disorders of the entire digestive and assimilative tract; among which may be named dyspepsias and diarrheas, indigestion, intestinal inertia, cancers and constipation, hepatitis, appendicitis, colitis and the like.

In THE JOURNAL, May 22, 1915, Graham Lusk discussed the preparation, proper proportioning and serving of foods, especially in connection with a catering concern that has a chain of such establishments in all large cities in this country; and while it may be said that the calories computation is perfect on paper, yet in actual everyday working the ignorance, inadequacy or inadvertence of the cook will nullify every provision, and this conclusion has been reached only after repeated patronage tests of the establishments belonging to the system that is operated in this city.

My criticism of the local catering concern in question would be directed toward the methods of handling the starches served, the half-baked breads and pastries and poorly cooked vegetables—the meats, stews, soups, etc., being as a rule better cooked but often spoiled by overseasoning.

In reply to an inquiry by me as to the possible remedy, Lusk said:

> I think that instruction along proper food lines might be taken up by the dispensaries of medical schools. The medical schools, however, could in my judgment scarcely establish schools of cooking; that should be a part of the curriculum of every public school. I remember in the course in the School of Mines at Columbia which I took you work with small cupel furnaces assaying ores during a period of four months,

giving knowledge which never can be forgotten. It seems to me that cooking schools of the public schools might be associated with municipal lodging houses and the product of such cooking schools could be sold at very nearly cost. Every girl should be taught how to prepare simple foods in a cleanly and proper manner, with full regard for the nutritive value of the article involved.

The public bread supply in St. Louis is a palpable reproach in respect of both integrity and decency; when fraud in half-baking, short-weight or loading the loaf with moisture is not in evidence, foul-fisted handling in delivery is to be seen in every direction. My suggestion would be that instead of the city government attempting to regulate the business of public bread production by legislative penalties, the better way would be for the city regularly to produce a loaf standardized in every respect of weight, quality, baking, price, etc., and by publication inform bread-buyers of those producers who fall below the standard in their goods, and if the people wished counterfeit stuff they would then buy with their eyes open. Years ago bread was baked at the poorhouse for the supply of other institutions that was of uniformly fair quality, and doubtless the same could be done again. In Canada the dominion government relies solely on publicity as a check on the sale and use of misbranded or adulterated goods that enter into household consumption by the inspectors making purchases in the open market; the results of analyses, special findings, etc., then being published, and a well-informed people soon learn to put the frauds out of business.

George Homan, M.D., St. Louis.

Transverse Incision in Operation for Appendicitis

To the Editor:—Since the publication of my paper on this subject (The Journal, Sept. 11, 1915, p. 939), my attention has been called to the fact that the incision at the outer side of the sheath of the rectus, which is an essential part of the transverse incision, was first proposed and described by Dr. Robert Weir in the *Medical News*, Feb. 17, 1900, p. 241. Dr. Weir proposed this as an extension of the McBurney incision, but described definitely the incision in both the anterior and posterior sheaths of the rectus, and the drawing of the rectus back into its sheath. I scarcely understand the mental process which caused me to omit giving Dr. Weir full credit for this important part of the procedure. Like many others, I had practically abandoned McBurney's incision, using chiefly the vertical incision, which is now, I believe, more used than any other. The transverse incision, with Weir's technic at the inner side, is destined by reason of its natural advantages, if properly studied and understood, to become the operation of choice.

A. E. Rockey, M.D., Portland, Ore.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

ODOR OF URINE IN PARALYSIS OF VESICAL SPHINCTER

To the Editor:—I have an incurable case of paralysis of the vesical sphincter, and I am anxious to give something to eliminate the foul odor of the urine in this case. What do you suggest?

W. Burnett Weaver, M.D., Miamisburg, Ohio.

Answer.—It is uncertain from the question whether the foul odor complained of is due to decomposition of the urine within the bladder from infection or simply to the decomposition of the urine after it escapes. In the former case it would be necessary to overcome the infection if possible, and it is difficult to give a definite line of treatment for a specific condition when the specific condition is not known. Hexamethylenamin in sufficient doses will prevent or rather retard the decomposition of the urine, provided the urine is of acid reaction, but it will have practically no effect on a foul decomposed alkaline urine, nor is there anything known which, taken by mouth, will entirely eliminate the foul odor in such conditions. If the urine is kept acid in reaction and hexamethylenamin given to delay its decomposition, by scrupulous cleanliness, the odor may be reduced to a minimum.

BOVINE AND HUMAN TUBERCULOSIS

To the Editor:—Will you direct me to the latest literature on bovine tuberculosis as it affects human beings?

E. R. Van der Slice, M.D., Kearney, Neb.

Answer.—The following is a list of references to articles on this subject:

Park, W. H., and Krumwiede, C.: Relative Importance of Bovine and Human Types of Tubercle Bacilli in Different Forms of Human Tuberculosis, *Jour. Med. Research*, December, 1911; ibid., September, 1912; abstr., The Journal, Jan. 27, 1912, p. 306; Oct. 5, 1912, p. 1322.

Establishment of the Exact Significance of Bovine Tubercle Bacilli in Human Disease, editorial, The Journal, Feb. 17, 1912, p. 482.

Eagle, R. T.: Tuberculous Cow, *Texas State Jour. Med.*, July, 1912.

Fraser, J.: Possible Test in Differentiation Between Human and Bovine Types of Tubercle Bacillus, *Brit. Med. Jour.*, Nov. 23, 1912; abstr., The Journal, Dec. 21, 1912, p. 2287.

BRAN BREAD

To the Editor:—Heretofore I have been inclined toward constipation. Recently I have been eating bran bread, which helps considerably. Can you give me the formula for making this bread? Please omit name.

X. Y., Fort Wayne, Ind.

Answer.—The following is suggested for bran bread: Prepare the two following mixtures:

2 cups of wheat flour
2 cups of graham flour
2 cups of bran flour
1 teaspoonful salt
½ cup sugar
1 level teaspoonful baking powder

2 cups milk
1 cup molasses
1 egg
2 level teaspoonfuls of soda
¼ cup hot water
1 cup raisins

Thoroughly mix the foregoing liquid and solid mixtures, and bake in a moderate oven for one hour. This makes two loaves.

THE DOCTOR'S BAG

To the Editor:—Some time within the past two years I saw an article in The Journal regarding a list of articles which the general practitioner should carry in his bag in order to make a diagnosis. Can you give me any reference to it?

H. Bryan, M.D., Shanghai, China.

Answer.—The article is entitled "The Doctor's Bag," published in the Miscellany department of The Journal, Feb. 27, 1915, p. 767.

REFERENCES TO RHUS

To the Editor:—I am doing a little research work on the rhus group, including sumach, ivy, etc. Can you direct me to the literature on the subject?

J. A. Van Der Hulse, M.D., Akron, Ohio.

Answer.—A very complete bibliography on the poisonous species of rhus, by L. E. Warren, will be found in the *Midland Druggist and Pharmaceutical Review*, 1910, xliv, 149, 218 and 288. Since then Dr. von Adelung has published an important paper in the *Archives of Internal Medicine*, February, 1913, p. 148.

COMING EXAMINATIONS

Arkansas: Regular, Little Rock, November 9-10. Sec., Dr. T. J. Stout, Brinkley. Homeopathic, Little Rock, November 11. Sec., Dr. Scott C. Runnels, 900 Scott St., Little Rock.

Connecticut: Regular, New Haven, November 9-10. Sec., Dr. Charles A. Tuttle, 196 York St., New Haven. Homeopathic, New Haven, November 9. Sec., Dr. Edwin C. M. Hall, 82 Grand Ave., New Haven. Eclectic, November 9. Sec., Dr. T. S. Hodge, 19 Main St., Torrington.

Florida: Jacksonville, December 7-8. Sec., Dr. E. W. Warren, 102 Front St., Palatka.

Kentucky: Louisville, December 7-9. Sec., Dr. A. T. McCormack, Bowling Green.

Louisiana: New Orleans, December 2-4. Sec., Dr. E. L. Leckert, 716 Macheca Bldg., New Orleans.

Maine: Portland, November 9-10. Sec., Dr. Frank W. Searle, 776 Congress St., Portland.

Massachusetts: Boston, November 9-11. Sec., Dr. Walter P. Bowers, Room 159 State House, Boston.

Nebraska: Lincoln, November 10-11. Sec., Dr. H. B. Cummins, Seward.

Nevada: Carson City, November 1. Sec., Dr. Simeon L. Lee, Carson City.

Ohio: Columbus, December 7-9. Sec., Dr. George H. Matson, Columbus.

South Carolina: Columbia, November 9. Sec., Dr. A. Earle Boozer, 1806 Hampton St., Columbia.

Texas: Dallas, November 9-11. Sec., Dr. M. P. McElhannon, Belton.

West Virginia: Elkins, November 9. Sec., Dr. S. L. Jepson, Charleston.

Kansas June Report

Dr. H. A. Dykes, secretary of the Kansas Board of Medical Registration and Examination, reports the written examination held at Kansas City, June 8, 1915. The total number of subjects examined in was 10; total number of questions asked, 100; percentage required to pass, 75. The total number of candidates examined was 22, of whom 21 passed and 1 failed; 25 candidates were licensed through reciprocity. The following colleges were represented:

College	PASSED	Year Grad.	Per Cent.
Howard University		(1914) 82,	84
Rush Medical College		(1915)	89
University of Kansas		(1915) 81, 82, 82, 83, 86, 86, 87, 88, 89, 89,	90
Kansas City Hahnemann Medical College		(1915)	77
John A. Creighton Medical College		(1915)	85
University of Oklahoma		(1915) 81, 81, 85,	86
Jefferson Medical College		(1912)	78
	FAILED		
Kansas City Hahnemann Medical College		(1915)	*

College	LICENSED THROUGH RECIPROCITY	Year Grad.	Reciprocity with
Chicago College of Med. and Surg.		(1911)	Illinois
Hahnemann Med. Coll. and Hosp., Chicago		(1889)	Iowa
Hering Medical College		(1909)	Illinois
National Medical College, Chicago		(1898)	Illinois
Northwestern University		(1911)	Illinois
University of Illinois		(1914)	Illinois
State Univ. of Iowa, Coll. of Med.		(1912)	Iowa
Hospital College of Medicine, Louisville		(1904)	Oklahoma
Kentucky School of Medicine		(1907)	Indiana
University of Louisville		(1910)	Missouri
Tulane University of Louisiana		(1913)	Louisiana

University of Michigan Medical School		(1894)	70.3
Fordham University		(1913)	72.3
University of Munich		(1912)	71.4

Book Notices

Educational Hygiene from the Pre-School Period to the University. Edited by Louis W. Rapeer, Ph.D., Professor of Education, Pennsylvania State College. Cloth. Price, $2.50 net. Pp. 650, with illustrations. New York: Charles Scribner's Sons, 1915.

The rapid expansion of the general field of preventive medicine is well illustrated by the publication of this book, covering the entire subject of educational hygiene from the preschool period through the university. The amount of ground covered precludes the possibility of its preparation by a single writer. Professor Rapeer has therefore undertaken to act as editor, each chapter being contributed by a recognized authority. After an introductory chapter by the editor, the public health movement is discussed by Dr. E. H. Lewenski-Corwin, secretary of the Health Committee of the New York City Academy of Medicine; health and heredity by Dr. Davenport of the Carnegie Institution; home hygiene for children by Dr. Ernest B. Hoag of Leland Stanford Jr. University; rural school administration by W. I. Larson, state inspector of rural schools of Wisconsin; open air and open window schools by Sherman C. Kingsley, director of the Elizabeth McCormick Memorial Fund; rural school sanitation by A. C. Monahan of the United States Bureau of Education, etc. The result is a book of thirty-three chapters, each written by a specialist. As only eight of these chapters are prepared by physicians, the book presents the point of view of the educator rather than the sanitarian and should, for this reason, be especially valuable to physicians interested in school hygiene, as offering an opportunity to acquire the point of view of the educator. Of the six chapters on medical supervision of schools, only one, that on medical supervision of the exceptional child, is written by a physician, the other five presenting the point of view of the teacher, the psychologist and the trained nurse rather than that of the physician. The illustrations, charts and diagrams used are numerous and add materially to the value of the work. Some of this illustrated material might perhaps be omitted without injury. Inasmuch as many of the practical problems discussed are still in the experimental stage, however, it is perhaps better to be diffuse rather than dogmatic. In the present stage of development of school hygiene, this book will prove a valuable contribution to the literature of the subject.

The Book of the Fly. A Nature Study of the House-Fly and Its Kin, the Fly-Plague and A Cure. By G. Hurlstone Hardy, with an Introduction by Halford Ross. Cloth. Price, 80 cents. Pp. 124, with illustrations. New York: Rebman Company, 1915.

One of the most important and far reaching developments of the modern scientific study of preventable diseases is the rôle of insects in the spread of disease. As a result, interest in the appearance, characteristics and habits of all insects which come in contact with man has been greatly stimulated. After centuries of close association with the common fly, we are just beginning to learn how little we know about him. Major Hardy's book is perhaps the most complete, from the standpoint of the naturalist, of anything that has so far been published. Evidently his interest in the subject has been lifelong, as the reader is told in the first chapter that, when barely more than 9 years old, he visited an aunt who was a veritable examplar of genteel breeding and propriety after the early Victorian pattern. She seriously reprimanded the child for cruelty in feeding the garden spiders with flies, which were, according to the aunt, "poor innocent creatures made by God for a useful purpose." To this admonition, the child replied that the devil made the flies and that God made the spiders to eat them. While this may not be an adequate explanation for the existence of the flies, it at least accounts for the spiders.

The average reader will be surprised to know that there are in Great Britain nearly 3,000 species of flies, of which 200 are exceedingly common and widely distributed. The characteristics, habits and distinguishing peculiarities of the more important species are described, their dangers as disseminators of disease discussed, and various methods for their control and extermination proposed. While little new matter is brought out under the latter heads, the discussion of the different species, their appearance and the variation in their personal habits is interesting and instructive.

Descriptive Catalogue of the Medical Museum of McGill University. Arranged on a Modified Decimal System of Museum Classification. Edited by Maude E. Abbott, B.A., M.D., Curator. Part 4, Section 1, The Hemopoietic Organs. Catalogue and Didactic Introductions by Oskar C. Gruner, M.D., Pathologist to the Royal Victoria Hospital, Montreal. Cloth. 1915.

McGill University has begun cataloguing the specimens in its large medical museum. A volume representing the portion of this catalogue on the hemopoietic organs has recently been received. Although it will be the fourth volume in the order of the museum classification, it is the first to appear in print. The book was arranged and edited under the personal supervision of Sir William Osler by the Oxford University Press, the cost having been met by funds raised by the medical alumni and friends of McGill University. The term "catalogue" scarcely does the book justice; it is more than that. In fact, it deals in a comprehensive manner with a subject which has not heretofore been attempted, and marks another step in the evolution of objective teaching. A series of specimens has been carefully selected illustrating each of the four subjects dealt with in this volume. For example, eighteen pages are devoted to conditions of bone marrow, thirty pages to lymph nodes, over 100 pages to the spleen and the splenic capsule and the balance of the book to the thymus gland. Each section is provided with a short introduction giving a brief review of the general pathology of the subject, which enables the reader to appreciate any departure from normal conditions. A number of blank pages after each subject have been allowed for subsequent additions. Altogether the book contains 203 pages and is illustrated by twelve elaborate plates. In the preparation of the book the author has carefully observed uniformity of arrangement, logical sequence of material, careful chronicling of macroscopic and microscopic details and a faithful coordination of clinical and pathologic data. Of particular value to those who are developing other museums is the elaborate scheme set forth in this book in numbering museum specimens, by which their proper classification is permitted. An examination of the book enables one to appreciate its great value in medical education, and it will be an important and useful addition to any medical library.

Miscellany

Government Reports on Wages and Hours of Labor

The Bureau of Labor Statistics in Bulletins 177 and 178 gives detailed analyses of wages and hours of labor in the hosiery and underwear industry, 1907 to 1914, and in the boot and shoe industry for the same period. These reports are of particular interest to physicians because of the relation of earnings and hours of labor to the health of the workers. The reports also give data on whole-time employment in these industries, which has an important bearing on questions of unemployment and the distribution of labor. In the underwear and hosiery industry it was found that the average full-time weekly earnings of the employees in 1914 were 2 per cent. higher than in 1913, 8 per cent. higher than in 1912, and 12 per cent. higher than in 1911 or 1910. The average full time hours of labor per week in 1914 were 1 per cent. lower than in 1913, 3 per cent. lower than in 1912, and 5 per cent. lower than in 1911 or 1910. The tendency, as will be seen, has been for wages to rise and for the hours of labor to become fewer. This affects to some extent the total earnings, and it was found that the increase in full time weekly earnings between 1910 and 1914 was not so great as in rates of wages per hour. The tables in the report set out all of this matter in detail. One table shows that in 1914 the average full time weekly earnings of males in ten occupations of the hosiery and underwear industry varied from $8.45 for certain lines of work to $22.31 as a maximum. The average full time weekly earnings of females for the same year in twenty-three occupations varied from $6.80 to $10.87.

In the boot and shoe industry the average full time weekly earnings in 1914 were the same as in 1913, 8 per cent. higher than in 1912, 6 per cent. higher than in 1911, and 9 per cent. higher than in 1910. The average full time hours of labor per week in 1914 were 1 per cent. lower than in 1913, 2 per cent. lower than in 1912, and 3 per cent. lower than in 1911 or 1910. The average earnings per hour for 1914 were 1 per cent. higher than in 1913, 9 per cent. higher than in 1912, 10 per cent. higher than in 1911, and 12 per cent. higher than in 1910. In this industry, as in that of the hosiery and underwear, owing to the reduction of hours, the increase in full time weekly earnings between 1910 and 1914 was not so much as in rates of wages per hour, thus affecting to some extent the total earnings. In 1914 the average full time weekly earnings of males in twenty-seven specific occupations varied from $15.37 to $27.68. In the same year the average full time weekly earnings of females in ten specific occupations varied from $9.12 to $13.14. On the whole, in both of the industries mentioned, the total earnings, notwithstanding the reduction in hours of labor, have been increased. It was found in eighty-three boot and shoe establishments in 1914 that the average loss of days during the year, aside from holidays, was eight days. No satisfactory comparison in this respect with other years is made on account of lack of data, the work of securing the information and many other considerations entering into the exact figures.

These reports indicate that in the cases of women employees the minimum wages are considerably below the amount considered by various investigation commissions in different parts of the country to be adequate for healthful and comfortable living, and the maximums mentioned do not much exceed the minimum requirements. In the cases of the men, the figures seem to be adequate, but, of course, do not take into consideration the fact that many wage earners are the heads of families in which there are a number of individuals depending on them for support of a kind which would insure sufficient nourishment, proper housing and living conditions to say nothing of provision for education or a few of the luxuries.

The Smoke Nuisance

O'Connor (*Popular Science Monthly*) remarks that the economic argument is the one commonly regarded as final on the smoke question. He thinks that a more powerful indictment may be drawn up under four heads, namely, the effect on (1) building materials, (2) meteorologic conditions, (3) vegetation and (4) health. 1. Apart from the soiling of surfaces, destructive of artistic effects from color contrasts, smoke helps to destroy stone and metal by the acid products of the combustion of coal. This action is especially marked on any stone containing calcium or magnesium carbonates. Metal work in a smoky city like Pittsburgh, moreover, lasts only half as long as in one free from smoke. 2. There are fewer hours of sunshine, and the sunshine is less intense in smoky cities than in those that are free from smoke. 3. Gases and smoke have an injurious effect on vegetation. Soot inhibits plant growth by the corrosive effect of the contained acid and also by blocking up the stomata and impeding transpiration, by coating leaves, thus reducing the intensity of sunlight and affecting the assimilation of carbon dioxid. 4. The results of medical investigators tend to show that smoke greatly increases the incident severity and mortality of acute diseases of the air passages; pneumonia and bronchitis increase directly as smoke increases. The purification of the atmosphere should therefore receive the same attention as pure food and pure water are receiving, for it is just as important.

Infant Mortality in Bavaria

In spite of all the efforts made to lessen the infant mortality in Bavaria, the death rate is higher now than before. During 1914, 38,467 children under 1 year of age died, as against 36,805 during 1913. There were 21,570 male children and 16,897 female children. Of the children born in 1914, 19.3 per cent. died, as against 18.2 per cent. in 1913; 21 per cent. of the male children and 17.4 per cent. of the female children died. More than one-third of the children that died during the first year of life were not more than 1 month old. About one-half died before the end of the third month. Most of the deaths occurred during August and September. The highest infant mortality by percentages occurred in the smaller communities.

The Power of a Trial Court to Order Physical Examinations

(State ex rel. Parmenter vs. Troup (Neb.), 152 N. W. R. 748)

The Supreme Court of Nebraska says that it is seldom that it is called on to determine a question of more importance or on which there is so clear and determined a difference of opinion among the courts of last resort in the several states, as that of the power of a trial court under any circumstances to order a party to submit his or her person to expert examination. The Supreme Court of the United States has been divided on the question, and has presented both sides of the controversy in an opinion and a dissenting opinion, the latter by Mr. Justice Brewer, and concurred in by Mr. Justice Brown. While the courts of last resort of nearly a dozen of the states of the Union have refused to indorse the reasoning of Mr. Justice Brewer, and have given reasons of undoubted force and clearness for such refusal, the courts of at least twenty of the states have reached his conclusion, in favor of the power in question.

Although the precise question here presented, whether the trial court has under any circumstances the power to order such an investigation, has perhaps never been directly and definitely considered and determined by this court, there are several cases in which expressions have been used that might be considered as indicating the opinion of the court as to the policy of the Nebraska law, and, since the case of Stuart vs. Havens, 17 Neb. 211, was decided thirty years ago, the trial courts have generally exercised such power. It has also been understood by the courts of other states that this court has decided that the trial courts have such powers, and their decisions class Nebraska among the states so holding. In view of this long-established practice in the state, and that there must otherwise often be a failure of justice, the court concludes that it should recognize this power of the trial courts. In other words, it is held that, in an action for damages caused by injuries to the person, the trial courts have power to order an expert examination of the person of the party injured, when the circumstances of the trial make it necessary to do so and no substantial harm can result therefrom. Such examination will not be ordered unless it clearly appears that a condition exists that can be definitely determined by such examination and cannot be satisfactorily determined without.

It is possible that, in some instances, a delicate and sensitive lady may suffer and endure a great wrong and injustice rather than present her cause for a public investigation to any court which would require her to allege in her petition and detail in her testimony facts in regard to the condition of her person which her sense of delicacy would forbid her doing. In such case she must elect, before bringing her action, whether she will bear the ills she has or fly to others that she knows not of. In bringing her action she must declare in public fashion the conditions to be investigated, and the law requires that in any legal investigation of facts the best evidence available must be produced. She may decline to present such conditions for investigation; but if she does bring them before the court, she cannot dictate the means of investigation by selecting such expert witnesses as she may have reason to suppose have opinions favorable to her cause, and rejecting those that might form contrary expert opinions on ascertaining the facts. In modern times the medical profession has the benefit of skilful women physicians, and ordinarily, other things being equal, such physicians ought to be preferred when reasonably practicable, if desired by the woman to be examined. If such an application is made for the purpose of embarrassing or coercing the plaintiff, the trial court will be quick to discover that purpose, and will order it only under conditions above indicated, and when it clearly appears that a condition exists that can be definitely determined by such examination and cannot be satisfactorily determined without it.

Sufficient Evidence of Promise to Pay for Operation

(Thomas vs. Boruff (Calif.), 148 Pac. R. 226)

The District Court of Appeal of California, Second District, affirms a judgment in favor of the plaintiff, a surgeon, who sued in his own behalf and as the assignee of another surgeon, a Dr. Southworth, for services rendered in performing an operation on one Henry Caystile, a brother-in-law of the defendant. The court says that the evidence tended to prove that, while Dr. Southworth had theretofore treated Mr. Caystile, he was not under employment by him at the time the operation was performed; that the defendant asked him to perform it, and the defendant, on being told by Dr. Southworth that the latter had spoken to Dr. Thomas regarding the matter, personally requested him to perform the operation, and said: "I want you to give him all the service that is possible, every attention, and I will foot the bills." On the morning when the operation was performed, in conversation with both the plaintiff and Dr. Southworth, the defendant said to the former, "I suppose you have called me in here for the purpose of having me say that I will pay for these services. Well, you boys go ahead and fix him up the best you can, and I will pay the bill." On the plaintiff telling the defendant that the operation was necessarily attended with great danger and uncertainty, he replied, "Go ahead and do the best you can for him." Another witness testified that the defendant said to the plaintiff to do the best he could for the man, and he (the defendant) would pay the bill. Not only did this testimony strongly tend to establish an original promise on the part of the defendant to pay for the services, both of the plaintiff and of Dr. Southworth, but the testimony of the defendant himself was corroborative of this view. His testimony was that, on Dr. Southworth requesting him to "stand for the expense," he said, "Yes, I will stand for the bill if you will allow me to select the man to operate," to which Dr. Southworth replied, "Well, I have selected a man and Henry wants me." "I know he does," said the defendant, "he prefers to have you, but I will not pay the bills on your account." To this Dr. Southworth answered, "I have secured Dr. Thomas; he is a good man," to which the defendant replied, "Go ahead, if he wants you; go ahead." This evidence might very properly be construed as a waiver of the defendant's wish to name the operator as a condition of paying the bill. Conceding that, even if the defendant had not promised to pay the bill, the plaintiff and Dr. Southworth might nevertheless have rendered the service, it was sufficiently clear, the court thinks, that before the performance of the operation the defendant made an original promise to pay the expense, and that the plaintiff and Dr. Southworth relied on such promise.

(Concluded from page 1397)

The Function of the Tonsil

Dr. Marcus Radvin, Evansville: The function of the tonsil is still a mooted question. Some authors believe that it secretes an antitoxin and furnishes moisture for deglutition. The last statement I believe is partly true, for I have seen several patients who complained of dry throats for months after their enormously hypertrophied tonsils had been removed. The close relationship that often exists between acute articular rheumatism and acute tonsillitis has been observed for many years. At times the joint and throat symptoms are simultaneous in their onset. Endocarditis and pericarditis not infrequently follow even very mild attacks of acute tonsillitis. Chorea may be present, with or without cardiac or arthritic symptoms. Acute, subacute or chronic parenchymatous nephritis are beginning to be looked on as possible sequelae of tonsillar infections. The relation of the tonsil to cervical adenitis seems to be well established clinically. Its relation to pulmonary tuberculosis has been noted by a sufficient number of careful observers. The tonsil bears some relationship to hyperthyroidism. I have heard of two cases of acute appendicitis which followed closely streptococcic tonsillitis. Is the voice sometimes injured by the operation, as the public seems to believe? Specialists who have had a considerable experience with professional singers guardedly admit that for a short time after the operation there is an alteration in the voice, followed in a few months by marked improvement, so much so that higher and more melodious tones were attained than before the operation, and they advise that singers should be cautioned to abstain from singing for a while, or to sing only in low registers. If alteration of the voice is permanently noted, it is due to injury of the pillars and adhesions, which hinder the mobility of the throat musculature.

DISCUSSION

Dr. William S. Tomlin, Indianapolis: I have had some experience in operating on tuberculous patients. In these cases the tuberculous process had seemed to be in the lung, the patients having previously had a slight temperature elevation and complained of being below par. In half a dozen of these cases I have removed the tonsils with most gratifying results. There has been improvement in general health, and the patients were able to leave the sanatorium. I have also had some experience in goiter cases, which in two was very satisfactory; but in two other cases, tonsillectomy did not seem to have any effect on the goiter.

Dr. C. Norman Howard, Warsaw: With regard to removing the tonsils in singers, I have come to the conclusion that it is not the removal of the tonsils but the damage to the pillars that makes the trouble. In every case in which we remove the tonsils, it should be done only because we know definitely that in that particular instance the patient will be better with them out.

Dr. F. V. Overman, Indianapolis: A man who treats most of the famous singers in the East insists that after a voice is placed while the singer has his tonsils, their removal invariably changes the timbre of the voice.

Dr. George W. Spohn, Elkhart: In hyperthyroidism, the literature tells us that patients grow worse on removal of the tonsils. According to some, there is a certain relationship between the ovaries in woman and the tonsils. Whether or not this is true, I do not know; but men working along the line of internal excretions say that it is. I cannot imagine that I would remove the tonsils to cure hyperthyroidism.

Dr. L. C. Cline, Indianapolis: I see an evidence of the profession coming around to a sane position on the question of tonsils and adenoids. They have run riot, until the public has been educated to the point where people come to a specialist and demand that their tonsils be removed, even without an examination. There are tonsils which do not need to be removed. Large, hypertrophied tonsils which are an obstruction ought to be removed, and also some of the tonsils which probably produce quinsy. The point I want to make especially is that there is a lot of this work of removal of tonsils being done which is absolutely wrong and unnecessary. We must examine our tonsil patients and treat them as we do patients with other conditions.

Dr. Lafayette Page, Indianapolis: I have had some very successful results with tonsillectomies in singers, some asserting that their voices were improved by the operation. Others have said that there is difficulty in getting the tones for a certain length of time, but after a year or two I have not seen a single case in which the quality of the voice has not been restored.

Dr. A. E. Bulson, Fort Wayne: The sooner we arrive at the conclusion that every case is a law unto itself, the better it will be for us. Not only must the tonsil be studied in every case, but also the patient as a whole. We have all had patients with repeated attacks of rheumatism who report themselves as improved or well following the removal of the tonsils, and some of them did not look very much infected either. On the other hand, we have had patients with rheumatism who did not recover following tonsillectomy, because the infection was elsewhere in the body.

Dr. C. J. Adams, Kokomo: Loeb asserts that there is no direct connection between the tonsillar glands and the apices of the lung.

Dr. Marcus Ravdin, Evansville: In operation on singers, Hudson Makuen favors tonsillectomy within the capsule. Leaving the capsule separates the pillars. It is the fossa tonsillaris, and not the tonsil, that affects the voice. The lymph supply of the tonsil is of great importance—greater than the blood supply. If we demonstrate that the tonsil has no direct connection with the cervical glands and other lymphatics, then the whole theory of the tonsil as an atrium of infection is wrong, and we are slaughtering tonsils for nothing. The latest German literature demonstrates the connection of the tonsils with the deep cervical glands, and again the deep cervical glands communicate with the lymphatic branches of the bronchial glands, forming a direct lymphatic connection with the apices of the lung.

Chronic Suppurative Mastoiditis, Accompanied by Intracranial Pressure: Case Report

Dr. Edwin J. Lent, South Bend: Man, aged 57, with negative family history, at age of 17 was struck on the head with a baseball bat, and had pneumonia at age of 22. A few years later he fell from a barn, a distance of about 25 feet, lighting on feet and buttocks in a sand pile. Sharp hemorrhage from right ear and nose occurred. He has had a foul-smelling discharge from right ear since childhood, without history of exanthems preceding. No treatment followed except an occasional washing. He has had a great deal of headache for the past ten years, especially during last two years, the pain being located chiefly in the vertex and radiating toward the frontal region. Examination disclosed external canal full of foul-smelling pus, eardrum practically destroyed and middle ear full of granulation tissue and polypi. Hearing reduced to watch contact. No tenderness over mastoid. Transillumination of mastoid cells showed bone to be eburnated. Caloric and rotary tests negative. Pulse 72, temperature 98.6. Vision 6/7 in both eyes. No evidence of choked disk. Tentative diagnosis of chronic mastoiditis with either extradural or intradural abscess complicating, was made. Operation advised, but refused. Patient continued to work.

Eight days after examination he fell on the street twice on his way to work. The next day he developed a paralysis in left arm and leg, and was taken to hospital. At this time cerebration was slow; urine and feces involuntary; severe pain in left temporal region and vertex; paralysis of left arm and leg; reflexes lost in left foot, normal in right; pupils equal in size; ocular movements slow. Temperature 98.6, pulse 70, full and firm. Drowsy most of the time. No neck rigidity. Operation on following day. Whole middle ear thrown into one large cavity, thoroughly curetted and dried. Eustachian tube burred out. Close inspection did not disclose any opening in floor of skull, except a small one which was made during excavation into antrum. This was enlarged, cavity flushed out with normal salt solution, and dura carefully inspected. It was not bulging. Incision then continued from upper angle to vertex; skull bared and a second button removed. In upper half of opening the dura was clearly bulging and looked pathologic. Drainage tube was inserted after dura was incised, and about 6 ounces of straw-colored fluid mixed with chocolate-colored débris evacuated. The day following operation the patient had fairly good use of left arm and leg; had some pain in the head. Continued in this condition for five days, when he became somewhat restless and noisy. Five days after operation complete paralysis of left arm and leg again ensued. Two days later he developed convulsive seizures, about fifteen minutes apart. March 15, five weeks following operation, drainage from the brain cyst was still continuing in large quantities. Much care had been exercised to keep the wound from becoming infected. At this time the nurse was directed to use no more caution, and the wound was deliberately allowed to become infected, as it was believed that by this time the brain tissue was well walled off. A smear was made from the pus, and an autogenous vaccine prepared, and given. The discharge began to lessen materially, and in twenty days had entirely ceased. The patient is now in good health.

DISCUSSION

Dr. John F. Barnhill, Indianapolis: I doubt very much that the ear had any relationship whatever to the brain cyst. It seems to me that the diagnosis in this case was made on too few symptoms, although the subsequent events proved that it was correct. As to the infection of the cyst, I do not know any precedent for it. It was very extraordinary, but the patient is well, and we never can speak against that sort of thing effectively. But I believe that if Dr. Lent were treating another similar case, he would be just as careful not to infect as he was in this case, although the infection possibly caused the closure of the cyst, just as a curettement might have done. But the dissection of the cyst, freeing it entirely from the brain cavity, would probably have done it at an earlier date than by the infection of the cyst wall.

Dr. George F. Keiper, Lafayette: This case brings up the question, How many brain cysts are due to trouble within the middle ear?

Dr. Edwin J. Lent, South Bend: This patient apparently had a general cerebral involvement. Whether or not there was meningeal irritation I do not know. The temperature never went above 99; pulse was from 70 to 80. The man was apparently normal, with this meningeal irritation and the focal symptoms going on. This case teaches that we should look for these symptoms and cysts once in a while. As Dr. Barnhill said, if I had another case of this kind to deal with, a smaller cyst, I would attempt to dissect it out.

The Defenses of the Upper Respiratory Tract and Their Preservation

Dr. Walter N. Culmer, Bloomington: The natural defenses of the body are essential and inherent elements of each involuntary act. The respiratory function of the nose is controlled by defensive means that involuntarily serve to maintain the proper amount, quality and physical conditions of the air entering the breathway. Adequate ventilation of the nasal chambers, sinuses and postnasal space serve to maintain, on the one hand, the useful purpose for which the defenses operate, and, on the other hand, to sustain the integrity of the mucous membrane in the remote parts of the nasal cavities. Further down in the upper respiratory tract is a collection of lymphoid tissue whose relationship to the surrounding parts and to the economy in general has not been accurately determined. In order to preserve these natural defenses it is necessary to know the conditions that prevent their successful operation. A knowledge of the physiologic defenses reveals the fact that the relation of the upper respiratory tract to the development and growth of the body is so intimate that a study of the local changes, without noting at the same time the constitutional requirements of the individual, will often accomplish very little. One of the most forward steps in the direction of the preservation of these defenses is the medical inspection of schoolchildren.

DISCUSSION

Dr. Paul B. Coble, Indianapolis: It is essential to good health and the general well-being of the individual that the upper respiratory tract be kept in the best possible condition. Much good can be accomplished by the medical inspection of schoolchildren in many instances.

Dr. W. S. Tomlin, Indianapolis: This paper deals with the basic principles of our work. Take, for instance, children with defective tonsils, which are interfering with the child, and in which we are sometimes asked how early they should be removed. My impression is that they should be removed as early as they give trouble. Regarding operative work in the nose, my position is a little different from that of most operators. I make submucous resections as early as 8 years of age, and would feel inclined to make them even earlier if the condition were sufficiently pathologic to demand more nasal space.

Dr. Walter N. Culmer, Bloomington: My object was to bring out a little more clearly the importance of the interrelationship of disturbances in the nose and throat with those in other parts of the body. I do not care to do septal and middle turbinal operations until after puberty, or until puberty, at least.

Chronic Suppurative Ethmoiditis

Dr. William S. Tomlin, Indianapolis: The diagnosis of chronic suppurative ethmoiditis to be effective must develop as far as possible the causative factors, nature and extent of the pathologic condition and its bacteriology. Displaced and supernumerary cells, abnormal or unusual relationships of the cells to each other and to surrounding structures, and dehiscences in so far as possible, all depending largely on the roentgenogram, are integral parts of a working diagnosis. Extension of ethmoid cells beyond the capsule in the frontal, orbital, maxillary, sphenoid and middle turbinate structures are not uncommon in suppurative cases, and not only serve to continue the processes before operation, but also may be the most important factors in determining the whole course of the case. Transillumination gives some information, especially of the maxillary and to a lesser extent the frontal sinuses, but is not so dependable as well-interpreted roentgenograms, which perhaps should not be omitted in any case. Stereoscopic plates have served to improve the interpretations, and are of the most signal advantage in cases with circumscribed involvement. The treatment of chronic suppurative ethmoiditis is essentially surgical. Vaccines have not given the satisfaction expected of them. Without operation no benefit whatever has been observed by me.

DISCUSSION

Dr. Joseph D. Heitger, Bedford: Rest of the diseased part, ventilation and drainage constitute three great principles of surgery, and in the nose we obtain the first by the application of the latter two. One should examine the visual field in all accessory sinus diseases, as there is often associated an enlargement of the blind spot, ring and central scotomas.

Dr. John F. Barnhill, Indianapolis: I look on the ethmoid as one of the most complicated pieces of anatomy in the human system. The brain is close above, the eye externally and the nose internally, with all its suppurating cavity emptying near by. The interior of this capsule is filled with two sets of large vessels, and the cells often extend abnormally up into the frontal sinus, extending posteriorly and overhanging frequently the sphenoidal sinus, and enveloping the optic nerve. It is our duty to know as much about the anatomy of the ethmoid cells as it is possible to know before we attempt this kind of surgery. I look on it as the most difficult of all surgery. As surgeons, we work too often under cover about the larynx, the ear and the sinuses. We ought to take the cue from the general surgeon and work in the open.

The Blood-Clot Dressing in Closing the Wound in Operations for Simple Mastoid Abscess

Dr. K. K. Wheelock, Fort Wayne: In thirteen consecutive operations for simple acute mastoid abscess I have closed the wound primarily, employing the coagulated blood as a dressing for the dead spaces in the exenterated mastoid. These thirteen patients had a necessary detention in the hospital of ninety days. This would show an average of six and one-third days for each case; all left the hospital at the end of seven days except one, and she left on the sixth day. This patient developed a mild attack of erysipelas on the fourth day, but the mastoid wound was not invaded. In another case, a young woman with a nursing baby developed a double mastoid abscess with suppuration from both ears. Her mastoids were exenterated and closed with catgut sutures over a blood-clot dressing. She left the hospital on the seventh day.

DISCUSSION

Dr. J. O. Stillson, Indianapolis: The same rule holds good with regard to this question of blood-clot dressing as holds good in surgery anywhere—each case is a law unto itself, and must be considered in that light. In acute cases, in which it is desirable to shorten the treatment, when there is no necrosis of bone, we all like to get healing by first intention, and I think that this method would probably be of value. But in cases of long sickness due to bacterial invasion, I do not think the process of treatment would be entirely satisfactory.

Dr. W. A. Hollis, Hartford City: I have used this blood-clot dressing in one case, with such satisfactory result that I am persuaded to use it again. It seems to me that if infection should occur, it would be a simple procedure to clean the cavity out and pack it in the usual way.

Dr. A. E. Bulson, Fort Wayne: The strange thing to me is that after having been introduced and carried on by some prominent operators for nearly fifteen years, this method is not more popular. The first case in which I used the blood-clot dressing was so successful that I thought it was ideal. In the second case in which I used it, the patient nearly died with infection. My third patient also had infection, and so I consulted some of my confrères with regard to their experiences. I found that their experiences had been very similar to mine—that some of the cases were very satisfactory, and when satisfactory it was ideal, but that occasionally they had infections, and that, in their judgment, it was a rather dangerous procedure.

Dr. John F. Barnhill, Indianapolis: My experience with this method has been similar to Dr. Bulson's; the failures were abominable, and the successes were brilliant. In the streptococcic infections and cases in which the wound must necessarily be very large, because the cells are extensive, it is hazardous to use this method in a certain percentage of cases, and we cannot tell beforehand. I use the modified blood-clot dressing in nearly all of my acute cases. It shortens the process of healing several weeks, as a rule, the average in my last hundred cases being something between two and three weeks. By the modified blood-clot dressing I mean putting in a small cigaret drain to carry away any infection that may be in the center of the clot.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA

Sixty-Fifth Annual Meeting, held in Philadelphia, Sept. 20-25, 1915

(Concluded from page 1484)

Pyelitis in Infancy and Childhood

Dr. Fred E. Ross, Erie: This condition is an acute infection of the urinary tract which may become chronic, and is almost always protracted in its course. It would seem that its supposed infrequency is due to its nonrecognition, as many cases hitherto differently diagnosed have been shown to be pyelitis. The infecting organism is most often the colon bacillus. While the route of infection is not known in all cases, a direct route from the ascending colon to the right kidney by way of a chain of lymphatics is suggested in many instances. Diagnosis rests on microscopic examination of the centrifugalized sediment of a sample of urine or on a series of such examinations. While most cases run their course uninfluenced by treatment, I use either alkaline diuretics to render the urine alkaline, or rather large doses of hexamethylenamin.

Albumin was found in the urine in 50 per cent. of my twelve cases.

DISCUSSION

Dr. George E. Holtzapple, York: This condition should be borne in mind as the possible cause of irregular, obscure fever, general debility attended by pallor, loss of appetite and gastro-intestinal disturbances in children. It may or may not be associated with cystitis, and a differential diagnosis is not always easy. Pain in pyelitis may simulate appendicitis, and I have seen a case of this kind brought to the hospital for operation. It is of paramount importance to discover the pyuria and determine the nature of the infection. The pediatrist should be alert lest a possible case of the condition be overlooked.

Dr. J. P. Crozer Griffith, Philadelphia: In every case of an infant with irregular temperature in which the cause is not absolutely clear the urine should be examined. The diagnosis is then readily made. I have had four or five cases of this disease under my care at one time.

Medical and Surgical Treatment of Tuberculous Peritonitis

Dr. Theodore J. Elterich, Pittsburgh: Since Koenig in 1884 proposed laparotomy as a cure for tuberculous peritonitis, surgery seems to have taken the place of medicine and claims an almost exclusive right for its intervention. It has never been shown, however, that laparotomy has had a specific influence in increasing the resistance to the tubercle bacillus. The most prominent symptom of the disease is ascites. While the pleural cavity may be tapped without danger, the needle in abdominal puncture for the relief of ascites may penetrate adherent intestinal walls. The medical treatment consists in hygienic, dietetic, local and internal therapeutic measures. Heliotherapy is warmly advocated in all forms of tuberculosis by Dr. Rollier of Switzerland. In visceral tuberculosis the results are said to be excellent. My own experience with the medical treatment, although limited, is gratifying.

Morbidity and Mortality From Certain Communicable Diseases of Childhood as Influenced by Public Health Control

Dr. B. Franklin Royer, Harrisburg: The total morbidity of any communicable disease is always greater than the reported figures, because of influences beyond public health control. The only true index of the communicable diseases of childhood is the death rate, because certificates of death must be issued. The morbidity of typhoid fever is well tabulated. From a total of 24,471 cases in 1906 the number of typhoid cases declined to 7,547 in 1914. Measures influencing the incidence of typhoid fever have an even greater effect on the mortality of diarrhea and enteritis. Deaths from measles have shown a general tendency to decline under the measures imposed by the public health authorities. This is also true of deaths from diphtheria. The number of deaths from whooping cough is cut in half. Scarlet fever has not shown the same tendency to decline. Until more is known of etiology and of the communicability of the disease, we may not hope for the best results. Educational work perhaps counts more, except sanatorium care, than any other line of public health work in the reduction of tuberculosis.

Significance of Cardiac Pain

Dr. David Riesman, Philadelphia: Causes of pain in the region of the heart may be classified as cardiac and extracardiac. Among the latter, dyspepsia, herpes zoster, pleurisy and pleurodynia are most common. Of the cardiac causes, myocardial weakness is of great practical importance, as it may be overlooked because murmurs are often absent. In addition to aneurysm and pericarditis as causes of cardiac pain may be mentioned angina pectoris and aortitis.

DISCUSSION

Dr. Lawrence Litchfield, Pittsburgh: Of two cases of which I have knowledge, one patient had been attended by the best men in the country and finally died from an anginoid attack without any one ever having told her that the cardiac pain was grave. The other case was of the type presenting pain in both arms. The cardiac disease was not regarded as serious, but the man died within a month in an anginoid attack.

Dr. James E. Talley, Philadelphia: In cases in which you suspect angina pectoris, the less you find wrong with the heart on examination, the surer you may be of your diagnosis. In a large series of cardiovascular and cardiorenal cases, about 500 in all, there were thirty-five of genuine angina pectoris; one third succumbed to an acute anginal attack and two thirds to gradual cardiac death.

Dr. S. Solis Cohen, Philadelphia: Two very important points in this discussion are syphilitic aortitis, and so-called pseudo-angina. Syphilitic aortitis is often mistaken for angina, the syphilitic nature is therefore overlooked, and the patient is allowed to get into a much worse condition than need be. I have observed many cases of so-called pseudo-angina in which the pain occurs without structural lesions in the myocardium, coronary arteries or the aorta, in which on proper recognition and treatment the pain may disappear and the patient live, as in one case under my observation, for more than twenty-five years.

Dr. Robert N. Willson, Philadelphia: There are two distinct types of true cardiac pain, the dull heavy pain of distention and dilatation, and the sharp cutting pain of aortic valve and aortic disease. It is questionable whether angina may properly be included under cardiac pain. I believe there is no such entity as pseudo-angina pectoris. The cardiac nervous mechanism, including the ganglions of the auricles and of the coronary sinus under the influence of nicotin, show definite signs of disease, and I believe that here eventually will be found the real seat of angina. If so, it will again become permissible to speak of angina as cardiac pain.

Treatment of Myocarditis

Dr. James M. Anders, Philadelphia: Treatment must be varied in accordance with the lesions and the dominating cause when ascertainable. When this cause is rheumatism, antirheumatic measures must be persevered with and the heart carefully guarded by stimulants. Modification of the antirheumatic treatment may be indicated by cardiac weakness. Digitalis is harmful when the myocardium is the seat of an acute inflammatory degeneration. In all forms of severe acute myocarditis prolonged, absolute rest is enjoined. When syphilis is the causal factor, intensive antisyphilitic treatment may be curative. In chronic myocarditis, the exclusion of chronic valvulitis is exceedingly difficult and often impossible after murmurs have appeared in chronic myocarditis. It is obvious that everything tending to throw strain on the myocardium must be avoided. In the treatment of the stage of compensation, gentle exercise that will not tax the physiologic reserve force of the already weakened myocardium should be encouraged, but fatigue is to be avoided. While there is no sovereign remedy for chronic myocarditis, in cases dependent on syphilis, mercury and salvarsan in alternation may be beneficial. The intravenous administration of the salvarsan, however, should not be employed. In diet, a low protein content, from 60 to 70 gm. daily, especially if nephritis be associated, is indicated instead of the average of 120 gm. The intake of flesh foods, strong stock soups and legumes should be minimized, and all articles causing intestinal fermentation in the individual case must be eliminated. My practice is to formulate a diet on these suggestions, adding about 60 gm. of fat, and modifying the dietary as indicated in individual cases. A suitable change of air may be beneficial in selected cases. Mineral springs may be useful, but these waters must be used cautiously. Carbonated baths are beneficial in appropriate cases. Symptomatic indications in this stage must be met in accordance with therapeutic principles. In the management of the stage of insufficiency, physical and mental rest are imperative and will in some cases overcome the dilatation; in others rest must be supplemented by the use of a cardiac stimulant to overcome passive visceral congestions and restore the compensatory mechanism of the heart. The untoward effect of prolonged rest may likewise be minimized by resistance exercises carefully conducted by a skilled operator. Digitalis if administered should be given cautiously in small doses combined with an arterial relaxant. In decided failure of compensation I have found most useful a combination of strychnin, 1/40 grain; caffein citrate, 1 grain, and spartein sulphate, 1/4 grain. Venesection may be useful in excessive hypertension in threatened apoplexy. Saline purgatives are beneficial. Diet here is of much importance. The digestible proteins may be freely allowed, with the exception of those rich in purin bases. The fluid intake should be lessened, especially when edema is present.

DISCUSSION

Dr. David Riesman, Philadelphia: The term "myocarditis" is rather loosely used when applied to acute diseases. Chronic myocarditis is never a single process. The functional and structural changes in the vessels, lymphatics, arterioles and viscera should be studied from the functional and anatomic standpoints. In the treatment of acute myocardial degeneration, the essential point is food. When milk is given as the sole diet, lactose should be added. We must adapt the patient's life and activities to the capacity of the heart as nearly as we can determine that capacity. Unfortunately, we have no definite test for the functional capacity of the heart. When compensation is once lost, rest and digitalis are the main remedies.

Inadequacy of Ordinary Methods of Disinfecting Typhoid Stools

Dr. Edgar M. Green, Easton: Reports received from about thirty hospitals throughout the state show that most of the institutions are disinfecting stools with chlorinated lime or phenol (carbolic acid) or some of the composite commercial disinfectants, while the period of time allowed for disinfection varied from a few moments to an indefinite period. Pathologic experiments show that such disinfection is useless. Steam sterilization can be made complete in a typhoid stool in from twenty to thirty minutes. The method is both thorough and economical, and should be insisted on in all hospitals. At present not more than 16 per cent. of our hospitals are using this method. In private practice where steam is not available, the well broken up stool should be exposed to a 6 per cent. solution of commercial formaldehyd for at least two hours, or else the stool should be treated with a cupful of commercial unslaked lime and hot water. This will generate enough heat to kill the pathogenic organism.

Hemoptysis in Pulmonary Tuberculosis and Its Treatment

Dr. Elmer H. Funk, Philadelphia: Among 373 patients with advanced pulmonary tuberculosis in the department for diseases of the chest of the Jefferson Hospital, hemoptysis was present in 164, or 44 per cent. Among 167 patients traced to the end, hemoptysis was noted in ninety instances, 54 per cent. The extent of the lesion does not bear a direct relation to the occurrence of hemorrhage; it may be the first or last symptom of the disease. The frank hemorrhages early in the disease probably result from the rapidity with which the tuberculous lesion erodes the vessels before they become thrombosed and occluded, as ordinarily they do in advance of the lesion. Rupture of aneurysmal dilatation of vessels within the cavity or embedded in its wall is probably the important factor in the profuse hemorrhage late in the disease. We have grouped pulmonary hemorrhage under: (1) frank profuse hemorrhage; (2) small and mild hemorrhages; (3) persisting hemorrhages, and (4) blood-streaked sputum. The expectoration of blood-streaked sputum ought to be given as careful thought as the profuse frank hemorrhage. There is noted at times what might be called an epidemic of blood spitting in a group of consumptives, and we are at present conducting a series of observations in this connection. In the treatment of hemoptysis in pulmonary tuberculosis, individualization is the keynote of success. Rest is by far the most important therapeutic procedure. Diet depends largely on the severity of the hemoptytic attack. Drugs play a minor, though if judiciously used, an important part in the therapy of hemoptysis. We are inclined to the belief that emetin is of distinct value in hemoptysis in which there is a tendency to repeated small hemorrhages or in cases suggesting capillary bleeding. The use of drugs to lower general blood pressure and for their action on the pulmonary circulation has not availed us much. We have discarded the time-honored ice bag on the chest. In cases in which blood gushes from the mouth, ligatures should be placed around the extremities, exerting just sufficient pressure, however, to retard the venous return and not to obstruct the arterial inflow. When the bandage is removed it should be done gradually. Persistent bleeding which fails to respond to the usual methods calls for a consideration of the therapeutic use of artificial pneumothorax. It is of vital importance, particularly in protracted cases, to secure free movements of the bowel daily, provided positive contraindications are absent. Evacuation is best accomplished by the salines, and of these preferably by magnesium sulphate.

DISCUSSION

Dr. C. R. Phillips, Harrisburg: From our observations at State Tuberculosis Dispensary 13 from March 1, 1908, to March 1, 1915, in a series of 5,700 cases diagnosed as tuberculosis pulmonalis, we concluded that about as many persons die from tuberculosis without having had hemorrhages as those who have; that hemorrhages are as likely to occur early in the disease as late; and that dispensaries and sanatoriums reduce the frequency of hemorrhage. In only 21 per cent. of the cases did hemorrhage occur after coming under our care. Hemorrhage per se cannot be considered: it is only a part of a vast clinical and pathologic picture, the significance of which depends on the accompanying conditions.

AMERICAN ROENTGEN RAY SOCIETY

Sixteenth Annual Meeting, held in Atlantic City, N. J., Sept. 22-25, 1915

The President, Dr. Alfred L. Gray, Richmond, Va., in the Chair

Roentgenographic Diagnosis of Metastatic Malignancy in the Lung

Drs. A. B. Moore and R. D. Carman, Rochester, Minn.: We examined 71 positive cases; average age of patients, 45½ years; average time since primary growth was noticed, three years and three months. The distribution of the primary focus was: breast, 20 cases; thyroid, 8 cases; soft tissues of forearm, 11 cases; kidney, 5 cases; soft tissues of neck and face, 5 cases; uterus, esophagus, prostate and testicles, 2 cases each, and 1 case each in the hard palate, larynx, suprarenal and sigmoid. In 59 cases the pathologic report was: carcinoma, 40, and sarcoma, 16; hypernephroma, 3 cases. Fourteen patients showed metastases in other organs besides the lungs, the most frequent being the liver, bones and brain. In 42 cases the primary growth was removed, with 19 local recurrences. Cough was the most common symptom, being present in 32 of the 71 cases. Dyspnea was present in 30 cases; pain in 14 cases, and pleural effusion, 12 cases, the fluid being bloody in 10. Only 16 patients gave evidence of pulmonary trouble. Loss of weight was not a marked clinical feature, being very indefinite in most cases. The roentgenographic findings were very positive, the manifestations appearing as clear-cut circumscribed areas of increased density.

Pulmonary Tuberculosis

Dr. Kennon Dunham, Cincinnati: The abnormal densities in the linear markings found in tuberculosis of the lung are due to tubercles situated along the bronchial tree. These tubercles when quite small break into the bronchus, forming minute microscopic cavities, the bronchus being a natural drainage tube of these cavities. Thus the spread of tuberculosis is along the bronchial branches, and until large cavities are formed, the lesion is limited to this particular distribution by means of its natural drainage tube, and not by a fibrous wall, as has been stated. The subsequent spread of the lesion is not from one small branch to its neighbor, but it goes back and extends along another main trunk or bronchus, either an adjoining bronchus or one lower down.

Roentgen Findings in Pulmonary Tuberculosis

Dr. Frank S. Bissell, Minneapolis: The interwoven appearance of pulmonary striae, described by Dunham, is a characteristic sign of pulmonary tuberculosis. It was present in 63 consecutive cases in which a positive constitutional reaction to tuberculin was obtained. In 12 negative cases (tuberculin test) the network was absent in 10 and typical in 2. The total number of lung cases examined and not diagnosed clinically was 111. A Roentgen diagnosis of pulmonary tuberculosis was made in 64 cases, sustained by clinical diagnosis in 38, and partially sustained in 8 cases. Thirteen cases reacted to tuberculin; the diagnosis was made by animal inoculation in 1 case, and by necropsy in 2 cases; by finding the bacilli in the sputum in 5 cases; by physical signs considered positive in 17, and by physical signs considered doubtful in 8 cases. Eighteen cases were unsustained by final clinical diagnosis, with symptoms not explained by any diagnosis in 13 cases, and extensive fibrosis or evidence of an inactive process in 5 cases. The total number of cases not diagnosed as tuberculosis by the Roentgen ray was 47, one of which was later shown to be tuberculosis. In 46 cases the negative Roentgen diagnosis was sustained by the clinical diagnosis. Therefore, the Roentgen ray has given the term "early diagnosis" a new meaning.

DISCUSSION ON PAPERS OF DRS. MOORE AND CARMAN, DUNHAM AND BISSELL

Dr. W. F. Manges, Philadelphia: We should not expect to see small pulmonary lesions except with the aid of the stereoscope. Some clinicians are of the opinion that we cannot show these lesions. I think this is due to the fact that they have not seen some of this good work, because it has been shown conclusively that the Roentgen ray can detect these lesions sooner than can be done by clinical methods. Recently I saw a patient who had been advised to have an operation for gastric ulcer. I examined him roentgenographically and found his stomach normal. I made fluoroscopic plates of his chest, and found the apices of both lungs densely infiltrated with small dense spots showing everywhere, the pleura much thickened. I did not believe, however, that it was an active tuberculosis, but even at that it was worth while knowing that these lesions were there, and if I had not incidentally made the examination of the lungs a part of my examination, this evidence would have gone undetected. Dr. Moore's paper indicates the necessity for more careful routine examination in all cases. Cancer cases should be examined in this way before any operation is performed, in order to determine whether metastases are present, not only in the lungs, but elsewhere, because if there are metastases it is useless to operate for the primary carcinoma. If there are none present, it is well to know it for the sake of record, if the patient should return later with a recurrence.

Dr. George E. Pfahler, Philadelphia: The diagnosis of pulmonary carcinoma should receive more attention. It would be well for surgeons to examine every patient before operation, especially those who show evidence of glandular involvement. Several surgeons in Philadelphia make it a rule to send these patients to me for Roentgen examination. In many cases referred to me for postoperative treatment I have found evidence of pulmonary disease. The early signs of pulmonary carcinoma are very much like those of pulmonary tuberculosis. Sarcoma is entirely different. I have seen a number of cases in which I could not make a differentiation between carcinoma and tuberculosis. In many cases of carcinoma of the lung secondary to breast cancer, the lesions are more marked on the side of the primary tumor in the breast than on the opposite side. Of course, carcinoma elsewhere in the body may cause pulmonary metastasis. We must search carefully for those areas of increased density. Some of these cases are primary in the lung.

Dr. Russell H. Boggs, Pittsburgh: I have examined a few cases of pulmonary carcinoma in which the primary lesion is in the bone. I think most of these cases are of the scirrhous type of carcinoma.

Dr. P. M. Hickey, Detroit: I should like to call attention to one point in the diagnosis of carcinoma of the lung, and that is the tendency of the infiltrating lines to extend across the lower part of the right lung. That is due to the interlobar infiltration between the middle and lower lobes. The presence of these lines, when they are well defined, is suspicious of malignant disease. The first infiltration in cases secondary to carcinoma of the breast is in the pleura. At the necropsy little nodules are found in the parietal pleura, extending along in rows like drops of wax. They give very characteristic Roentgen shadows, which should be studied stereoscopically.

Dr. S. B. Childs, Denver: The early stages of pulmonary tuberculosis can be detected on the roentgenogram. The lesion shows in the form of areas of increased density around the root of the lung. These areas are so small that they cannot be detected by clinical examination.

Dr. H. W. Dachtler, Toledo, Ohio: The Wassermann test may explain some of these cases of râles all over the lung without evidence of tuberculosis. I have found that to be true in a number of cases. I always make roentgenograms of all patients operated on for carcinoma of the breast, and have found this to be of value in checking up later, when these patients return with a recurrence. As to the direction of travel of the infection: I always thought it was out along the peribronchial gland, but I am not so certain about that now. Infection usually follows the lymph stream, and I have seen cases in the last few years in which there were definite tubercles along the axillary region, with no evidence of infection in the hilus.

Dr. James T. Case, Battle Creek, Mich.: I have had a case in which the diagnosis of lung cancer was based on the presence of a single, small, rounded shadow, at the level of the nipple, the shadow resembling those pointed out by Dr. Moore. I made stereoscopic plates and they showed plainly that this was the nipple shadow. This might be a source of error. For several years I have made a stereoscopic chest examination of every patient about to be operated on for carcinoma of the chest, in order to be forewarned as to the presence of metastasis, and as a matter of record for future comparison, if a patient should return with symptoms suggesting metastatic involvement.

Dr. David R. Bowen, Philadelphia: A boy was operated on for sarcoma of the forearm. A recurrence was treated with the Roentgen ray, and the boy apparently recovered, although he remained in the hospital. He was the sort of individual who never failed to complain when he did not feel well, but this time he made absolutely no complaint, in spite of the fact that when we made a Roentgen examination of his chest we found a marked metastasis in the lung.

Fluoroscopic Bronchoscopy

Dr. George W. Grier, Pittsburgh: Fluoroscopic bronchoscopy is indicated only when the foreign body is located in the bronchus or other structure which is inaccessible to the bronchoscope. In such cases the extracting forceps can be projected beyond the end of the bronchoscope, grasping the foreign body and removing it under the direction of the fluoroscopist.

Intensive Deep Roentgen Therapy

Dr. George C. Johnson, Pittsburgh: This method is capable of producing rapid destruction of superficial malignancy without pain in from one to three sittings, even in such locations as the eyelid. Postoperative radiation should be carried out conscientiously over a wide area beyond the apparent limitations of the disease, and sufficient radiation must be employed to insure the complete sterilization of the tissues. Often the area treated is not sufficiently large, and many malignant cells lying in the tissues beyond the reach of the ray survive and the result is an early recurrence. Deep Roentgen therapy will also produce quickly and painlessly and safely an artificial menopause in various gynecologic conditions.

Roentgen Observations on the Duodenum

Dr. James T. Case, Battle Creek, Mich.: I saw one case of carcinoma of the duodenum at about the papilla of Vater. In two other cases a diagnosis of pancreatic tumor was made, differentiating it from gallbladder disease. I have seen four cases of true diverticula of the duodenum occurring in the pars inferior, and three cases of dilatation of the ampulla of Vater. One case was complicated by multiple diverticula of the colon, and in two cases there were multiple diverticula of the jejunum.

Treatment of Epithelioma

Dr. J. H. Edmonson, Birmingham, Ala.: In treating cutaneous malignant disease I begin with fulguration, cauterization or coagulation. This destroys the most superficial and a great number of the deeper cells. It renders the field immediately accessible to treatment, and it closes the metastatic channels. Following this I expose the neoplasm to the unfiltered ray, thoroughly protecting the neighboring tissues. The next day I repeat the treatment, including about one-half inch of the surrounding tissues. If there is any evidence of the growth after the reaction subsides, I repeat the treatment. If not, I give a light treatment only to destroy any cells that may have escaped.

Effect of Moderate Doses of Opium Derivatives on Gastro-Intestinal Tract

Dr. Henry K. Pancoast, Philadelphia: Observations were made on a series of eleven persons getting morphin and one heroin habitué. With one exception there was a decided lack of uniformity in the effects produced in different individuals. Small doses produced more marked effects than large doses. Females appeared to be more susceptible than males. In the stomach a rather high spasmodic hourglass contraction is observed rarely, but we have not seen it near the pylorus, as described by others. In some instances the stomach may show no appreciable change from the normal. In most cases there is more or less pyloric spasm, increased peristalsis, and a decided prolongation of the emptying time. In the small intestine, morphin causes decreased motility almost uniformly, apparently as a result of a lack of propulsion and not of spasm. When marked, it is most noticeable in the upper bowel. The effect on the large bowel is variable and probably of little consequence. Oral administration produces practically the same effect as subcutaneous injections.

COLORADO STATE MEDICAL SOCIETY

Forty-Fifth Annual Meeting, held at Denver, Oct. 5-7, 1915

The President, Dr. George B. Packard, Denver, in the Chair

Five Cases of Relapsing Fever, Originating in Colorado

Dr. Charles N. Meader, Denver: We have had five patients and probably a sixth who have been ill with precisely the same train of symptoms. The outstanding features are, in brief, slight prodromal weakness and malaise; abrupt onset of fever accompanied by intense headache, chiefly occipital, with severe loin and leg ache; nausea or vomiting with constipation; marked prostration, and a high fever of 102.5 to 104.8 F. running a definite course of two or three days and ending by an abrupt crisis, the fall being accompanied by profuse sweating. There is, further, a recurrence of similar attacks to the number of three or four at rather definite intervals. Convalescence from the single attacks is rapid and is marred only by a slow return of muscular strength. The striking point on physical examination in the two cases seen during the height of the attacks has been a pulse which is weak out of all proportion to the apparent severity of the disease, due probably to a slight cardiac dilatation, with a moderately enlarged and tender liver and spleen. Of the laboratory findings, the appearance and disappearance of a considerable amount of albumin and large numbers of fine hyaline casts in the urine are strikingly rapid. The normal or diminished leukocyte count, accompanied by a fall in the proportion of polymorphonuclears and a rise in the transitionals during the attack, with a slightly increased white count, and a return to normal cell proportions in the intervals, is noteworthy. The feature of the blood examination, which is the criterion of diagnosis, is, of course, the demonstration of the spirochetes. This was accomplished in smears stained by the usual Wright stain in two cases. Spirochetes could never be found in the intervals between attacks. There seems, then, little room to doubt that these cases represent a small local outbreak of relapsing fever.

DISCUSSION

Dr. Henry Sewall, Denver: I see no reason why we should not have an endemic focus started in Colorado which would be very serious to the people whom we invite in the summer. The disease may become endemic, but by a very little precaution we can avoid that. Our health authorities should communicate with the central quarantine authorities. It is time for action.

Dr. William T. Councilman, Boston: These blood diseases can spread only through the medium of some agent which outside of the body conveys the parasites in the blood to some other person. We have a striking example of that in malaria. We must not only have the parasite which is the cause of the disease, but we must also have some other parasitic organism to convey the disease. So far, we have been very fortunate in regard to those diseases because the parasites which are within the blood have been brought to this country or from other countries where the two parasites are endemic. We have a blood parasite brought to us again and again, but so far we have been very fortunate in that the parasite which conveys the disease, either a tick or a louse or some other agent, has not, as a rule, found a suitable environment in this country. We have had striking examples of that in regard to sleeping sickness. Sleeping sickness was brought to this country by Africans, and they died in this country; but the disease was not recognized, and there was never occasion for the spread of the disease, because the fly, which was the necessary agent for the reproduction of the disease, was not brought to this country.

The Effects of High Altitudes on Cardiac Affections

Dr. A. Zederbaum, Denver: The heart is endowed with a wonderful recuperative power, and with an unexcelled faculty of adjusting itself to situations and circumstances. This adjustment is often given better facilities in high altitudes than in the lowlands. There are conditions of the heart which strongly contraindicate residence in a high altitude, but they are not many, and should be studied carefully in each individual case before a final judgment is pronounced.

DISCUSSION

Dr. G. Walter Holden, Denver: It has been my observation for the last seventeen years in Colorado that there is little or no change in the heart conditions in cases I have met in my special work with tuberculosis. The cases run practically the same course in this altitude as they do at sea level. If patients come out here early with an aortic stenosis, with pericardial or pleuritic adhesions, they are bound to have trouble. They have to be extremely quiet for a long time, and their exercise and muscular movements should be controlled. That applies to patients residing at sea level as well as to those living in Denver.

Dr. O. M. Gilbert, Boulder: Ordinarily, I say to people that about 98 per cent. of what you hear about the serious effects of high altitude on heart disease is simply imaginary, based on some preconceived notions, and the other 2 per cent. is real; but one of those realities may be a mitral stenosis.

Dr. A. S. Taussig, Denver: If a patient has a moderately good heart muscle, regardless of the character of the lesion, we are safe in saying that that patient can come to a high altitude and be benefited thereby. Physicians in the East are not able to form a proper idea of the influence of high altitude on account of two things: first, from a lack of personal experience and, second, from their own negligence in sending patients to a lower altitude after they find seriously damaged hearts. I do not believe any practitioner in the East can obtain an adequate idea of what high altitude will do in cardiac cases.

Immunity in Tuberculosis

Dr. Gerald B. Webb and Dr. G. Burton Gilbert, Colorado Springs: Experimenting for some years with minimum lethal doses of tubercle bacilli, we find that virulent cultures probably vary somewhat, but in general ten bacilli inoculated subcutaneously will produce tuberculous disease in guinea-pigs. We have not yet found any safe method of injecting a single minimum lethal dose to produce infection in guinea-pigs without producing a spreading infection in these animals. We have injected these doses with immune blood platelets, with immune lymphocytes and with immune serum, yet infection has resulted in many cases. We have excised the local lesions early, and we have caused local lesions in strips of skin anchored only at one end to the guinea-pig, but too frequently we have found disease has spread beyond to neighboring lymph nodes. We have succeeded in producing safely some immunity to tuberculosis when we have inoculated very small numbers of tubercle bacilli of moderate virulence, gradually increasing these numbers. With the most virulent cultures, however, even this cannot be achieved, as infection will take place. We are at present attempting to isolate a culture of tubercle bacilli which will be virulent enough in these small progressive numbers to produce immunity in guinea-pigs without producing infection.

Tuberculosis of the Kidney

Dr. Oliver Lyons, Denver: Evidence obtained by palpation should be accepted with caution. For example, a diminution in the size of the kidney, due to cicatricial contraction subsequent to caseation, may lead the physician into error, particularly if the healthy kidney has undergone compensatory hypertrophy. The patient may or may not present the general character of tuberculosis elsewhere in the body. In the average case anemia, wasting and cachexia are not observed for many months or even years. Sweating, chills and fever are signs of secondary infection, and are due to the absorption of toxins after suppurative processes have begun. In this case the loss of weight, appetite and strength may be very marked. The main reason for the failure of early recognition of renal tuberculosis lies in the fact that we are not on the outlook for it.

4 *Form of Reflexes in Chorea; Technic of Elicitation; Studies in Neurologic Technic No. 4. W. B. Swift, Boston.

4. **Form Reflexes in Chorea.**—Swift urges that the form of the reflex in chorea calls for four precautions in elicitation. *A.* The relation of the reflex to the choreic contraction demands a number of trials. *B.* The less frequency found in the milder forms demands that in mild cases more trials are necessary, and in severe cases less trials, usually ten trials, rarely twenty-five or fifty. *C.* As a choreic contraction has more time to occur in a reflex describing a large arc, choose reflexes with long pendulums, as the knee-jerk and triceps. *D.* As choreic contractions increase their frequency with efforts to control them, precede each test with the instruction to "hold still." In a word, Swift would make numerous trials, the more the milder the case, on reflexes with long swings, knee-jerk and triceps and precede each test with the order to "hold still." Then watch for the form of the reflex response, which a choreic contraction may turn into a jerk, a flop, or a wabble.

8 *Birth Fractures of Humerus from Wards of New York Lying-In Hospital. E. D. Truesdell, New York.
9 Modern Children's Pavilion (Abraham Jacobi Division for Children of German Hospital, New York). A. L. Goodman, New York.

5. **Cubic Air Space for Institutional Infants.**—In the hope of securing some definite data of value and authority on this subject Southworth sent a questionnaire to each member of the American Pediatric Society. Thirty-three answers containing sufficient data to incorporate were received from pediatricians who reported on forty-nine hospitals and institutions containing infants. The majority (twenty-one in number) of the hospitals and institutional wards for infants from which reports of cubic air space were received provide 1,000 cubic feet and upward of air space for each inmate, and only five reported 600 cubic feet or less. Even with 1,000 or more cubic feet of air space, free ventilation is deemed highly important, and as the space decreases such free ventilation becomes more and more imperative. No allowance of cubic air space is at present made for the necessary attendants in wards. Reduced cubic air space means less square feet of floor space and less separation between cribs, with proportionately increased opportunity for the spread of cross infections. There is a growing belief that even with free ventilation separation of the beds plays as important a rôle as cubic space. Such adequate separation, however, is only attainable with large cubic air space. The majority of pediatric physicians believe that infants should have as much cubic air space as adults, if not more, and this is especially true of bottle-fed infants, because they are more susceptible to infection, suffer in their nutrition in confinement, and notoriously do badly in all except the best equipped institutions. Even with a liberal allowance of cubic air space free and abundant ventilation is of equal importance. In addition, provision for roof-gardens, porches and sun parlors is advisable, if not imperative. The mere presence of windows does not of itself constitute ventilation but their proper use must be provided for. A low minimum of cubic space established by law, without definition of what constitutes efficient ventilation, and without enforcement, Southworth believes may be more harmful than beneficial, and constitute a virtual license to overcrowd in ill-ventilated wards.

6. **Prophylactic Vaccination for Varicella.**—During an epidemic of varicella in the wards of the Hebrew Infant Asylum during the winter just passed, Rabinoff tried out prophylactic vaccination. In the majority of instances it was necessary to use material directly and immediately from either the vesicles or the pustules. The method used was similar to that of Kling, except that instead of multiple punctures small scarifications were made on the arm to be vaccinated. In none of the vaccinated cases was there any evidences of systemic disturbance. Among 142 susceptible children, 114, or about 75 per cent., developed varicella. In the group of seventy-six vaccinated children there were only six cases, or about 8 per cent. of the total number. Of these six cases, two developed on the day following vaccination, two seven days later, one nine days and the last ten days later. In other words, all the cases among the vaccinated children developed within the incubation period of the disease, which is about sixteen days. Rabinoff is convinced that in this epidemic the vaccinations undoubtedly limited the spread of the disease.

8. **Birth Fractures of Humerus.**—Twenty-four fractures in twenty-one infants were collected by Truesdell. All have been followed to their final outcome, roentgenograms and clinical examinations having been made at intervals in each case until this had been determined. In a few cases the deformity was extreme; in every case there was some. In no case has the roentgenogram failed to show a uniformly progressive elimination of the deformity. Of the twenty-four fractures, seventeen occurred during version with breech extraction, four during simple breech extraction, and three in vertex presentations, difficulty having been experienced in extracting the anterior arm, either because of narrowing of the pelvic outlet, or of the size of the child. In three cases the fractures were double, and of the twenty-one infants, seventeen survived. In all cases but one the line of fracture was practically transverse, a typical pipestem fracture, the site of fracture being at or near the center of the shaft of the bone, just below the insertion of the deltoid muscle. In one case, a shoulder presentation, a fillet had been applied to the prolapsed arm and traction maintained on this during the version, causing some twisting or torsion of the extremity. In this one instance the line of fracture was oblique.

The prevailing deformity was an external angulation attributable directly to the action of the deltoid, and quite excessive in a few cases. A second variety of deformity was a lateral displacement, the fragments lying parallel, but more or less separated. Overriding of the fragments was not noted in any case, nor was displacement in an anteroposterior direction. Each fracture was accompanied by a well marked wrist-drop, due to some injury to the musculospiral nerve at the time of fracture, since the paralysis was immediate and so not likely due to accumulation of extravasated blood or callus inclusion. The paralysis gradually disappeared during the first three or four weeks in the majority of the cases, and in none was evidence of it observed after the end of the sixth week. In one case the fracture was complicated by an Erb's birth palsy of the same arm. The repair of the fracture was as prompt in this as in the other cases, the bone finally uniting with a moderate degree of external angulation. The treatment of these fractures varied from time to time. A V-shaped splint cut from thin wood, deeply crotched at one end to fit the axilla, and applied to the inner side of the arm and flexed forearm, was employed, with good results.

October 14, CLXXIII, No. 16, pp. 565-602

10 *Analysis of Three Hundred and Eight Cases of Typhoid in Children. K. G. Percy, Boston.
11 Therapeutic Value of Occupation for Insane. E. L. Haines, Boston.
12 Teaching of Applied Therapeutics at Tufts Medical School. F. H. McCrudden, Boston.

13 Workmen's Compensation Act and Physician. H. J. Cronin, Cambridge.
14 *Method of Testing Gastric Secretion by Use of Self-Closing Dredge. A. M. Burgess, Providence, R. I.
15 Sunshine; Its Neglected Analgesic-Sedative Action. J. Bryant, Boston.
16 Neuroma of Ulnar Nerve; Analysis of Case. J. B. Ayer, Boston.

10. **Typhoid in Children.**—In compiling these statistics Percy procured percentages from the total number of records which mentioned the point desired. Fever was noted in the histories in 82 per cent. Headache was a marked symptom in 57 per cent. Malaise was present in but 38 per cent. Vomiting occurred as a definite symptom in 26 per cent. Twenty-five per cent. of all patients gave a history of abdominal pain. Diarrhea is mentioned but sixty-two times, 21 per cent. Nosebleed occurred in 17 per cent. of this series, and of those, 78 per cent. within the first week of the disease. Constipation was a common symptom. Cough was noted in 8 per cent. Percy obtained a record of positive family history in sixty-six, or 23.7 per cent., while 76.6 per cent. gave no known contagion. The spleen showed enlargement to palpation on entrance in 68 per cent. of cases and was noted as enlarged to palpation in 79 per cent. of all cases some time during their stay in the hospital. Rose spots were noted ninety-four times in 280 careful records, or 33 per cent. at entrance and a total of 57 per cent. sometime during the course of the disease.

Widal's test was done on 280 patients of this series. On admission 80 per cent. were positive; 13.2 per cent. more were positive during their stay; 7.8 per cent. were negative. White blood cell count was done in 258 patients at or within three days of admission. Of these 14 per cent. were below 5,000; 57 per cent. were between 5,000 and 10,000; 29 per cent. were between 10,000 and 15,000. Fifty-one cases, or 67 per cent., either at entrance or within the first ten days gave positive diazo reactions. Blood cultures were done in seventeen cases only of this series. Twelve cases, or 70 per cent., were positive. Relapses occurred in sixty cases of 300 records in which the patients stayed in the hospital until discharged well, or in 18 per cent. of this series. Five patients had two relapses. Hemorrhages of the intestines occurred in four patients one of whom died and another of whom had as the apparent etiology a severe purpura with hematuria. There were no cases of perforation of the bowel. Complications were noted in 102 cases, or one third of this series. This series shows a mortality of 2.9 per cent. in 306 cases.

14. **Testing Gastric Secretion by Use of Self-Closing Dredge.**—Burgess' method consists of the use of a capsule, which is so constructed that it automatically closes as it leaves the stomach, and thus protects its contents from contamination.

Bulletin of Johns Hopkins Hospital, Baltimore

22 Antagonism Between Lactic-Acid and Spore-Bearing Organisms in Milk. W. S. Kiester, Baltimore.

19. **Foot-and-Mouth Disease in Man.**—The clinical picture presented by Clough's patient was that of a mild febrile infectious disease, characterized by the appearance of an erythema and a superficial vesicular eruption over the mucous membrane of the mouth and on the skin of the hands and feet; by salivation; by swelling, burning and parasthesias of the affected parts, with subsequent desquamation; and by healing of the ulcers without scar formation. The disease was present at the time in cattle in the neighborhood of Baltimore, and infection by means of milk or cream was possible, though it could not be demonstrated. Experimental proof of the nature of the disease by animal inoculation could not be obtained. Nevertheless the clinical picture was so characteristic that the diagnosis seemed reasonably certain. Treatment consisted of mouth washes of potassium chlorate and permanganate, and the application of skin lotions to relieve the itching. On the seventh day some of the exudate scraped from the vesicles in the mouth was inoculated into the mouth of a young dog after scarification of the mucous membrane. No lesion developed.

30. **Relation of Urinary Findings to Pulmonary Tuberculosis.**—The pavilion for tuberculous patients at the Sacramento County Hospital has an average of from twenty to thirty inmates, nearly all of whom have advanced lesions. This group seemed to offer a good opportunity for checking up the urochromogen and diazo tests clinically and not infrequently pathologically as well. During his service Cummings examined 100 patients. In making the so-called urochromogen test the technic of Weiss was used. In 100 successive admissions of patients suffering from pulmonary tuberculosis only fourteen could be given a favorable clinical prognosis. In no case considered as "favorable" from a clinical standpoint did the so-called urochromogen reaction appear in the urine. In seven of the fourteen cases (50 per cent.) clinically considered "favorable" a positive diazo reaction was obtained. In thirty-nine of eighty-six (45 per cent.) clinically unfavorable cases the urochromogen test was positive while in fifty-three (61 per cent.) the diazo test was positive. Seventeen of 100 patients died in six months. Of these seventeen, eleven (65 per cent.) showed a positive urochromogen, and thirteen (76 per cent.) a positive diazo while ten (59 per cent.) showed both. Of seventeen patients showing a positive urochromogen test with a negative diazo (a combination considered especially ill-omened by Weiss) none has died to date. Of thirty-nine patients having a negative urochromogen and a positive diazo, five have died.

45. **Second Infection of Syphilis.**—September, 1914, Blackshear's patient consulted him for a sore on the penis. This proved to be a chancroid, which healed up promptly under local treatment. Blackshear saw him again three months later. He then presented a typical sore of ten days' duration. Period of incubation uncertain, owing to various exposures. This lesion on examination by dark field illumination, showed the presence of *Spirochaeta pallida*, and the diagnosis of syphilis was made. He had a moderate degree of inguinal adenitis. The patient stated that he had contracted syphilis three years before; had been given three intravenous injections of salvarsan. At that time he presented a typical case of syphilis, stiff joints, swollen glands, headache, throat symptoms and a beautiful eruption.

53 Tuberculosis of Tongue. W. Blancard, New York.

50. **Pemphigoid Eruptions.**—The cases in Mook's report were all primary vaccinations. The lesions showed a predilection for certain areas, localizing around the mouth, neck, extremities, and especially the joints. He states that the pemphigoid variety may appear as small vesicles, resembling chickenpox and smallpox, or as papulovesicles, and may become pustular. The bullae are usually clear and tense on normal skin, though they may be on inflamed and eczematoid areas of great variety in sizes, forms and configurations in the same individual. Hemorrhagic bullae are frequent. Circinate and concentric rings of bullae are marked features. In some cases the central bulla is hemorrhagic, with concentric, serous vesicles and bullae and not necessarily intercommunicating. Others have a tendency to the production of large, gyrate patches of peculiar inflammatory areas, resembling mostly eczematoid dermatitis. The period of incubation may vary from three to four days to four months. A majority of the cases vary from three to five weeks. The benign cases are manifested by smaller bullae. Mouth lesions may or may not be present, and there may be slight or severe febrile disturbance. They may terminate in complete, uncomplicated recovery in a few weeks, or recur as a vesicular or bullous eruption, in crops, over a period of years as a true or pseudodermatitis herpetiformis. The vegetating and scar-forming varieties are fortunately rare. All of the cases have a rise of temperature at the onset or during the course of the disease.

Inoculation experiments were negative in two monkeys, a calf, several guinea-pigs and rabbits. Blood cultures from a fatal case and two recovered cases were negative under aerobic and anaerobic conditions, on agar and blood serum medium. Numerous cultures from various bullous lesions yielded ordinary staphylococci and some of them were sterile. Smears from one case showed diplococci, but the culture from this case showed staphylococci and the guinea-pig inoculated was negative. A mild or marked leukocytosis occurred early in all of the cases, continuing in two of the fatal ones and disappearing in those recovering or having a tendency to relapse. The eosinophilia appeared in the later stages, though it was not constant. The disease begins as a primary lesion, namely, the vaccination, followed by mild or severe constitutional involvement, with a multiformity of lesions involving the skin and mucous membrane, and running a short, acute, or chronic course sometimes over a period of years, and in many is fatal.

69. **Typhoid Treated with Typhoid Vaccine.**—A review of the literature by McWilliams shows that more than 550 cases treated in this manner have been reported in the literature. In more than half of these cases the disease was cut short, the patient having been saved from one to several weeks of fever. McWilliams believes that a few deaths must undoubtedly be attributed directly to the injections of vaccine. However, this is likely to occur with any new and radical method of treatment. As the contraindications and dosage are better understood, such deaths should become extremely rare. No one type of vaccine seems to possess any great superiority over other types with regard to treatment. The proper dosage for intravenous injections appears to be from 100 to 250 million bacilli. The injection of the vaccine calls forth first a marked leukopenia and several hours later a high-grade leukocytosis in typhoid patients. Variations in the number of polynuclear leukocytes are responsible for these changes, the lymphocytes remaining relatively constant. The eosinophil cells undergo an increase shortly after the injection. The various types of vaccine call forth similar changes in the blood picture.

112. **Splenectomy in Pernicious Anemia.**—A review of the literature has convinced Penrose that splenectomy is of unquestionable service in selected cases of pernicious anemia. In his case while the enlargement of the spleen was a most favorable indication for operation, the lack of regenerative forms in the blood made him dubious. The fact that this patient had put forth all his power for recuperation a year before was also against him. At that time a splenectomy would possibly have been of greater value. In all cases, Penrose says, it would seem wiser to perform, as was done in this case, a transfusion of blood, from a carefully selected donor, at the time of the operation. In this patient there was practically no surgical shock, and in all probability, while the splenectomy did not save him, his life was somewhat prolonged by the transfusion.

116. **Amyl Nitrite in Chloroform Poisoning.**—The results obtained by the authors indicate that the inhalation of amyl nitrite definitely increased the dose of the chloroform solution required to cause the death of the animals.

120. **Errors in Diagnosis of Renal Calculus.**—The following rules for avoiding errors are laid down by Cabot: In all cases of abdominal pain of a chronic or recurring type, in cases of backache, lumbar or sacro-iliac joint strain and lumbago, careful repeated examinations of the urine, including a microscopic examination of the sediment in all cases whether albumin is present or not, and of a catheter specimen in all female patients, should precede positive diagnosis. In most of these cases in which the symptoms warrant the consideration of operation, roentgenograms are essential. The evidence presented by the Roentgen ray alone is insufficient to warrant operation in most cases of stone in the kidney or ureter. Possibility of error by mistaking other foreign bodies should be excluded by the use of the ureter catheter, stereoscopic plates, injected roentgenogram, or the wax-tipped catheter. In any case in which the symptoms suggest ureteral calculus and a doubtful shadow appears in the roentgenogram, if the ureter cannot be catheterized on repeated attempts or the catheter is arrested at the same point on various occasions, the decision for or against operation must be made on the apparent gravity of the symptoms. In cases with symptoms suggesting stone in the kidney, with a normal urine, a negative roentgenogram and an unobstructed ureter, the wax-tipped catheter will not infrequently lead to a correct diagnosis and will be likely to fail only in the cases in which the stone lies in a dilated calix and is therefore out of reach of the catheter.

121. **Postoperative Renal Infection.**—Ward believes that postoperative renal infection is more frequent than has been formerly appreciated, owing to the fact that in many cases it is overlooked on account of the mild character of the infection, the severe types being comparatively rare. Vesical irritability occurring after operation may be an important precursory sign of renal infection, and therefore should not necessarily be attributed to a cystitis caused by carelessness. Ward says that a study of the urine will show the probable type of the disease present, and thus be a guide to the treatment. He advises that a careful study of the pathologic con-

dition of the kidney should be made at the operation in order that nephrectomy may be avoided if possible.

123. **Bladder Function After Confinement.**—While there are all gradations of deficiency in bladder function after confinement and operation, Taussig says, that for practical purposes patients may be divided into four groups: 1. Those who show at such times no appreciable change from normal micturition. Those who, although able to void spontaneously, do not for a day or two empty their bladder completely. Those who require catheterization one or more times in the first few days, but are then able to void without further trouble. Those with prolonged interference of bladder function. The character and duration of the operation or labor, the form and amount of the anesthetic, the age of the patient, the nervousness of the individual and the degree of sensitiveness of her bladder mucosa, are all factors that to a greater or less degree come into play in introducing urine retention; and the object should be to regulate the therapy so far as possible in accordance with the probable factors in each case.

124. **Laboratory Diagnosis of Chronic Renal Infections.**—Curtis advises that the source of even small amounts of pus in the urine should be investigated. He believes that persistent pyuria in the absence of a gross bladder lesion is almost invariably due to kidney disease. In those frequent cases with bladder irritability which yield clear, bacteria-free urine, cultures from the traumatized urethral canal, or from introduction of a probe into Skene's ducts, may demonstrate the cause of infection. When bacteria are widely scattered or grow with difficulty, a mixture of the urinary sediment with blood followed by the making of a large number of ascites-blood-agar tubes of high dilution, results in conditions favorable for the development and isolation of the bacteria present. The chief lesions in urinary tuberculosis are usually renal. In obscure cases, laboratory diagnosis is facilitated by potassium iodid, tuberculin, kidney massage, limitation of liquids, repeated examinations of fresh specimens after high power centrifugation, Petroff's cultures, and injection of series of medium-sized guinea-pigs. Curtis is of the opinion that there is seemingly a tendency to lay undue stress on functional urinary tests at the expense of careful routine examination.

126. **Shock and Hemorrhage.**—The data from experiments reported by Mann may be summarized as follows: In a normal dog 66 per cent. of the blood can be obtained from the femoral artery and 10 per cent. from the heart, making a total of 76 per cent. which can be secured, leaving 24 per cent. in the tissues. In an animal in which the cervical cord is sectioned, producing medullary vasomotor paralysis, 54 per cent. of the blood can be obtained from the femoral artery and 12 per cent. from the heart, a total of 66 per cent., leaving 34 per cent. in the tissues. In an animal in which blood pressure is depressed practically to zero by an overdose of ether, 46 per cent. of the blood can be obtained from the femoral artery and 13 per cent. from the heart, making a total of 59 per cent., leaving 41 per cent. in the tissues. In an animal in which the viscera have been exposed until the clinical signs of shock are present, but in which the vasomotor reflexes are as active or even more so than in the normal condition, only 28 per cent. of the blood can be obtained from the femoral artery and 11 per cent. from the heart, making a total of 39 per cent., leaving 61 per cent. in the tissues.

Mann concludes that the clinical signs of shock which appear after section of the abdomen and exposure of the viscera are due to a loss of circulatory fluid. This loss of fluid is not dependent on any primary impairment of the medullary vasomotor center and takes place at a point beyond the control of the vasomotor mechanism. The causes for this loss of fluid are apparently the same as those which determine the accumulation of fluid in any other irritated area and produce the signs of inflammation. The nervous system probably plays no greater part in the former case than in the latter. The condition is made grave when the viscera are exposed because of the great vascularity of the tissues involved.

129. **Fibrin as Hemostatic in Cerebral Surgery.**—Grey suggests the use of sheep's fibrin for controlling hemorrhage in certain types of intracranial surgery. After washing the fibrin repeatedly it is allowed to stand in distilled or tap water for twenty-four hours or longer until all of the enmeshed red blood cells have been laked. After placing the fibrin (previously divided into smaller pieces) into a roomy glass jar containing normal salt solution, the mouth of the latter is covered with cotton and gauze and sterilized. The sterilization softens the fibrin and thus facilitates its absorption by the tissues. It is now ready for use. In this form the fibrin will keep for months. When dipped into a physiologic salt solution and pressed against bleeding points with a sponge or a wisp of dry cotton, fibrin was found to control the hemorrhage even better than wet cotton. The soft and pliable nature of this substance made it adhere to rough and smooth surfaces alike. The difference between fibrin and cotton in this respect was clearly shown when pledgets of each material were pressed over bleeding spots and then removed again after a lapse of a minute or two. Fibrin was found to adhere to the underlying structures much more firmly than cotton. This fact probably accounts for the more efficient hemostasis noted with the former when larger vessels were dealt with.

131. **Abderhalden Reaction in Malignant Tumors.**—In cancer Goodman and Berkowitz examined the blood of sixty-four patients. They obtained positive reactions in fifty-eight. In all of the fifty-eight patients the positive diagnosis of malignancy was confirmed later by clinical, operative, or postmortem evidence. Of the remaining six patients, three are still under observation. In a large series of pregnancy tests, the results were uniformly satisfactory. In a series of cases of angiosclerosis, the authors obtained positive reactions with artery and in several instances with suprarenal substrata. In a series of thyroid transplants they have been able in seventeen instances out of twenty-three to show positive reactions with suprarenal, and in two instances a positive reaction also with pancreas, but only one positive reaction with spleen. All of the specimens of blood taken from animals following the transplantation of organs with the use of blood vessel suture reacted positive with the substrate artery.

133. **Economic Treatment of Hand Infections.**—The treatment of hand infections, in order to give the best results from every viewpoint, Mock holds, must include the proper preventive measures, especially the prophylactic use of tincture of iodin and the early reporting of all minor injuries; the treatment of hand infections as a serious surgical condition from their inception, and whenever indicated the adoption of hospital treatment early; the proper and early diagnosis of the type and nature of infection and the exact location of the pus. Mock advises a proper incision of the abscess in order to establish adequate drainage and yet not spread the infection to other spaces.

134. **Hysterical Joint Neuroses.**—Rand's patient was subjected to sudden trauma, falling on her right hip. The obsession of some severe injury possessed her. She was unfortunately examined before a large body of physicians, in a case in which a diagnosis of fracture of the neck of the femur was made, and its symptoms, prognosis and treatment, discussed. Only after repeated negative Roentgen-ray examinations and the stormy manifestations of her hysterical attack was the condition of true joint neurosis established. The fact that function returned as soon as the patient's confidence was gained supported this diagnosis.

144. **Intra-Abdominal Use of Oxygen.**—Collier has used oxygen intra-abdominally in twenty-five laparotomies, and the results have been most favorable in all. The lessening of shock, the absence of nausea and vomiting and the early recovery from the anesthetic have been the most marked features of its use, and he has not in any case seen any untoward effects. The absorption of the oxygen is quite rapid, and even though there might be some apparent embarrassment of the respiration due to overdistention of the abdomen, Collier has never felt that this was an element of

fear, owing to the rapid absorption of the gas. The distressing postoperative results, so often seen, have been eliminated in those cases in which oxygen has been used, and Collier believes there will be a more widespread use of this valuable adjunct of the surgeon.

1. **Cinchona Derivatives Inquiry.**—The main object of MacGilchrist's investigation was to determine the relative therapeutic value of the more important cinchona alkaloids and their derivatives. The five alkaloids, quinin, quinidin, cinchonin, cinchonidin and quinoidin and the two quinin derivatives, hydroquinin and ethylhydrocuprein (optochin) were examined and their relative therapeutic value was determined in the following order, hydroquinin being the most and quinoidin the least effective: (1) hydroquinin hydrochlorid; (2) cinchonin sulphate; quinin sulphate; quinidin sulphate, for all practical purposes of equal value. If any difference, cinchonin is superior to quinin and quinidin is inferior. (5) optochin hydrochlorid; (6) cinchonidin sulphate; (7) quinoidin. As regards unpleasant by-effects of these alkaloids, buzzing in the ears was most frequently associated with quinin and quinidin; amblyopia, with quinin and cinchonin; diarrhea with cinchonin if administered for over a week; and nausea with quinoidin, cinchonidin, even in large doses, caused no unpleasantness of any kind.

The first notable effect of these alkaloids is to arrest sporulation; sporulating forms are the first to disappear from the peripheral blood. Small rings and, somewhat later, half-grown parasites are the next to become rare and disappear. The last forms discoverable in the blood are full-grown schizonts and gametes. The natural protective forces of a person in relatively good health greatly aid the antimalarial action of these alkaloids. At certain stages of development the parasite is more resistant to these alkaloids than at other stages; and, to effect a complete disappearance of the parasite from the peripheral blood, the vulnerable stage in the cycle of development must be reached. It would appear that the minimal lethal doses for the vulnerable stage of the benign tertian, malignant tertian, and quartan parasites are, respectively, about 0.1, 0.15 and 0.2 gm. per 70 kilogram of patient's weight. The dosage being sufficient, the average number of hours required to cause a disappearance of parasites from the peripheral blood is roughly proportionate to the duration of the life cycle of each parasite, the number of hours required in any individual case depending on the period required for the parasite to reach a vulnerable stage in its developmental cycle.

A curious but important fact discovered in this investigation is the smallness of the dose of quinin which is able to free the peripheral blood of asexual parasites, and is possibly able to check the production of gametes. It is rare indeed in practice to give such small doses to patients. The dose usually given being, therefore, generally sufficient, or more than sufficient, in cases in which one has failed hitherto is obviously in the duration of treatment. To a patient in whom gametes have developed it would appear that quinin should be administered daily for a period equal to the life-span of the individual gamete if there is to be any prospect of curing and disinfecting that patient. If malarial patients were really cured and disinfected, malaria would become a rare disease. There is reason to believe that gametes are produced only when the asexual forms of the parasite are becoming exhausted or are exposed to inimical surroundings, as a last defense against total extermination. Ordinary doses of cinchona alkaloids have little influence on crescents when once these are fully developed in the peripheral blood; but they apparently (1) check the production of crescents if administered before these bodies have appeared in the peripheral blood, and (2) greatly shorten the period during which these bodies, having made their appearance during treatment, can be found in the peripheral blood.

Parallelism or harmony between laboratory and hospital results is marked in the case of the five natural alkaloids, quinin, quinidin, cinchonin, cinchonidin and quinoidin; but is entirely wanting in the case of the two synthetic derivatives of quinin, hydroquinin and optochin, indicating that artificial products are more liable to show differences between in vitro and clinical results, as they are not so stable as the natural alkaloids. Improvements in the manufacture of cinchona derivatives, for use in malaria, suggested by the results of this investigation, are as follows: (1) to obtain a bark containing as little quinoidin as possible; (2) to extract quinin for use as such and for the manufacture of hydroquinin; (3) to issue the remaining alkaloids as residual alkaloid, which should contain as little quinoidin as possible, but have a high percentage of quinin, cinchonin and quinidin combined.

4. **Tests for Syphilis.**—The first of the tests worked out by Brown and Iyengar is dependent on the fact that when an aqueous solution of platinum chlorid is added to an alcoholic extract of normal serum, a much heavier precipitate is produced than in the case of an extract of syphilitic serum. They have tested 230 serums by this method and have found that the results follow, with few exceptions, those obtained by the Wassermann reaction and by Fleming's modification; moreover they have found a closer agreement between their test and the Wassermann reaction than they have been able to obtain when comparing the latter with Fleming's modification. The second test is the natural consequence of the first. If one of the properties of lecithin differentiates a syphilitic from a normal serum, the other should do so also. In other words, the capacity of activating cobra venom should be different in the two serums. The authors have tested fifty-five serums by this method and consider that the results bear out the conclusions obtained by their platinum chlorid test.

24 Case of Influenzal Meningitis. C. V. Boland.
25 Testing of Disinfectants. S. Rideal and J. T. A. Walker.

16. **Stock Vaccine in Treatment of Typhoid.**—The cases quoted by Wiltshire and MacGillycuddy are a consecutive series of fifty in which two or more doses of vaccine were given. Seven of these patients died, giving a mortality of 14 per cent. Six of the fatal cases were complicated by severe bronchopneumonia; the seventh died from perforation which occurred at a time when vaccine had certainly reduced the general typhoid toxemia. In all cases the clinical diagnosis was confirmed by bacteriologic means. In forty the bacillus typhosus was obtained by blood culture. In seven it was isolated from the feces. The remaining three patients were uninoculated men who gave a positive Widal reaction, and in two of these the strength of this reaction was found to increase during the course of the disease.

The fifty cases are divided into classes as follows: Class 1, vaccine did harm, 6 cases (12 per cent.); Class 2, vaccine without effect, good or ill, 12 cases (24 per cent.); Class 3, vaccine did good, 32 cases (64 per cent.). Class 1: In three of these cases the harmful effect was due to doses being given with too short an interval (forty-eight hours) between them. They all recovered, the harm done being quite slight. Class 2: (*a*) In five cases the vaccine received a good trial, but appeared to have no effect. As regards general severity of disease, or the stage at which the vaccine treatment was started, these cases did not differ from many in which the vaccine has done good. In all of them, however, the treatment was coincident with a steady increase of bronchitis or bronchopneumonia. Class 3: Group A. Twenty-four cases (48 per cent. of the whole series) showed definite improvement which started after the first or second dose of vaccine, and was continued. Group B. Five cases (10 per cent. of the whole series) showed no improvement from the first two doses of vaccine, but were definitely improved by doses following these. Group C. In one case vaccine was not used until the later stages of the initial fever. Group D. In two cases the initial doses gave good results, but later doses (in one case the third, in the other the fourth) appeared to coincide with the beginnings of intercurrent relapses, which ran an unmodified course. The stock vaccine used was supplied by the Royal Army Medical College.

The authors urge that the treatment should be started as early as possible with an initial dose of 250,000,000. A reasonable suspicion that a patient is suffering from typhoid is sufficient indication for commencing vaccine treatment. The treatment is quite harmless to patients who may subsequently be proved not to be suffering from typhoid. An interval of three days should be given between doses. Shorter intervals are not well tolerated. When a longer interval is given, if four days the dose should not be increased, if over four days the dose should be reduced. Great care must be used in dosage if secondary infections of the lung are present. If possible, the typhoid vaccine should be combined with a vaccine suitable for the secondary infection. Doses should be continued for ten days after the temperature is normal as a preventive against relapse. Preventive inoculation exerts slight, if any, influence on subsequent vaccine treatment.

31 Origin of Stimulus for Mammary Secretion. P. Zuloaga (Valladolid).
32 Embryologic Study of Double Monster. (Anadidyme Monocéphalien.) A. Keilin.

29. **Rupture of the Uterus During Pregnancy.**—In the three cases reported by Meyer the women had borne several children before and the pregnancy was at term or within eight weeks of term. The symptoms of the rupture were not characteristic, merely indicating some serious lesion in the abdominal cavity requiring prompt laparotomy. The only cause that could plausibly be incriminated for the rupture was a curetting of the uterus three years before in one case and, in the second, expression of a macerated six-months' fetus the year before. The tear in the uterus in both these cases was long and jagged. In the third case a small round hole was found in the fundus of the uterus, suggesting possible attempts at criminal abortion although such were denied. The round ligaments and vessels of the uterus indicated a somewhat infantile development, and this might have been responsible for the rupture. Sudden intense pain at stool was the first sign of trouble.

30. **Origin of Jaundice in the Newly Born.**—Bang's article is practically the same as the one summarized in these columns Aug. 7, 1915, p. 566.

37 *Degenerated Condition of Leukocytes in Urine as Early and Reliable Sign of Urogenital Tuberculosis. (Signe de Colombino pour le diagnostic rapide de la tuberculose uro-génitale.) E. Micheli (Padua).
38 Fibromyoma of the Prepuce in Scar of Syphilitic Ulcer. E. A. Delfino (Genoa).
39 *Pyelography in Eighty Cases. T. Plotkin.
40 *Cancer of the Prostate; Two Cases. C. Perrier (Geneva).
41 *Access to the Kidney. (Les voies d'abord du rein.) G. Marion.

37. **Early Diagnosis of Urogenital Tuberculosis.**—Micheli expatiates on the ease, simplicity and reliability of what he calls Colombino's sign, that is, the discovery in the sediment of the urine of deformed leukocytes along with a few red cells. In two cases reported, this first suggested tuberculosis as the cause of the symptoms. No tubercle bacilli could be detected, but the polynuclear leukocytes and some of the mononuclears showed the most remarkable shapes, the edges as if gnawed and fringed. No characteristic lesions could be found, but treatment as for tuberculosis of the bladder soon brought marked improvement and examination later revealed traces of tuberculous granulations.

39. **Pyelography.**—Plotkin gives fourteen pyelograms with an accompanying description, saying that complications developed in three of the eighty cases in which he applied pyelography in Joseph's service at Berlin. One patient had severe colic after the injection of the silver salt solution, and had to be kept in bed for twenty-four hours. Another had mild colic, and in the third case there was fever and much agitation for four hours. The pyelography was done on outpatients, as a rule, and the catheter was always narrow enough to permit reflux of any excess of fluid. If catheterization causes pain or hemorrhage, no attempt should be made at pyelography. In skilful hands the latter is free from danger, he declares. It is merely a simple rinsing out of the pelvis.

40. **Cancer of the Prostate.**—The hardness of the tumor in the prostate was the only sign that suggested malignant disease in one of Perrier's two cases. In the other the cancer had softened and broken down until the palpation findings were approximately normal. In one case there were also hard presacral lymph glands. In one case there was metastasis in the corpora cavernosa. If a catheter is not tolerated, suprapubic cystostomy gives the most relief with inoperable cancer of the prostate.

41. **Modes of Access to the Kidney.**—Marion's study of the various technics for exposing the kidney is accompanied by ten illustrations.

Presse Médicale, Paris

42 *Extraction of Projectiles in the Lungs. G. Marion.
43 *Atypical Sunstroke. (De l'insolation.) C. Lian.
44 Experimental Pharmacologic Study of Colloidal Gold. H. Busquet.

42. **Extraction of Bullets and Scraps of Shell from the Lungs.**—Marion has been surprised at the ease with which he extracted intrapulmonary projectiles in all but one of the twenty-seven cases in which he attempted it. In the one case that failed he had neglected fixation of the lung before opening the pleura. In two cases the projectile was in a pus pocket that had opened into the air passages; in three others it was found in a pus pocket which there had been nothing to suggest beforehand. All the patients promptly and completely recovered. Each case is described in detail.

43. **Atypical Sunstroke.**—Lian reports three cases in which men working several days in the sun gradually developed the syndrome of meningeal irritation, symptoms of subacute meningitis bringing the men to the hospital by the end of the week. The intense headache, vasomotor disturbance and slowing of the pulse were accompanied by extreme depression and slight fever. The clear fluid spurted under pressure on lumbar puncture. In one case there was stupor for twenty hours and slight stiffness of the neck. Another atypical form of sunstroke was encountered in one soldier who had been digging for several hours in the sun. There was sudden and acute dilatation of the heart, with extreme arrhythmia. The man was a robust farmer and was sweating freely when attacked by this cardiac form of sunstroke. Lian tested the heart functioning in a number of soldiers known to have slight cardiovascular derangement, and found that the myocardium showed signs of weakness after prolonged exposure to the sun. Complaints of progressively increasing headache during exposure to the sun should suggest the slow meningeal form of sunstroke, while symptoms on the part of the heart call for heart stimulants, and possibly a purge, with nothing by the mouth but water at first and then milk.

Berliner klinische Wochenschrift

September 13, LII, No. 37, pp. 961-988

45 *Hemorrhagic Aplastic Anemia. (Aleukia haemorrhagica.) E. Frank.
46 *Intraneural Injection of Antitetanus Serum at First Local Symptoms. A. W. Meyer.
47 Brain Lipoid as a Hemostatic. A. D. Hirschfelder (Minneapolis).
48 Perforation of Aortic Aneurysm into the Trachea. C. Hart.
49 Localization of Projectile in Tissues. (Das Aufsuchen des Fremdkörpers durch den Arzt nach Lokalisation.) W. Salow. (Zur Röntgenstereoskopie.) W. Salow.

45. **Aplastic Anemia.**—The affection which Frank calls aplastic (aregenerative) anemia-panmyelophthisis develops as hemorrhagic purpura which continues a steadily progressive course until the patient succumbs to the anemia in the course of a few weeks or months. In 11 of Accolas' 19 cases the age was under 30; Türk's 2 patients were a girl of 18 and a boy of 12, and Kleinschmidt's patient was a girl of 4½. Frank reports in detail a case in a woman of 33. She had contracted syphilis fourteen years before but was apparently in perfect health when given an additional mild course of mercury and salvarsan. Eight days after its conclusion the hemorrhagic purpura developed and progressed to a fatal termination in fifteen days. In this, as in all the cases on record, the small numbers or total absence of blood platelets was a striking feature of the cases. The affection seems to be a primary leukomyelotoxicosis, with secondary anemia partly from the loss of blood and partly myelophthisic anemia. It is quite distinct from pernicious anemia. Without examination of the blood, the cases would usually be classed as sepsis. The "hemorrhagic aleukia," as he also calls it, opens the portals to septic infection. It may develop as an ulcerating or necrotic throat or mouth trouble; in his case there was buccal periostitis. The sepsis is merely an accident in the course of primary toxic destruction (aleukia) or overproduction (aleukemia) of myeloid tissue.

46. **Intraneural Injection of Antitetanus Serum with Local Tetanus.**—Meyer calls attention to his success in aborting tetanus by an intraneural injection of antitetanus serum into the trunk nerve of the limb, above the injury, when the slightest tendency to twitching or contracture became evident in the limb. These local symptoms long precede the systemic and general symptoms, and a prompt intraneural injection may arrest the further spread of the tetanus and restrict it to the limb involved and cure it there. He impresses on the soldiers in his charge the necessity for watching for twitching and contracture of a muscle in the limb, and the importance of immediately notifying the physician.

Correspondenz-Blatt für Schweizer Aerzte, Basel

September 4, XLV, No. 36, pp. 1121-1152

50 *Deforming Osteochondritis of the Hip Joint in the Young; Five Cases. G. A. Guye and H. J. Schmid. Concluded in No. 37.

September 18, No. 38, pp. 1185-1216

51 Present Status of Bacteriotherapy. J. L. Burckhardt.
52 *Sulphur Disinfection. L. Kloemann.

50. **Juvenile Deforming Osteochondritis of the Hip Joint.**—Guye and Schmid give a detailed study of four cases of what they call Calvé-Perthes' disease, with the Roentgen-ray findings. The children were from 4½ to 8 years old, all boys, but they encountered later a fifth case in a girl of 6. The various features of the group of cases are tabulated for comparison. In all the cleft in the joint was abnormally wide as seen by roentgenoscopy. The head epiphysis was crushed down and deformed, the epiphyseal line irregular or no longer recognizable, or studded with spots and gaps. The neck was broader than normal and curved in all but one case. The future will decide whether tuberculosis has nothing to do with the affection as at present assumed by most writers on the subject. The head epiphysis seems to pass through four stages, first a flattening out and spreading over the neck, then a splitting into two or three fragments abnormally rich in lime, then a splitting of these fragments into numerous smaller fragments which have lost their lime, and, finally, a stage in which the head epiphysis disappears, or, if lime is given systematically some of the fragments may regain their consistency and strength.

Treatment should be based on the cause, which some think is incomplete and tardy ossification; and others ascribe it to some disturbance in the local circulation. In either case weight-bearing aggravates the condition, and immobilization is the logical treatment. The affection always tends to a spontaneous cure and operative measures are not called for. Extension of the limb, keeping the child in bed, relieved the pain and the complications rapidly subsided in their experience. General measures to strengthen the organism as a whole are important aids, sun-baths and massage in particular may prove useful. The contracture of the adductors disappeared completely under a month of bed rest and immobilization by extension in one case; another patient required eight months of treatment, but all finally were clinically cured and have no perceptible limp.

52. **Improved Technic for Sulphur Disinfection.**—Kloemann has found that sulphur sterilization is much facilitated by adding potassium chlorate to make it burn more readily. He mixes about four tablespoonfuls of pulverized sulphur with an equal amount of $KClO_3$ and strews this on the bottom of the vessel. The sticks of sulphur are then placed on this and what is left of the mixture is poured on paper and this is placed between the sticks and the paper lighted with a match. The whole mass then burns quickly and completely.

61 The Medical Officer with the Reserve Battalion. (Der Arzt beim Ersatz-Bataillon.) Torkel.

53. **Lymphogranulomatosis.**—In the first of Hoffmann's two cases a butcher of 37 had typical Hodgkin's disease accompanied by a skin affection suggesting pemphigus and evidently of toxic origin. This assumption was confirmed by the aggravation of the pemphigus as the glandular tumors retrogressed under Roentgen treatment. With hard Roentgen tubes, 20 X, and 2 mm. aluminum filter, all the lymphomas subsided, and also the infiltration in the skin. There was a mild recurrence four weeks later. A second similar course was followed by improvement again. The patient now, four months after he was first seen, feels quite well and the glands are all normal in aspect except for slight enlargement of some in the neck and axillae. A third course of Roentgen treatment has just been instituted including the spleen also. Roentgen treatment was promptly effectual likewise in the second case. The spleen was enlarged and there was eosinophilia reaching 30 per cent. Roentgen treatment also helped in some cases of fungoid mycosis. Tuberculous lymphomas did not retrogress so fast and transient fever developed, suggesting a tuberculin reaction.

56. **Uremia.**—Machwitz and Rosenberg have examined and applied various tests in 160 cases of nephritis in the last two years. The findings and deductions all confirm the advantages of classifying the uremia with nephritis as true uremia, uremia with convulsions, and the pseudo-uremia of arteriosclerosis. As a rule these types are distinct. True uremia is found with acute glomerular nephritis, and with secondary and genuine contracted kidney. The diagnosis is based on the high urea and residual nitrogen content of the blood and the indicanemia. Restriction of the amount of albumin in the diet is desirable in this form of uremia. Uremia with convulsions occurs most commonly in acute nephritis in the young. The prognosis is generally favorable. In treatment, lumbar puncture is the most important measure at our command. Pseudo-uremia is encountered with purely atherosclerotic affections of the kidneys. It is the result of atherosclerotic changes in the brain, and is distinguished from true uremia by there being no retention of nitrogen and no indicanemia. Treatment should be addressed to the atherosclerosis, aiming to arrest the progress of the arteriosclerosis and ward off heart failure. Stimulants for the heart may be necessary, and restriction of intake of fluids. Volhard lays great stress on this reduction of the amount of fluids taken, and it has proved surprisingly effectual also in their experience. The systolic blood pressure was up to 250 mm. mercury in some of these cases, and moderate amounts of albumin and casts of all kinds were found in the urine. The necropsy findings in a typical case described showed atherosclerotic changes in the brain ample to explain all the symptoms suggesting true uremia, even the epileptiform convulsions. This patient was a woman of 47 who had swollen feet for six months, and then an attack of unconsciousness for a few minutes. Six months later there was another attack, followed by headache, disturbances in vision and recurring convulsions for fifteen minutes at a time. There was pronounced excentric hypertrophy of the left ventricle but no albuminuric retinitis. There was no indican in the serum but 3 per thousand urea in the blood. No treatment was instituted except restricting the intake of fluids, and in four weeks the patient was free from all disturbances and had no further trouble for five months. Then the heart symptoms, edema, dyspnea and convulsions returned and fatal heart failure soon followed.

60. **Functions of the Spleen.**—Hirschfeld discusses in detail the various functions of the spleen as an organ for production of blood and for destruction of red corpuscles, for iron metabolism, and as regulator of the red corpuscle production in the bone marrow, and, finally, as an organ concerned in some way with digestion. It swells and becomes full of blood at the height of the digestive process. At the same time, he adds, none of these functions is indispensable; any one of them can be promptly assumed by some other organ, and there is no appreciable general disturbance after removal of the spleen in most cases. Exceptionally, however, persons are encountered who are unable to get along without the spleen and respond to splenectomy with a severe disturbance, polycythemia.

71. **Passive Hyperemia in Treatment of Shell Wounds.**—Sehrt has been much impressed with the benefit from a constricting band to the limb to induce Bier's stasis hyperemia. He has applied it in seventy-three cases of shell wounds, and found that it had an unmistakable effect in warding off general infection. It seemed particularly useful in this respect when it was applied at once after the injury, and kept up until a wall of granulations had been thrown up to protect the rest of the body. The results were particularly striking in cases of injury of large joints, even after suppuration had already set in. Preservation of function is the main advantage. The constricting band also seemed to aid in the delimitation of gas phlegmonous processes or even arrested the whole process. By the end of a few hours the pain from the lesion is abolished. The constricting band is applied in such a way that the pressure from the bandage is scarcely felt. It is left in place for six or seven days or longer, up to twelve days. The wound itself is left entirely unmolested except for a gauze covering.

81 Specific Treatment of Tuberculosis. (Die neueren Methoden der specifischen Tuberkulose-Behandlung und ihre experimentellen Grundlagen.) E. Toenniessen.

Another early sign on the part of the nervous system is the increased sensitiveness of the tissues on the side affected. Gasperini and Goldmann have established the connection between local hypersensibility (skin, muscles, bones and joints) and the site of a tuberculous lesion. The local muscle reactions are also liable to be exaggerated. This is most evident in the pectoralis and sternocleidomastoid muscles, as a rule. Neuritis, a tendency to polyneuritis, may be the first manifestation of a latent tuberculosis. In such cases the neuritis generally develops insidiously and affects the nerves connected with the pectoralis, deltoid, biceps or bronchial musculature. While the nerve trunks involved may present signs of inflammation or degeneration, the muscles between which they pass respond normally to all tests. This is a special feature of tuberculous nervous derangement. The spinal cord and the brain may suffer likewise from the tuberculous toxins, and the sexual organs may be abnormally stimulated while the normal inhibitions become less evident. He cites experimental data and observations on cattle testifying to the exaggerated erotic state liable to be induced by incipient tuberculosis.

There does not seem to be any parallelism between the extent of the tuberculous focus and the nervous disturbances. In fact, the latter are generally most pronounced in the earliest phases and in the walled off, sclerogenous, rather benign foci. The toxins in the closed foci are all taken up by the blood or lymph and none are cast off, as with an open lesion. Esquirol has recently reported that in the tuberculous insane, in his asylum, the mental derangement grew worse as the local tuberculous affections improved and vice versa.

105. **Nodular Mycosis of the Hair: Piedra.** — Torres describes this parasitic infection of the hair which attacks the young by preference, forming minute gritty nodosities along the hairs of the affected scalp. All his patients were promptly cured by application of a 5 per cent. alcoholic solution of salicylic acid after bathing or washing the hair. The alcohol cuts out the grease and as it evaporates the acid is deposited in a fine powder on the nodules. It never seemed to injure the hair in any way. Cultures of the parasite kept their virulence up to five months in his experiments.

106. **Pus-Generating Diphtheroid Bacillus.**—In 200 cases of various suppurations in wounded soldiers Pavlovsky found the pyogenes diptheroid bacillus in 6 per cent. in pure cultures, and in 6 per cent. mixed with staphylococci. The microbe in question he described in 1909. It is usually located outside the cell; stains with the Gram, and resembles a diphtheria bacillus recently cultivated. It grows on agar in twenty to twenty-four hours at 35 C. and on Loeffler's serum, and does not liquefy gelatin. Guinea-pigs injected in the abdominal cavity with 1 c.c. of the bouillon culture died within from thirty-six to fifty-two hours, and the cultures from their liver and blood gave on Loeffler's serum the same diphtheroid cultures. Clinically there is suppuration with formation of grayish or whitish-gray pus, moderate fever (102 C.), and occurrence of fistulas, but the infection seems to be rather localized, the symptoms of systemic or general infection being mild. The prognosis is therefore good. Pavlovsky thinks that this microbe should be added to the group of those considered as the primary cause of suppuration.

107. **Gas Asphyxiation in War.**—Beloff treated fifteen soldiers poisoned with asphyxiating gases who came under his care four days after the onset of the poisoning. The symptoms were those of bronchitis (cough and slight dyspnea), accompanied by headache and loss of consciousness. The cases were rather mild; there were no blood changes, but the skin was dry and the conjunctiva pale. In one case only was the conjunctiva hyperemic. The heart beat was accelerated (96 per minute); the sounds were dull, with the second pulmonic accentuated. The appetite was poor, the temperature normal. Digitalis gave better results than expectorants, Dover's powder, etc.

110. **Experimental Chancroid in Rabbits.**—Terebinsky succeeded in inoculating rabbits in the scrotum with chancroid. Only those inoculations proved successful in which he artificially temporarily prevented phagocytosis. This he accomplished by causing on the animal's abdomen an artificial irritation with tincture of iodin. A small piece of gauze soaked in the latter was passed underneath the skin, after two cutaneous incisions had been made at a short distance from each other, so that the gauze passed from one incision to the other. The bacteriologic and microscopic examinations both showed that the inoculations were successful. The inoculation chancroids on the day following the inoculation showed very small bloody scabs, surrounded by slight redness or without any reactive changes. Pus was occasionally present. A typical chancroid showed on the fifth day, containing numerous streptobacilli. The latter are taken up by the nuclear leukocytes, marked phagocytosis thus taking place. By the eighth day the process of repair was in evidence and healing was complete by the tenth day, in some. In others it took nineteen days to heal, the average having been two weeks.

113. **Early Signs of Exophthalmic Goiter.**—*Popoff found in* 33 per cent. of his cases of Graves' disease a sign which much resembles Graefe's sign. When the patient's eye is fixed at an elevated object which is gradually lowered, the eyeball and the lid normally move synchronously. Early in exophthalmic goiter, however, the upper lid becomes very irregular in its movements. It either gets ahead of the eyeball or lags behind. In some cases this lack of parallelism is to be observed only in the very beginning of the experiment, disappearing after repeated trials, which are followed by perfectly normal movements. Popoff looks on the described sign as a forerunner of Graefe's sign.

115. **Bacteriology of Typhus.**—Milman discovered in the blood of soldiers sick with typhus fever a diplobacillus which was nonmotile, Gram positive, and did not coagulate milk, or form indol, or ferment grape sugar, and did not split milk sugar. Inoculation of rabbits gave positive results, and the same diplobacillus was found in the blood and tissues. The twenty-four hour bouillon culture was injected hypodermically into a guinea-pig and rabbit. The former remained alive but developed an abscess on the spot of the inoculation, in which the diplobacillus was found in pure cultures. Cadavers also showed its presence. The agglutination test was hard to carry out in many cases, but it proved positive. Milman proposes to call the described microbe, the streptococcus exanthematicus because it very much resembles an ordinary streptococcus with the acquired property of inducing typhus fever pyemia.

116. **Primary Cancer of the Lung.**—In the course of 16,047 autopsies performed in one of the large hospitals of Petrograd, during the last ten years, primary carcinoma of the lungs was found sixty-one times, that is, in 0.38 per cent. Of the total cases of carcinoma the rate was 3.7 per cent. The age was from 45 to 60, the male sex prevailing (forty-two men, nineteen women). In about 46 per cent. there were no metastases. The correct diagnosis was made only in nineteen out of the sixty-one cases, the disease having been mistaken usually for pulmonary tuberculosis. The latter, however, was found frequently combined with carcinoma. Other diseases which were diagnosed instead were pleurisy, pneumonia or aortic aneurysm. The reason of the mistaken diagnosis was metastasis in the tracheal, bronchial, or clavicular glands, in the liver, kidneys, etc., which complicated the clinical symptoms, overshadowing those of the primary cancer in the lung. This was especially the case with secondary carcinoma of the liver and the stomach. The clinical signs of pulmonary carcinoma are usually cough, pain in the chest and dyspnea entirely out of proportion to the physical findings and very severe. Pleurisy with effusion was found with pulmonary carcinoma in 26.2 per cent. In eight cases it was hemorrhagic, in three purulent, and in five fibrinous. The temperature was elevated in half of the cases. The best diagnostic aid proved to be roentgenoscopy.

119. **Iodin Internally in Place of Potassium Iodid.**—Zaussailoff warmly recommends tincture of iodin as a substitute for potassium iodid in diseases like syphilis, rheumatism, gout and obesity. The dose is one drop given three times a day, and is daily increased by one drop to a dose. In many cases fifty drops were given three times a day without any of the by-effects which are so common with potassium iodid, and without any gastro-intestinal irritation. He used it in 352 cases, and gives detailed reports of twenty-four cases.

127 **Intoxication from Adalin.* A. Nieuwenhuijse.

122. **Heart Block with Exophthalmic Goiter.**—The patient was a woman of about 45 who had long presented symptoms of exophthalmic goiter when signs of heart block became evident, and there were also indications of Adams-Stokes disease. The effect of treatment is discussed and also the light thrown possibly on etiology of each of these three affections by their coincidence in this case.

123. **Amenorrhea and Extra-Uterine Pregnancy.**—Nijhoff relates some convincing clinical experiences which demonstrated that an extrauterine pregnancy may be under way and rupture occur, even when the interval since the last menstruation is less than four weeks.

127. **Adalin Poisoning.**—Called to a young man absolutely unconscious, Nieuwenhuijse found symptoms like those of veronal poisoning, and an empty box that had contained adalin powders. The young man recovered under saline subcutaneously, stimulants and clearing out the stomach and bowels, but the symptoms were very severe while they lasted. The unconsciousness persisted for nearly sixty hours. The dose had been about 3 gm., namely, ten powders of 0.3 gm. each. It was taken on a friend's advice to relieve insomnia.

129 Treatment of Laryngeal Tuberculosis in Sanatoriums for Pulmonary Tuberculosis. T. Begtrup-Hansen.

128. **Syphilitic Cardiovascular Disease.**—Øigaard reports in detail fifteen cases of aortitis or myocarditis or both in persons known to have had a history of syphilis at some time. The Wassermann reaction was negative in ten and weakly positive in five. Treatment with heart tonics, iodid, morphin, etc., had given no relief, but all were benefited and some apparently cured by treatment for the syphilis. The lack of improvement under the usual measures first gave the clue to the syphilitic nature of the trouble. He has long warned that the symptoms of syphilis may subside before the Wassermann reaction becomes negative, and, on the other hand, that symptoms may recur later without the Wassermann accompanying them. The reaction-free recurrence requires treatment just the same as if the Wassermann were positive. He found further that by using twice or four times the amount of serum, it sometimes was possible to obtain a positive Wassermann reaction when otherwise it was constantly negative. In his group of fifteen cases, those with a positive Wassermann all had myocarditis. In a total of thirty-five cases the most intense reaction was in the patients with aneurysms; next came the cases with aortic insufficiency, then myocarditis cases with a weak reaction, and then the pure aortitis in which group all the cases were negative. In conclusion he says that treatment of syphilitic cardiovascular disease is not difficult, and the results may be more gratifying than in almost any other field.

THE NEED OF FULL-TIME HEALTH OFFICERS*

J. W. KERR, M.D.
Assistant Surgeon-General, U. S. Public Health Service
WASHINGTON, D. C.

Public health has been demonstrated time and again to be a purchasable commodity. Its value is not generally appreciated, however, and the price is not cheap. Three requirements must be fulfilled before any improvement of sanitary conditions may be guaranteed to a state or a community. These cornerstones on which public health administration rests are:

1. Wise legislation.
2. Adequate appropriations.
3. Efficient health organization.

Behind the three must of course lie public sentiment to cooperate in the enforcement of the measures deemed advisable and make possible their success. In other words, this is the minimum price which any human collectivity, be it nation, state or community, must pay to conquer preventable diseases, and through better health gain increased prosperity.

As a matter of fact, public health organization in the United States has been a plant of slow growth and has been stimulated for the most part by epidemics. The many federal, state and municipal health laws placed on our statute books, having been enacted independently of each other and to meet some emergency of the time, lack uniformity, and not every section has been provided with a local health organization. Moreover, the funds provided to carry on public health work have not been generally sufficient for the purpose. For instance, the total amount appropriated for the work of the State Board of Health of Minnesota in 1915 represented but 0.0034 per cent. of the total revenues of the state based on the figures of 1912, and Minnesota is above the average in support of such work. In at least one state no funds were voted for this purpose.

The conditions in counties and townships all over the land are even worse, practically none of them having full-time health officials. In Kansas, for instance, there were no full-time health officials prior to 1915. The report of the Kansas Commission on Public Health emphasized how unsatisfactory are present conditions from the standpoint of efficiency. The total amount spent for salaries to health officers in the whole state did not reach $42,000, the highest salary paid being in Kansas City, $1,500 per annum, and the average salary being about $310. Naturally, all these officers were also engaged in private practice to gain a livelihood, and many of them held other offices, as coroners and as county or pauper physicians. In many cases it was admitted that politics controlled the appointments, and that it was not unusual to let the lowest bidder have the health office.

In Illinois also, with the exception of Chicago, and of the cities of La Salle, Oglesby, and Peru, which have joined forces, there are, so far as reported, no full-time local health officers. Furthermore, out of 614 cities, towns and villages within that commonwealth, which responded to requests for information, no specific appropriations for health purposes were reported by 425. Of the 189 remaining, 106 had paid health officers, some of whom received as low as $5 per annum.

From the above it is evident that there is opportunity for great improvement, and in my opinion this may best be brought about by the systematic development of local health organization and employment of full-time health officers who are properly equipped to undertake the special duties that should be required of them.

THE IMPORTANCE OF LOCAL HEALTH ORGANIZATION

Of late, special emphasis has been laid on the exercise of larger powers by the federal government in the public health domain. In consequence, the need of strengthening local health administration, especially in rural communities, has been in large measure overlooked, and this subject is only beginning to receive any attention commensurate with its importance.

In other words, while local health administration should be the strongest, in reality it is the weakest link in our chain of national defenses for disease prevention.

It is true that many large cities are well provided, and the reduction in morbidity and mortality rates for the country as a whole in the last twenty-five years is largely attributable to such metropolitan provisions. It must be remembered, however, that 52 per cent. of our total population is rural, that is, live in the country or in towns having less than 2,500 inhabitants. It is for this class that provision should be made.

The federal and state governments cannot be expected to act locally except in great emergencies, it being their function rather to exercise advisory and supervisory powers in respect to local matters. They should encourage the establishment of local health agencies, therefore, and cooperate with them after they are established, to the end that public health work shall be coordinated and conducted in large part automatically in so far as the individual citizen is con-

---

* Read before the Section on Preventive Medicine and Public Health at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

113. **Early Signs of Exophthalmic Goiter.**—Popoff found in 33 per cent. of his cases of Graves' disease a sign which much resembles Graefe's sign. When the patient's eye is fixed at an elevated object which is gradually lowered, the eyeball and the lid normally move synchronously. Early in exophthalmic goiter, however, the upper lid becomes very irregular in its movements. It either gets ahead of the eyeball or lags behind. In some cases this lack of parallelism is to be observed only in the very beginning of the experiment, disappearing after repeated trials, which are followed by perfectly normal movements. Popoff looks on the described sign as a forerunner of Graefe's sign.

115. **Bacteriology of Typhus.**—Milman discovered in the blood of soldiers sick with typhus fever a diplobacillus which was nonmotile, Gram positive, and did not coagulate milk, or form indol, or ferment grape sugar, and did not split milk sugar. Inoculation of rabbits gave positive results, and the same diplobacillus was found in the blood and tissues. The twenty-four hour bouillon culture was injected hypodermically into a guinea-pig and rabbit. The former remained alive but developed an abscess on the spot of the inoculation, in which the diplobacillus was found in pure cultures. Cadavers also showed its presence. The agglutination test was hard to carry out in many cases, but it proved positive. Milman proposes to call the described microbe, the streptococcus exanthematicus because it very much resembles an ordinary streptococcus with the acquired property of inducing typhus fever pyemia.

116. **Primary Cancer of the Lung.**—In the course of 16,047 autopsies performed in one of the large hospitals of Petrograd, during the last ten years, primary carcinoma of the lungs was found sixty-one times, that is, in 0.38 per cent. Of the total cases of carcinoma the rate was 3.7 per cent. The age was from 45 to 60, the male sex prevailing (forty-two men, nineteen women). In about 46 per cent. there were no metastases. The correct diagnosis was made only in nineteen out of the sixty-one cases, the disease having been mistaken usually for pulmonary tuberculosis. The latter, however, was found frequently combined with carcinoma. Other diseases which were diagnosed instead were pleurisy, pneumonia or aortic aneurysm. The reason of the mistaken diagnosis was metastasis in the tracheal, bronchial, or clavicular glands, in the liver, kidneys, etc., which complicated the clinical symptoms, overshadowing those of the primary cancer in the lung. This was especially the case with secondary carcinoma of the liver and the stomach. The clinical signs of pulmonary carcinoma are usually cough, pain in the chest and dyspnea entirely out of proportion to the physical findings and very severe. Pleurisy with effusion was found with pulmonary carcinoma in 26.2 per cent. In eight cases it was hemorrhagic, in three purulent, and in five fibrinous. The temperature was elevated in half of the cases. The best diagnostic aid proved to be roentgenoscopy.

119. **Iodin Internally in Place of Potassium Iodid.**—Zaussailoff warmly recommends tincture of iodin as a substitute for potassium iodid in diseases like syphilis, rheumatism, gout and obesity. The dose is one drop given three times a day, and is daily increased by one drop to a dose. In many cases fifty drops were given three times a day without any of the by-effects which are so common with potassium iodid, and without any gastro-intestinal irritation. He used it in 352 cases, and gives detailed reports of twenty-four cases.

127 *Intoxication from Adalin. A. Nieuwenhuijse.

122. **Heart Block with Exophthalmic Goiter.**—The patient was a woman of about 45 who had long presented symptoms of exophthalmic goiter when signs of heart block became evident, and there were also indications of Adams-Stokes disease. The effect of treatment is discussed and also the light thrown possibly on etiology of each of these three affections by their coincidence in this case.

123. **Amenorrhea and Extra-Uterine Pregnancy.**—Nijhoff relates some convincing clinical experiences which demonstrated that an extrauterine pregnancy may be under way and rupture occur, even when the interval since the last menstruation is less than four weeks.

127. **Adalin Poisoning.**—Called to a young man absolutely unconscious, Nieuwenhuijse found symptoms like those of veronal poisoning, and an empty box that had contained adalin powders. The young man recovered under saline subcutaneously, stimulants and clearing out the stomach and bowels, but the symptoms were very severe while they lasted. The unconsciousness persisted for nearly sixty hours. The dose had been about 3 gm., namely, ten powders of 0.3 gm. each. It was taken on a friend's advice to relieve insomnia.

129 Treatment of Laryngeal Tuberculosis in Sanatoriums for Pulmonary Tuberculosis. T. Begtrup-Hansen.

128. **Syphilitic Cardiovascular Disease.**—Øigaard reports in detail fifteen cases of aortitis or myocarditis or both in persons known to have had a history of syphilis at some time. The Wassermann reaction was negative in ten and weakly positive in five. Treatment with heart tonics, iodid, morphin, etc., had given no relief, but all were benefited and some apparently cured by treatment for the syphilis. The lack of improvement under the usual measures first gave the clue to the syphilitic nature of the trouble. He has long warned that the symptoms of syphilis may subside before the Wassermann reaction becomes negative, and, on the other hand, that symptoms may recur later without the Wassermann accompanying them. The reaction-free recurrence requires treatment just the same as if the Wassermann were positive. He found further that by using twice or four times the amount of serum, it sometimes was possible to obtain a positive Wassermann reaction when otherwise it was constantly negative. In his group of fifteen cases, those with a positive Wassermann all had myocarditis. In a total of thirty-five cases the most intense reaction was in the patients with aneurysms; next came the cases with aortic insufficiency, then myocarditis cases with a weak reaction, and then the pure aortitis in which group all the cases were negative. In conclusion he says that treatment of syphilitic cardiovascular disease is not difficult, and the results may be more gratifying than in almost any other field.

fix minimum compensations, but these were so small as to preclude the idea of their providing for full-time services.

In North Carolina, however, there are now not less than ten full-time health officers, and their number is increasing. In Massachusetts also, the well-known experiment of several towns combining to secure efficient health service has been successful.

The principle of properly qualified full-time health officers appointed by the local authorities with proper compensation and fixed term of office has also been embodied in legislation recently proposed in a number of states, among which may be mentioned Indiana and Kansas.

The Kansas bill proposed to divide the state into not more than thirty sanitary districts, consisting of one or more counties each. A district board of health was to be created and composed of representatives of the county or counties, and each municipality within their borders. Each board thus formed was to appoint a full-time health officer whose qualifications were to be determined by examination conducted by the chancellor of the State University. These district health officers were to be prohibited from engaging in other business, and, in consequence of the importance of their duties, were to receive a minimum compensation of $2,000 per annum. The tenure of office was to be dependent on faithful and efficient performance of duties, and the jurisdiction of these health officers was to extend throughout their respective districts unless any incorporated city therein might elect to maintain a full-time city health officer.

By the above means it was expected to establish sufficiently large health duties to insure the full-time employment and retention of efficient public servants. It is legislation having this last mentioned object that should be encouraged.

ABSTRACT OF DISCUSSION

Dr. James Adams Hayne, Columbia, S. C.: We believe in a strong central government in Columbia, the capital, in the management of the public health affairs of the state. Our idea of full-time health officers for a county is that they should be paid by the counties and appointed by and hold office at the pleasure of the State Board of Health. In that way we feel that we remove them from local influences and political entanglements. I am fully in accord with Dr. Kerr. The full-time health officer is most important in public health work. No man can serve two masters. A man doing public health work must at once separate himself from the medical profession, because he at once becomes antagonistic to the profession, that is, the general practitioner. The hardest work that any public health official has to do is to get active cooperation on the part of the general practitioner. The physician is the stumbling block of the public health work. He will not report contagious diseases unless compelled to do so by public opinion. As long as public opinion supports him in concealing his cases of contagious diseases he will continue to conceal them; because he loses his bread and butter if he offends his patients by reporting them to health authorities, subjecting them to the discomfort of having quarantine signs put on their houses, and interfering with their going in and coming out. The public is being educated and soon the doctor who does not report will lose his practice. Whenever we arrive at this condition, then we will get some sort of effective public health work. A physician practicing medicine and doing public health work at the same time is going either to fail as a general practitioner, because he will not have any practice, or will fail as a public health worker, because he will pay attention to his practice and not to his public health work. It is, therefore, absolutely essential to differentiate, and recognize that because a man is a doctor of medicine he is not a doctor of public health. This must be impressed on the public, as they will not realize it. I am certain that soon a man will not take an M.D. in order to be a doctor of public health. He will study the general medical course perhaps two years, but after that will specialize on public health work, which is a distinct branch of the medical profession, and should not require the degree of M.D. in order to practice it. Men who do public health work in future will be those who specialize on public health. They must have a certain field open to them after graduating, and this field must be made attractive by its emoluments.

In regard to the cooperation of physicians and acts originating with the physicians, in South Carolina the State Board of Health is the entire medical profession of the state, and constituted so by law. We have 750 members of the State Board of Health, and they appoint or elect an executive officer, and a man from each congressional district, making seven in all; so that any act of the State Board of Health in South Carolina, or any bill from the state board, must of necessity arise from the medical profession of the state. They elect this committee, and the committee passes regulations and so forth, and then the physicians themselves do not obey their own committee.

Dr. A. F. Gillihan, Oakland, Calif.: Dr. Hayne did not mention one thing which has forced itself on my attention since I have been in office; that is, as a *full-time health* officer I can visit other physicians' patients without raising one particle of jealousy on the part of those physicians. This would be absolutely impossible for a part-time health officer in general practice without causing a great deal of animosity, from the very natural fear that he might pick up an occasional patient for himself. The words "to engage in no other occupation" have been used by the speaker. I think this is a good way to express the sentiment. A man doing public health work should not do any other kind of work—should not practice a little on the side. He should not only be occupying his time legally with his position, but he should be morally and actually occupying his whole time with his position. When he is not working at his job he should be dreaming it.

Another condition I desire to mention is the defective administration of public health laws of the state. In California there are some four or five full-time men in charge of public health in municipalities. I am one of these. The State Board of Health can write requesting action on certain matters and I can say "thank you," and throw the communication into the basket. In other words, the State Board of Health of California, as it exists today, has comparatively no authority. It cannot enforce its legislation. I personally do not believe in a health administration consisting of individuals engaged in private practice sitting on a board of health, either in a city or in a state. I am in accord with the New York method and with the United States Public Health Service—whole-time men and whole-time jobs. I believe public health will be advanced only through an organization in which every member is responsible through proper channels to the head of the department. The state should be the central controlling unit; city and country districts mere subdivisions, amenable directly to state control; and finally the state amenable to the federal service. All employees should be on full time. Public health work should be organized along the lines of preventive medicine and not as today, in California, along the old lines of curative medicine. We should lock the door before the horse is stolen. The method in use today is to lock the door after the horse is stolen; in other words, the disease is here and epidemic before the State Board of Health comes in to correct it.

Dr. Adelaide Brown, San Francisco: In California we have a law that has been passed on by our supreme court, that any city can do better than a state law but it cannot do worse. So if the city of Oakland is doing better than the state law on all those points they do not need the state law to help. Governor Johnson has signed a bill giving to the State Board of Health $30,000 for two years for the establishment of a sanitary engineering department; and this we, as members of the State Board of Health, consider the most fundamental thing that could be done for the public health of the state, because water supply and sewage are two prominent questions to which no consulting engineer has time to devote. Governor Johnson signed a bill for the establishment of a bureau of tuberculosis, including a distribution to the counties of the state, that come up to the standard of the bureau in their care of tuberculous people, a per capita assignment. This will jack up the county hospital; and they need the treatment. The bureau of tuberculosis will control the distribution of that money. The hospital will have to take proper care of its tuberculous people before they will get any money from the state.

A very good vital statistics bill was finally passed, although it had fifty-seven changes before it got through.

An antivivisection bill went into the hands of the governor for signature with a pile of telegrams. It was vetoed on the criticism of it on legal grounds by two prominent men. Those of you who have to face antivivisection legislation ought to learn to attack it as soon as it gets to the legislature, and not wait until it gets to the governor.

We have now a milk law which requires general pasteurization of milk. Its enforcement is a matter of state duty.

We have also passed a law advising the use of the prophylactic treatment of ophthalmia neonatorum, and an appropriation for the drugs necessary. We have had also for two years the registration of nurses. Nurses cannot come up for state examination unless the course has been intellectually correct for the young women, and they have been housed correctly, and their course has covered what it should cover and really be an educational course.

The salary of the secretary of the State Board of Health has been increased, which is a recognition for able work. One speaker said that you had to dream public health. I asked a young physician who had a public health position in an adjacent town, a school position, "How many hours do you have to work?" She said, "My salary requires five hours' work a day, and I generally do seven." I think that is practically the proposition. As soon as you limit your day to office hours you cease to be a public health officer. We are taxed by what the work needs and not by any system of hours.

Dr. J. N. Force, Berkeley, Calif.: It is one thing to get the law, and another thing to get it enforced. Here in California we had pretty nearly enough milk law without this new one, but the burden of enforcing the milk law was put on a few inspectors of the state milk bureau and on the local health officers, and of course the milk law was not enforced. I believe with Dr. Kerr thoroughly in the great need of strengthening local health administration. Dr. Gilihan spoke about jealousy of the local health officer. As soon as the local physicians cease to be jealous of the health officer he is beneath contempt, that is, providing that he is engaged in competitive practice. Now, take an illustration of this jealousy. The local health officer says that before children may return to school they should come to his office for a sort of bill of health. Immediately people who are doing pediatrics in the town say, "Oh, the health officer is steering the children down to his office." A man may have the soul of an angel, he may be extremely high-minded in his motives, but just so long as he engages in general practice or even special practice, I maintain he is subject to that criticism, and he is going to get it from somebody. One way apparently of getting round the full-time requirement is to put in a certain working day, and at its close shut down that section of your mind which deals with the public service just as you would shut down your desk. That does not answer the problem, because competitors are going to be just as jealous of a man in the evening as in the morning or between 2 and 4 in regular office hours. It cannot be done on any split basis. The point of view of preventive medicine is entirely different from that of curative medicine. I tried to mix them. I found they would not mix, and I had to give up the practice end of it.

California got as far as having a bill introduced, printed, and referred to the Committee on Public Health and Quarantine, where it was quietly knifed. Some of the features in the bill were that the state should be districted and these districts should have in no case less than 20,000 inhabitants. To develop a population of 20,000 small counties might combine, or a small city might get enough people from the surrounding country. Large counties were not to be subdivided. These small divisions would be inside of the county. There might be deputy district health officers as well as district health officers; and those deputies might either be graduates in medicine or must have a degree in public health from a recognized institution of learning. We put the public health graduate alongside the doctor of medicine with public health training; not saying that he was either better or worse, but saying that there is now a place in the scheme of things for a deputy health officer, not necessarily a medical officer of health; that is still another function; but the health officer having the public health degree.

Dr. William Simpson, San Jose, Calif.: I think I can explain where Dr. Force seems to be at a loss. I am chairman of the legislative committee which at a meeting held in San Francisco decided to ask the withdrawal of the bill until the next meeting of the legislature, for the reason that the bill had not been presented to the committee prior to its introduction into the legislature, and it was then too late to get an opinion from the health officers of the state, as had been agreed at the Del Monte meeting. We were sure it could not pass in the exact form in which it was presented. Every member of the committee was in favor of the full-time health officer, but we felt, as was expressed at the Del Monte meeting, that the men who had been doing the work should have a voice in such important legislation. I am sure no bill can pass unless it allows the counties and districts to make their own appointments. As a part-time health officer I have not had the difficulties with the general practitioner of which many complain, perhaps because our practitioners feel that the health officer is handy to lay things on, and that as a consultant in contagious cases it saves his families an extra fee and relieves him of a trying responsibility.

In California with its cosmopolitan population your inspector's value depends on his knowledge of languages and his ability to explain and give directions in all the dialects there are. The main difficulties of the health officer are in the families in which no physician is called, and here, if he has their confidence, teachers are of great assistance, and probation officers and truant officers valuable in digging out suspected cases. With most parents there is no effort to conceal reportable cases. The child is not sick enough to have a doctor, but may return to school soon enough to infect the school unless a certificate is required in every case before a pupil is allowed to return. Every minute of every health officer's time should be given to his work, for it is because he is not giving it full time that he not only dreams of his work, but has nightmares as well. In framing laws for this purpose in California, or any other state, however, the power of appointing the local health officer must be left to the local authorities.

Dr. T. D. Tuttle, Seattle: Dr. Hayne spoke of the state having $54,000 and the city $150,000. That on the surface looks badly out of proportion, and undoubtedly is; but I have been trying to find out what health officers are paid in Washington. They will write me, "Our appropriation for public health work in our city or county is $250,000." Beautiful. What does that mean? It means what they call "public health work," garbage collection, sewage disposal, sanitary sewers and all that. It is not public health work. It is some of the branches of public health work, but not as we understand public health work. Our state appropriations are not as big as they appear in a great many places. One of the speakers said that the county health officer service is under the direction of the state board of health, and removable by the state board of health alone. That is nice. We have that in Washington. We proceed to remove some county health officer for failure to perform his duty, and call on the county commissioners to appoint his successor. Dr. Jones is removed. We receive a notice by next mail, "We beg to advise you that we have this day appointed Dr. Jones county health officer." Beautiful theoretically; tommyrot otherwise. Unless your state board of health has the appointing power, to a certain extent, you have absolutely no control. Let your county commissioners appoint if you want to; but let your state board of health say who in that locality is subject to appointment; and let the state board or other authority have the power to remove him, and when removed provide that he cannot be reappointed until his stigma has been removed by your approving power. Then your central body has a certain amount of control over your local body and cannot be rebuffed by the local body. Your central body says, "Mr. Mayor, your health officer has failed to perform his duty. We call on you to remove him." He is removed. "Thank you. We recognize your power to remove. We immediately reappoint him." I was for ten years or more thoroughly opposed to the idea of the nonprofessional health officer. Now I am not. I have been converted absolutely over to the other party. The medical man, the practitioner, is not going to help the health officer to a very great extent in eliminating disease. Why should he? Why should I, a practitioner, devote my time or a part of my time, or any of my time, we will say, to a town of 300 people without just recompense not only for that time but for the practice that I cut myself out of? What right have the people to ask the practitioner to help them cut out the practitioner's income? They have no right to it and they are not going to get it. Human nature in the physician is the same human nature that we find in the lawyer, the governor, the president or any other politician. I as an individual have no right to ask you as a physician to deprive your children of bread and butter in order that my children should not have the measles.

DR. OTTO P. GEIER, Cincinnati: Dr. Kerr in his opening remarks said, "wise legislation, adequate appropriation and efficient health organization" were the three desiderata. From my experience as a volunteer in health work in our city I take it that one of the fundamentals has been omitted, because health administration cannot be efficient, no matter whether we have full-time health service or part-time health service, unless that service is free from political control. I believe that most counties, most cities, most states are suffering from poor health administration from the fact that they are under a miserable political control; where men with good intentions have their arms tied and their eyes blindfolded, rather than that they have not inherently good qualities and are ready to serve the public. In the direction of a full-time health service I believe that every man is made of good enough stuff, so that when he gives all of his time to the work he becomes efficient. Most men are intelligent enough, and the job itself brings enthusiasm with it, so that most men will succeed if they are given the opportunity and paid sufficient so that they can give whole service to the job. As to how to get the health service out of politics, that is a larger question which we can hardly cover; but I do believe that the medical profession is largely responsible for the fact that health service is jeopardized by political control. I find in moving about the country that very few county organizations are definitely and wholly in accord and working in harmony with the local health officer. They know not what he is doing, and they seem to care less. Now it does seem to me that the American Medical Association owes it to itself to evolve some sort of propaganada that will get the county society interested in the subject of health work, and that we are lamentably weak as a national organization in having failed to appreciate how that reflects on the medical profession, and how it lowers the dignity of the profession, not only in its public health work, but in private work. Nothing so brings the medical profession to full recognition in a community as good, efficient local health work. In Cincinnati up to 1909 the political organization had absolute control of our organization. The people were disinterested. All meat and milk and other inspection work done by that department was miserably done, and we were spending for a city of nearly 400,000, $55,000 a year. Since 1909 it has been under the domination of the medical men of that city. The medical men dictated nominations to the board of health that was created as the result of a pure milk crusade, and since then the board of health is above reproach, and there is not a suggestion of political interference in the board's work. And we have instead of a $55,000 appropriation, $110,000, and that is restricted to strictly health work. I believe with Dr. Kerr that the larger you make the unit the more forceful will be the work, because the more likely you are to get away from political interferences, and petty jealousies; and I think the department gathers a momentum and a dignity because of its size.

DR. O. B. NESBIT, Gary, Ind.: When I hear health officers talk about lack of cooperation of physicians, I sometimes am inclined to blame the health officer. Unless your public health work originates in your medical society you are going to fail. The health officer who is daily in the newspaper doing his work is not going to get much cooperation from the medical profession. If his campaigns originate in the medical society, and he will get his medical society behind him, he can do anything. A health officer who does not get the medical society in his work is at fault, and can never be an efficient health officer.

DR. J. W. KERR, Washington, D. C.: It is a satisfaction to know that the section endorses the employment of the full-time health officer. Personally I think this is the great problem in this country today in so far as public health is concerned. Few of us realize this fact, notwithstanding there is a great national movement going on for the improvement of health and living conditions. The first laws in the country relating to public health provided for the establishment of local health agencies. The first federal law provided for the cooperation of the national government with local authorities. The first state laws delegated the powers of the respective states to localities, enabling them to establish local boards of health. The relation of the local, state, and federal authorities is therefore fixed; and whether we want to or not we have to recognize that relation. The fact that a particular locality is backward in public health matters does not relieve it of responsibility.

In the desire for larger things we have rather lost sight of the fact that over 52 per cent. of the population of this country live in rural sections, that in these sections lie the real public health problems of the present day, and that the need of public officers is greater in rural sections than in our cities—greater because it is not being met. We have not in the past placed enough dependence on local health organizations. When a society or an individual begins to stir up interest in public health matters, the first thing that is attempted is to establish a commission or agency different from the health department to carry out the work, and the proposed law that is introduced often makes no mention of the local health officer, but aims to establish a new health agency. I think the best example of this is in the tuberculosis laws, of which there has been a mass enacted in the last several years. In many instances the local health officers have not had imposed on them the responsibility for the prevention of tuberculosis, the disease that causes more deaths than any other in the country. This is not the case abroad. In Germany, for instance, they depend on local health organization in local matters. If we in this country expect to advance local health administration and to have it run smoothly so far as the individual is concerned, we must make it our first business to establish a sufficient local organization and give it a living relation with the state and national health organizations.

Predigested Foods.—Experiments of all sorts have been made with predigested foods, compressed foods and the like, but the normal digestion rejects them all. A certain bulk of food is needed to keep the stomach and intestines in order, and unless the juices and ferments required for digestion are called forth in the normal way, the amount secreted will be lowered beyond the point of good health.—J. B. Harrington, *Bulletin*, Kansas State Board of Health, September, 1915.

VARIATION IN THE PLATELET COUNT

ITS CAUSE AND CLINICAL SIGNIFICANCE *

W. W. DUKE, M.D.
Professor of Experimental Medicine, University of Kansas, School of Medicine
KANSAS CITY, MO.

Remarkably little interest is taken in blood platelets by clinicians, so little in fact that I really hesitate to present a paper on this subject before the section. There are scarcely more than ten or twelve investigators working in this field at the present time, I believe. Nevertheless, platelets are very interesting and remarkable little bodies, and if time permitted me to enumerate some of the interesting facts and problems concerning them, I feel sure you would be convinced that they are worthy of more attention than they receive. This paper must be confined, however, to a brief report of clinical and experimental observations which are thought to throw new light on some of the factors which influence the number of platelets in the circulating blood. They should aid one, therefore, in drawing conclusions from the platelet count in clinical cases.

The platelet count is altered in a great number of diseases.[1] The alterations noted by different observers have been uniform in but few diseases; in fact, there are few lines of investigation in which opinions have been so divergent. One fact on which there is general agreement is that the count is reduced during the febrile period of acute infectious disorders, and increased during convalescence. This interesting change in the count was first observed by Hayem, and was referred to as a hematoblastic crisis. Hayem considered it an effort at blood regeneration. There are striking exceptions to the foregoing generalization. In Escherich's clinic I made a series of platelet counts in diphtheria—a good example of an acute infectious disease. The count was usually reduced during the febrile period of the affection (lowest count 3,000), and increased during convalescence (highest count 750,000). Occasionally, however, the findings were diametrically opposite to this; that is, the count was normal or increased during the febrile period (highest count 750,000), and normal or reduced during convalescence (lowest count 135,000).

In many chronic diseases the majority of observers have noted an increased count, and some have considered this a general rule. In Romberg's clinic I made a series of counts in tuberculosis—a good example of a chronic infectious disease. In harmony with the results of other writers, the count was usually increased, occasionally very much increased (highest count over 1,000,000). In two instances, however, it was very much reduced for several days (in one case to 55,000, in another to less than 1,000). Likewise in a series of observations made in nephritis, the count was often increased when an acute process was demonstrable or when there was marked evidence of renal insufficiency. Occasionally the count was very much increased (highest count 1,260,000). In one case, however, it was very much reduced (lowest count below 10,000).

One interesting feature has characterized the counts which I have made both in man and in animals. When the individual was normal and remained in a given environment, the count remained relatively constant. When the count was markedly increased or markedly reduced by pathologic conditions, it had a tendency to fluctuate. In Chart 1 is shown graphically the platelet count of four normal individuals in the same environment. During a period of eleven days, there was relatively little variation. It fell constantly between the limits of 200,000 and 400,000. In marked contrast to this is the extreme variability of the pathologic counts shown in Chart 2. In one, a case of advanced tuberculosis, the count varied from less than 1,000 to 720,000. In the other, a case of nephritis, the count varied from 350,000 to 1,400,000.

It is believed that the experiments to be reported subsequently throw light on the cause of these apparently errotic results.

EFFECT OF DIPHTHERIA TOXIN ON THE PLATELET COUNT[2]

Diphtheria toxin offered a most promising means of studying pathologic variation in the platelet count. In the first place, the platelet count is highly variable in diphtheria; in the second place, we might reasonably suppose that this variability is a direct result of the action of diphtheria toxin. For this reason, diphtheria toxin was introduced into rabbits in doses of different sizes and its effect on the platelet count noted.[3]

In Chart 3 are recorded the platelet counts of three rabbits following the injection of a dose of diphtheria toxin which caused death in from three to four days. In each case there was a rapid fall in the count. Necropsy showed degeneration of the marrow in high degree. The nuclei of a majority of the megakaryocytes were vacuolated or pyknotic.

In contrast to the foregoing are the results recorded in Chart 4. Here is shown the effect of sublethal doses of diphtheria toxin in three rabbits. The amount of toxin given in these experiments made the animals appear ill for several days. All recovered, however, and were lively throughout the remainder of the experiment. There was first noticed a marked rise in the platelet count. In one instance the count reached a height of 2,000,000. There was next noted a rapid fall in the count. In one instance the count reached the low level of 4,000. This was followed by a second rise in the count, which in one instance reached a height of 2,000,000.

Deduction.—Diphtheria toxin in large doses causes an immediate fall in the platelet count. This is presumably the result of a poisonous action of diphtheria toxin on the bone marrow. In sublethal doses it causes first a rise and later a fall in the count. The latter effect may be followed by a secondary rise in the count. In some cases the count does not descend below normal, so that the only effect actually observed is an increased count. These changes are believed to be due to an irritant effect of small doses of diphtheria toxin on the marrow or an irritant followed by a poisonous effect.

Helber, E.: Ueber die Zahlung der Blutplattchen im Blute des Menschen und ihr Verhalten bei *pathologischen* Zustanden, Deutsch. Arch. f. klin. Med., 1904, xxi, 316. Kemp, G. T.; Calhoun, Henrietta, and Harris, C. E.: The Blood Plates: Their Enumeration in Physiology and Pathology, The Journal A. M. A., April 7, 1906, p. 1022; April 14, 1906, p. 1091. Wright, J. H., and Kinnicutt, Roger: A New Method of Counting the Blood Platelets for Clinical Purposes, The Journal A. M. A., May 20, 1911, p. 1457.

[2] The platelet counts in these experiments have been reported in detail in a previous paper (Duke, W. W.: Causes of Variation in the Platelet Count, Arch. Int. Med., January, 1913, p. 100).

[3] Blood platelets in rabbits are more difficult to count than those in man. They are smaller and more variable in size and shape, and unless the ingredients of Wright's solution are balanced with care, the platelets will either clump or go into solution. The precautions necessary to obtain reliable counts have been mentioned in a previous paper (Duke, W. W.: Rate of Regeneration of Blood Platelets, Jour. Exper. Med., 1911, xiv, 265).

THE EFFECT OF TETANUS TOXIN ON THE PLATELET COUNT[4]

Because of the interesting results obtained with diphtheria toxin, tetanus toxin was tried. The counts recorded in Chart 5 were observed in three animals which received subcutaneously a large dose of a recently prepared solution of tetanus toxin (eight times the minimum lethal dose for a guinea-pig weighing 250 grams). Although this amount of toxin caused the death of one animal, and marked toxic symptoms in the other two, there was little change in either the platelet or white count. It hardly seemed worth while to pursue this line of work further.

Deduction.—These experiments are hardly complete enough to justify a sweeping conclusion concerning the action of tetanus toxin. At any rate, it may be said that its effect on the platelet count is not nearly so great as that of diphtheria toxin.

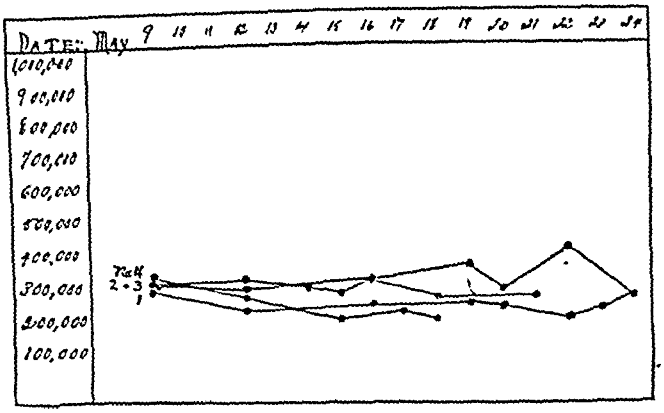

Chart 1.—Platelet count of four normal individuals in the same environment. Note the relatively slight variation of the counts during a period of eleven days.

THE EFFECT OF KILLED TYPHOID BACILLI ON THE PLATELET COUNT[4]

Killed typhoid bacilli were chosen for study because of the marked changes in the platelet count which occur in typhoid fever. It was hoped that some of the poisons which produce these changes might be present in the dead bacilli. Killed cultures were employed instead of living bacteria in order that the dose given could be definitely known and not modified by multiplication of bacteria in the animal. The resulting changes in the platelet count were definite and marked, but not so great as those which followed the use of diphtheria toxin.

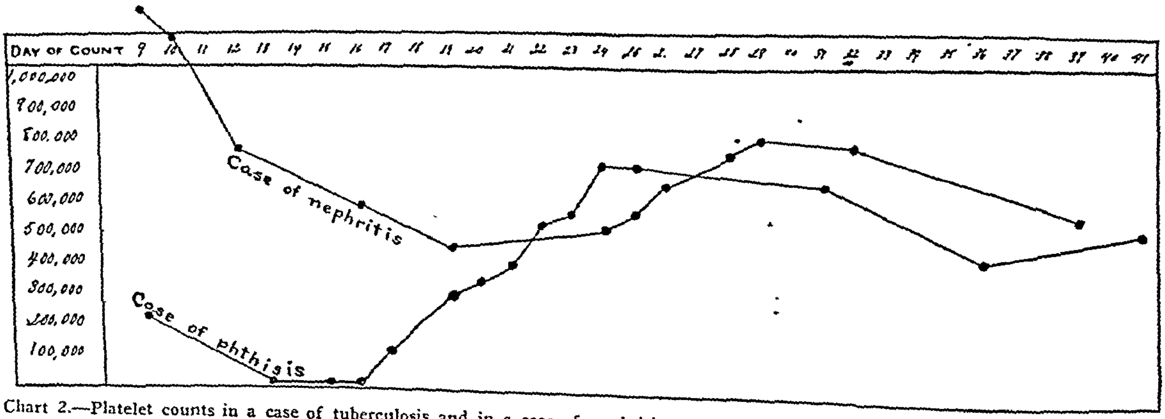

Chart 2.—Platelet counts in a case of tuberculosis and in a case of nephritis. These illustrate the variability of pathologic counts.

In Chart 6 are recorded the platelet counts of three rabbits which received subcutaneously 1,000 million dead typhoid bacilli, suspended in 1.5 c.c. of salt solution. The culture used had been obtained from a case of typhoid fever several months previously. The bacilli were obtained from a forty-eight-hour growth on agar-agar, were suspended in salt solution, and killed by heat (58 C. [136.4 F.] for one-half hour). The animals appeared ill for three days following the injection, but were lively and well throughout the remainder of the experiment. There was in each instance a definite rise in the platelet count which persisted for a few days. In one instance the count reached a height of 1,375,000.

In Chart 7 are recorded results showing the effect of 4.5 c.c. of the same suspension given intravenously instead of subcutaneously. The dose in this case was 3,000 million. Two of the animals were found dead the day following the injection. The one that lived appeared very ill for three days, but was lively and well throughout the remainder of the experiment. There was a marked fall in the platelet count (from 1,210,000 to 340,000) which persisted for a few days. This line of investigation did not promise to yield results of great interest and was discontinued.

Deduction.—The effect of killed typhoid bacilli on the platelet count is marked but not extreme or prolonged. Large doses given subcutaneously increase the count. Large doses given intravenously decreased the count for a few days in the one animal which survived this treatment. One might judge that large intravenous doses poison, and smaller subcutaneous doses stimulate the production of platelets.

THE EFFECT OF BENZOL ON THE PLATELET COUNT[3]

The effect of benzol (benzene, C_6H_6) on the platelet count was studied in both dogs and rabbits. L. Selling[5] had previously shown that benzol poisoning causes a reduction in the leukocytes in man and rabbits and concluded that this was a result of the degenerative changes he found in the bone marrow. It seemed that benzol might have an interesting effect on the platelet count also.

Twelve dogs were given subcutaneously several doses of from 2 to 40 c.c. of Merck's benzol. They all showed profound symptoms of poisoning and died in from four days to three weeks after the first injection. The platelet count fell rapidly in almost every instance. Little if any initial rise was noted. Typical experiments are summarized in Tables 1-4.

Necropsy showed in each instance a hyperemic degenerated bone marrow. The nuclei of most of the megakaryocytes were vacuolated or pyknotic.

Rabbits are not so severely poisoned by benzol as dogs, and are better adapted to this study. In Chart 8 are recorded results showing the effect on the platelet count of five 2 c.c. doses of benzol, given at intervals of twenty-four hours. There was first a marked rise in the count, which in one instance reached a height of 1,230,000. This was followed by a rapid fall in the count, which in one instance reached the low level of 56,000. One rabbit died and the other was killed. The bone marrow was degenerated in high degree. Few megakaryocytes were to be found.

---

[4] These experiments are of little interest except as recounted here, and hardly justify a more detailed report.

[5] Selling, L.: Benzol als Leukotoxin, Beitr. z. path. Anat. u. z. allg. Path., 1911, li, 576.

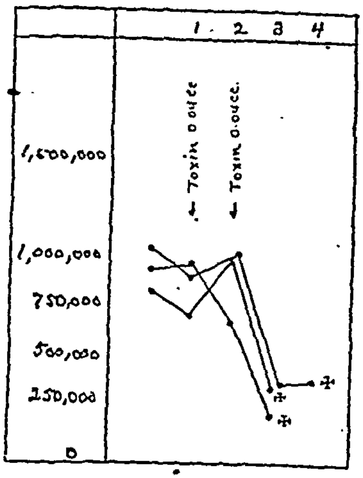

Chart 3.—Effect of diphtheria toxin on the platelet count of three rabbits in doses which caused death in from three to four days.

Chart 9 shows the effect of three 2 c.c. doses of benzol. This caused simply a rise in the count, which in one instance reached a height of 1,780,000. These rabbits showed no visible ill effects from the benzol. They remained lively and apparently well throughout the experiment.

Deduction.—Benzol given subcutaneously in large doses to dogs causes an immediate fall in the platelet count. In smaller doses it causes a lowering of the count, but the effect is not so rapid. This effect is believed to be a result of a toxic action of benzol on the bone marrow. Benzol given in large doses to rabbits causes first a rise and later a fall in the count. In smaller doses it causes a rise only. This is believed to be an irritant effect of benzol on the marrow or an irritant followed by a toxic effect.

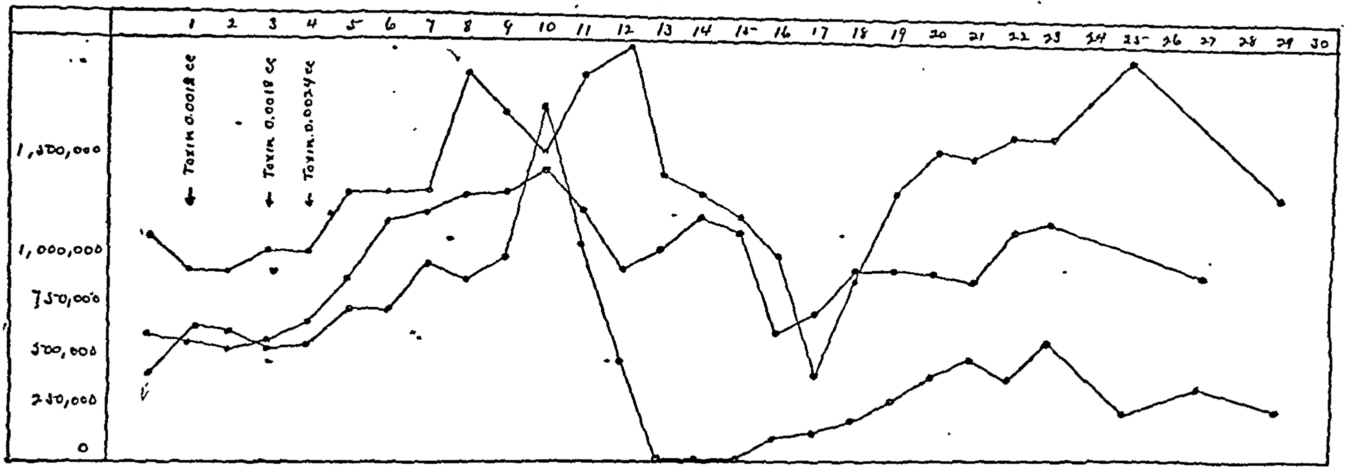

Chart 4.—Effect of sublethal doses of diphtheria toxin on the platelet count of three rabbits.

THE EFFECT OF THE ROENTGEN RAY ON THE PLATELET COUNT[6]

Heineke[7] found that intensive doses of the Roentgen ray cause a reduction in the leukocyte count and destruction of the parenchymatous elements of the marrow. It seemed possible that this agent might also have an effect on the platelet count.

Chart 10 shows the effect of an intensive dose of the Roentgen ray on the platelet count of three rabbits. (Exposure made at 13 inch anode distance with Coolidge tube, 2 mm. aluminum filter, 7 inch spark gap, one-half erythema dose with Hampson's pastille. Exposure repeated in two days with three-fourths erythema dose at skin.)

These were typical experiments. A similar result was obtained in six other cases. In every instance there was a marked fall in the platelet count. There was also a marked fall in the leukocyte count.

Chart 11 shows the effect of a shorter exposure (one-fourth erythema dose at skin through 1 mm. aluminum filter). In each instance a rise eventually followed. One of the three rabbits had a very high count to begin with. In this case rapid fall preceded the rise. A second dose of the sam intensity caused in these rabbits a rapid fall in the count. I these experiments a leukopenia also appeared.

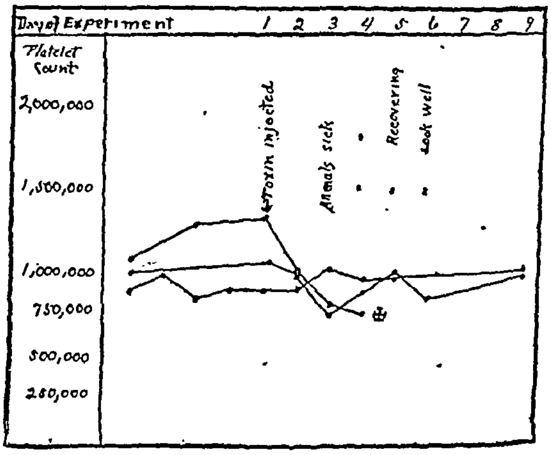

Chart 5.—Effect of large doses of tetanus toxin on the platelet cou in three rabbits.

---

[6] These experiments were carried out in collaboration with Dr. E. H. Skinner, and will be reported in detail subsequently.

[7] Heineke: Untersuchung über der Einwirkung der Röntgenstrahlungen auf der Knockenmark, nebst einigen Bemerkungen über die Röntgentherapie der Leukamie und [illegible] des Sarkoms, Deutsch. Ztschr. f. Chir., 1905, lxxviii, 196.

Deduction.—The Roentgen ray in massive dose causes a fall in the platelet count. In smaller doses it causes a rise in the count.

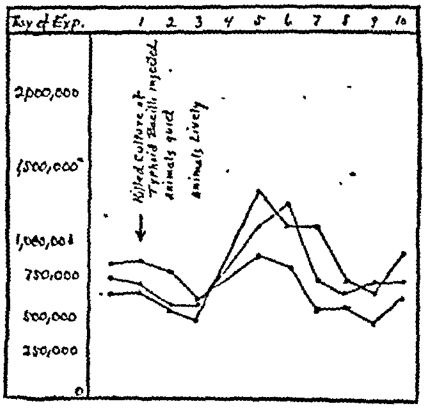

Chart 6.—Effect on the platelet count of 1,000 million killed typhoid bacilli given subcutaneously to each of three rabbits.

Heineke's experiments showing that the Roentgen ray in large doses is followed by degeneration of the marrow suggest that the foregoing results are the effect, respectively, of toxic and stimulating doses of the Roentgen ray on the bone marrow.

THE EFFECT OF TUBERCULIN ON THE PLATELET COUNT

Tuberculin was given subcutaneously or intravenously, in doses varying from 0.1 to 5 c.c. in eighteen experiments. It was hoped that some of the interesting changes in the platelet count observed in tuberculosis might be reproduced. Tuberculin caused a slight change in the platelet count in every instance. When injected subcutaneously it caused a rise in the count which persisted for a number of days. The effect, as a rule, was not great or prolonged, unless some complication, such as anemia or ulceration of the skin, developed. It seemed impossible to give subcutaneously a dose great enough to cause a fall in the count. This was accomplished in all of the six experiments in which tuberculin was given intravenously, but the lowering of the count was transitory (two days) and was quickly followed by a rise. Second doses, given from six to eight weeks after the first, caused a similar change. In Charts 12 and 13 are recorded six typical experiments.

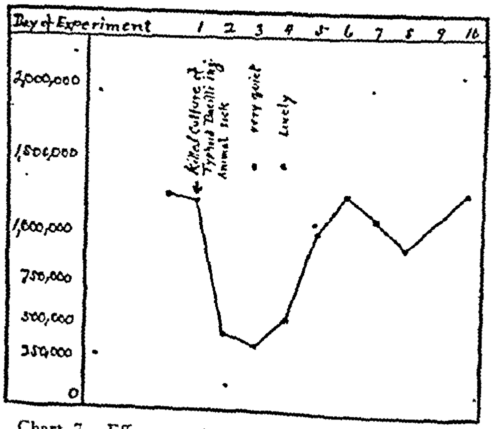

Chart 7.—Effect on the platelet count of 3,000 million killed typhoid bacilli given intravenously to one rabbit.

Deduction.—The effect of tuberculin on the platelet count is similar to that which follows the use of typhoid bacilli. It is marked but not great. Large doses given subcutaneously invariably cause a rise in the count. Large doses given intravenously cause a fall in the count which is quickly followed by a return to normal or a rise.

GENERAL SUMMARY AND THEORETICAL CONSIDERATIONS

The experiments reported here are believed to have disclosed several facts which can be applied to explain the behavior of the platelet count in certain types of diseases. *First of all, it may be stated that it was possible to reduce the platelet count by using a large dose of any agent which in smaller dose caused a rise in the count and vice versa.* The agents used were varied in character, namely, toxins, bacterial emulsions, a chemical poison and the Roentgen ray. Some of the agents used had a rapid and profound effect on the count (diphtheria toxin and benzol). Others had a smaller effect (the Roentgen ray, typhoid bacilli and tuberculin). One of them (tetanus toxin) had almost no effect, although the dose used killed one of three animals and caused toxic symptoms in the others. *The agents with which it was possible to produce the most rapid and extreme rises in the count, namely, diphtheria toxin and benzol, were also the ones with which the most rapid and extreme falls in the count were produced.*

These facts are in harmony, I believe, with the numerous well-known biologic observations concerning stimulants or irritants which act as poisons if employed in sufficient dosage. The most powerful stimulants are also the most powerful poisons, as a rule.

The foregoing generalizations may be employed in the following way to explain the changes in the platelet count in disease. It is believed that diseases in which the platelet count is effected directly by circulating poisons may be divided into two classes.

In the first class come diseases in which powerful irritants to the platelet-forming organs (such as diphtheria toxin and benzol) are elaborated. It is believed that, in diseases of this sort, both high and low counts frequently occur, and also rapid changes from high counts to low counts and vice versa. Some change in the count might be expected even in the mildest cases. That is, when the toxin has such a profound influence on the count, we should expect that a sufficient quantity would be formed in nearly every case, to have its irritant effect, at least. We should also expect that the irritant dose would be exceeded frequently so that the lowered counts would be found as often, or perhaps more often, in the average run of cases, than high counts. The first phase of Hayem's hematoblastic crisis (the fall during the febrile period of an acute disease), according to this view, would be the effect of a quantity of toxin which acted as a poison to the platelet-forming organs. The second

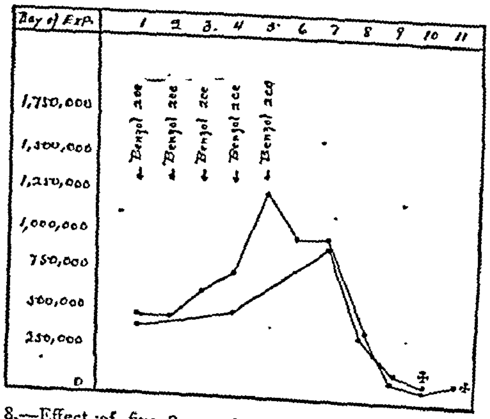

Chart 8.—Effect of five 2 c.c. doses of benzol in two rabbits.

phase (the rise during convalescence) would be a secondary rise after neutralization of the poison. This type of change is the rule in diphtheria—an excellent example of an acute infectious disease. The opposite type of change observed in diphtheria, that is, a rise during the febrile period followed by a fall during convalescence, is believed to occur when the toxemia is less intense. *A hematoblastic crisis would be the rule, then, in all acute diseases in which toxins or irritants are produced in the average case in quantity sufficient to act as a poison to the platelet-forming organs.*

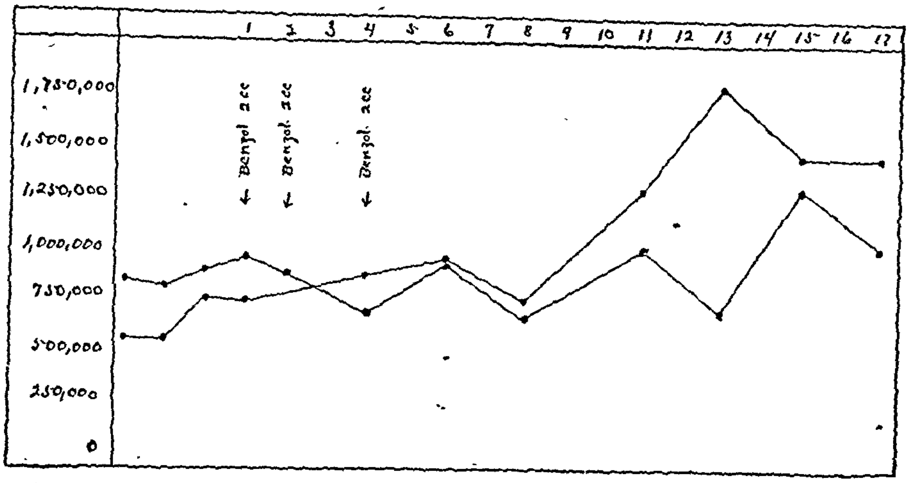

Chart 9.—Effect of three 2 c.c. doses of benzol on the platelet count in rabbits.

Chart 14, in which is shown graphically the effect of varying doses of diphtheria toxin on the platelet count in rabbits, illustrates graphically experiments which seem to be a substantial basis for these statements, and shows the extent to which the platelet count may vary in different grades of the same pathologic condition.

In the second class come diseases in which the irritants produced are mild. One might infer that the counts would here follow the same general law, but that the relative frequency of increased and decreased counts would be different. Increased counts in this case would be the rule. Perhaps a mild irritant, the effects of which could continue as an irritant for a prolonged period, would give rise to a greater increase in the count than the more powerful ones, the poisonous effects of which would appear more quickly. Low counts, the effect of an overwhelming dose, could occur, but would be less frequently observed than in the case of a stronger agent. Tuberculosis and nephritis would appear to be good examples of such a disease. Here the count is almost always increased, but is in rare instances reduced. The experiments with killed typhoid bacilli and tuberculin are thought to be imitations of this type of disease. It was easy to increase the count with these agents. A reduced count was brought about only by giving very large doses intravenously.

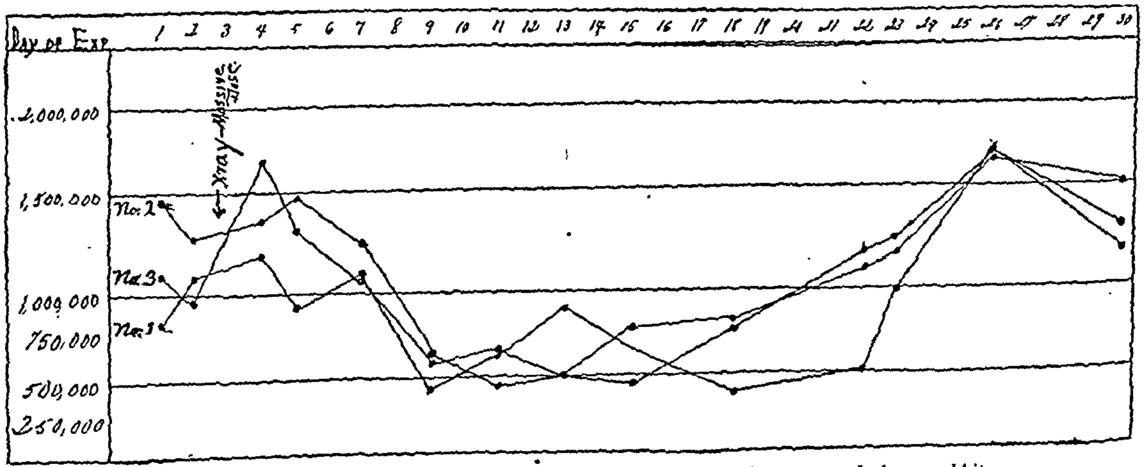

Chart 10.—Effect of an intensive dose of the Roentgen ray on the platelet count of three rabbits.

One might believe, and perhaps with reason, that there exist toxins which can have *only* a poisonous effect on the marrow, and can never increase the count. The existence of such, however, is not proved by these experiments.

There exist, without question, toxins which have very little if any influence on the count. Tetanus toxin is perhaps an example of this type.

Factors other than those noted above also modify the platelet count. It is difficult to say whether or not they may have played a rôle in some of the cases and experiments here reported. The very interesting observation has been made by Hayem, Gley and others,[8] that, following the injection of peptone, in dogs, the platelets tend to clump and can be found forming capillary plugs in the lungs, liver and other organs. Von Behring and others observed the same phenomenon during anaphylactic shock. I endeavored to find the degree to which the platelet count could be lowered in dogs by an intravenous injection of peptone. The count was lowered without question, but accurate counts were impossible on account of clumping of the platelets. Masses of 100 or more were observed. The day following the injection, the count had returned to normal—in fact, it became greater than normal. The tendency to clumping was no longer noticeable.

TABLE 5.—EFFECT ON THE PLATELET COUNT OF A DOSE OF HORSE SERUM GIVEN TO SENSITIZED RABBITS

	Rabbit A	*Rabbit B*
Count before injection of second dose of serum	1,320,000	1,610,000
Intravenous injection of horse serum	0.5 c.c.	0.5 c.c.
Anaphylactic symptoms	Very slight	*Marked*
Platelet count five minutes after injection	2,120,000	490,000
Six hours later	*Animal well*	*Complete recovery*
Platelet count	2,040,000	1,060,000

The experiments given in Table 5 show the change in the platelet count in two rabbits which received 0.5 c.c. of horse serum. Each had been sensitized by an injection of horse serum, nine weeks previously. Rabbit B displayed marked symptoms of anaphylactic shock. The platelet count in this animal was reduced

---

8. Gley: Compt. rend. Soc. de biol., 1896, iv, 44. Von Behring: Deutsch. med. Wchnschr., Oct. 15, 1914, xl, No. 42.

for a short time, and a slight tendency to clumping was observed. Rabbit A displayed little or no evidence of shock. The platelet count was actually increased. No clumping was observed.

The experiments given in Table 6 are reported for comparison with the preceding. In these experiments, varying doses of horse serum were given intravenously to unsensitized rabbits. The changes are small.

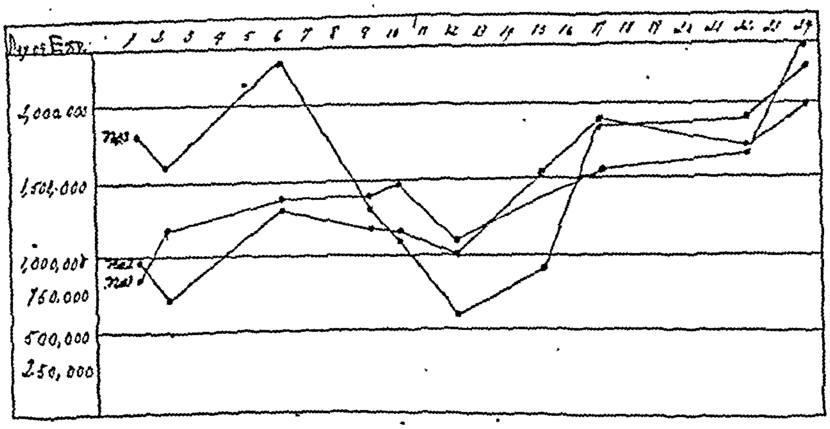

Chart 11.—Effect of a smaller dose of the Roentgen ray on the platelet count of three rabbits.

Other factors also modify the platelet count. Richardson[9] and others state that it is increased after hemorrhage. Kemp, Calhoun and Harris,[1] and Webb[10] find that it is increased by altitude. Rebaudi[11] reports a marked increase during pregnancy. Kemp, Calhoun and Harris state that it is higher in cold seasons than in warm seasons.

To conclude, it may be stated that evidently several factors play a part in modifying the platelet count in disease. This fact, however, does not conflict with a conclusion that, in many diseases, substances are formed which may act as either irritants or poisons to the platelet-forming organs, and, depending on the intensity of their action, may exert their influence either to increase the count or reduce it. If this conclusion is substantial, the apparently contradictory reports in the literature on platelet counts seem in reality harmonious.

CONCLUSIONS

It is believed that the experiments here reported may be employed to explain the behavior of the platelet count under pathologic conditions. Primarily, it may be stated that every agent with which the animals were treated, which exerted any marked influence on the platelet count, increased the count when small doses were used and reduced it when larger doses were given.

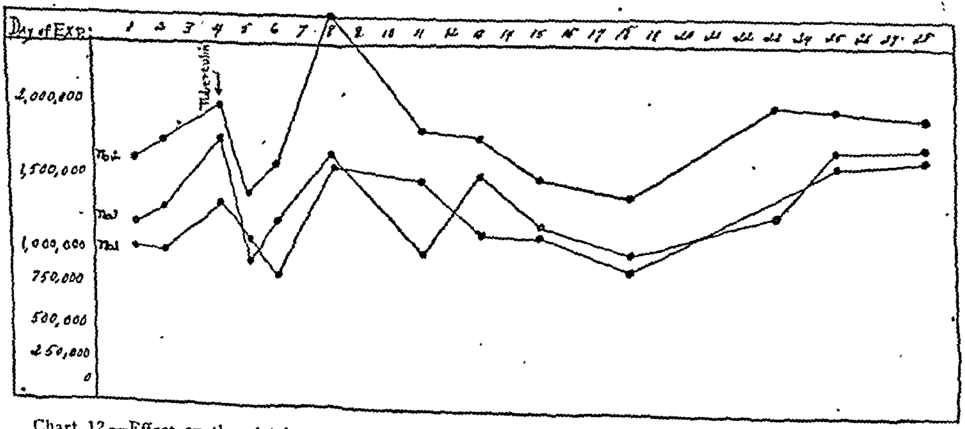

Chart 12.—Effect on the platelet count of 3 c.c. of Koch's old tuberculin given intravenously to three rabbits.

The agents employed were varied in nature, namely, diphtheria toxin, benzol, the Roentgen ray, killed typhoid bacilli and tuberculin. Tetanus toxin, in the dose used, had very little effect on the count. It is reasonable to conclude, I think, that the foregoing agents in the smaller doses acted as irritants to the platelet-forming organs, and in this way caused a rise in the platelet count. In larger doses they acted as poisons, or first as irritants and then as poisons, and caused thereby a fall in the count, or a rise followed by a fall.

The experimental data harmonize with observations on the platelet count in the clinical conditions thus far studied. For example, in a large number of counts made by the writer in diphtheria, tuberculosis and nephritis, both increased and reduced counts were observed. A review of the literature shows that in most diseases in which the platelet count is profoundly altered, both increased and reduced counts have been observed. In the light of the foregoing experiments, these clinical observations would not appear contradictory. It is believed that in almost every disease in which the number of platelets is markedly influenced by circulating toxins or poisons, the count may be either increased or reduced according to the intensity and duration of their toxic action on the bone marrow. It must be added here that, as has been mentioned in the text, the platelet count may be influenced also by other factors, such as altitude, hemorrhage, peptone poisoning, anaphylaxis, and also by *some* of the so-called diseases of the bone marrow.

TABLE 6.—EFFECT OF VARYING DOSES OF HORSE SERUM ON THE PLATELET COUNT IN RABBITS

	Rabbit 1	Rabbit 2	Rabbit 3
Normal count	2,000,000	1,450,000	1,450,000
Horse serum	0.001	1 c.c.	5 c.c.
One hour after injection	1,910,000	1,780,000	1,270,000
Twenty-four hours after injection	2,380,000	2,220,000	1,660,000

One other important generalization is possibly justified. In certain chronic diseases, tuberculosis and nephritis for example, *the* count is increased as a

rule and reduced in rare instances only. In other diseases, diphtheria, pneumonia, and typhoid fever, for example, the findings are diametrically opposite; that is, the count is reduced as a rule and increased in rare instances. It is believed that in the former type of diseases (increased counts the rule), the platelet count is influenced by some mild irritant to the platelet-forming organs, such as killed typhoid bacilli or tuberculin, and that for this reason, an irritant effect is the rule, and a toxic effect, the result of an overwhelming dose, is not reached in the average case. In the latter type of disease (reduced counts the rule), the platelet count is believed to be influenced by some powerful *irritant to the marrow, such as* diphtheria toxin or benzol, so that the irritant dose is exceeded in the average case and a reduced count is the rule. The few cases showing an increased count are probably the milder ones in which the toxic dose is not reached.

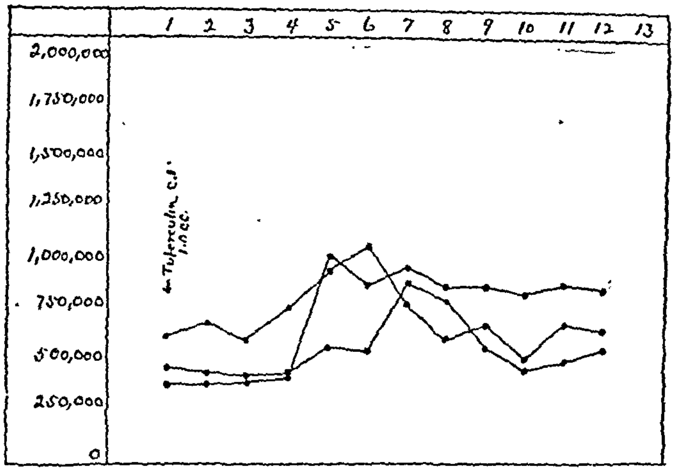

Chart 13.—Effect on the platelet count of 1 c.c. of Koch's old tuberculin given subcutaneously to three rabbits.

ABSTRACT OF DISCUSSION

Dr. Gerald B. Webb, Colorado Springs, Colo.: Dr. Duke's contribution is most welcome, inasmuch as blood platelets have been too little studied. In one case of miliary tuberculosis, and in one of a rapidly fatal tuberculosis following measles, we found the blood platelet count very low, whereas in almost every other case of tuberculosis both in human beings and in laboratory animals, we have found the numbers increased. Nature does not often increase elements without design. Thanks to Metchnikoff, we can now better understand the reason for a leukocytosis. More careful investigations should discover the reason for the increase, under certain conditions, of blood platelets. From our own experiments we have found that (1) blood platelets either contain or supply opsonin; (2) blood platelets are increased at a high altitude; (3) blood platelets can be increased by an artificial hyperemia of the marrow of long bones; (4) blood platelets are increased in carbon monoxid poisoning; (5) blood platelets appear to be increased in the early stages of measles; (6) blood platelets added to a minimum lethal dose of virulent tubercle bacilli do not constantly prevent infection.

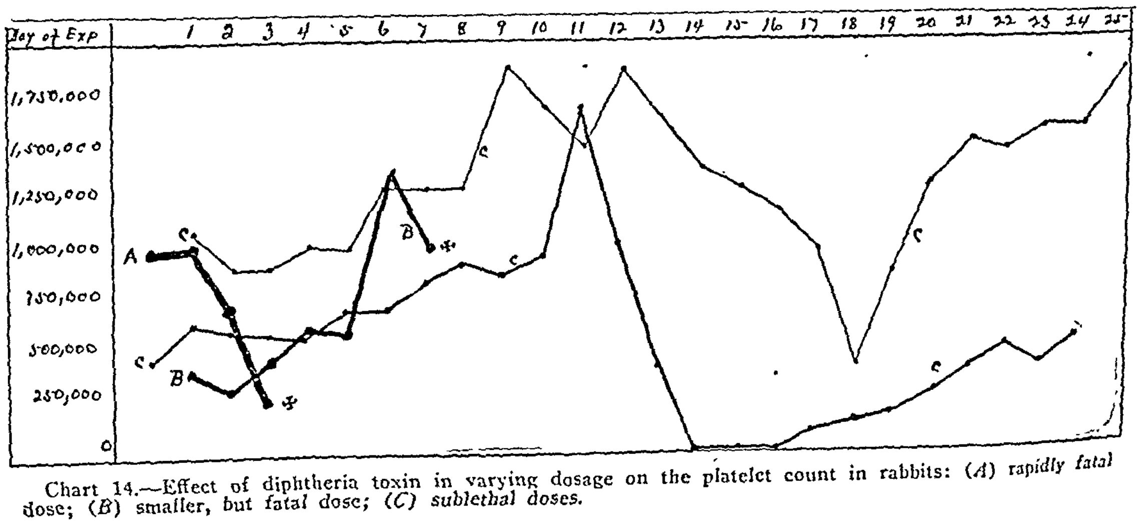

Chart 14.—Effect of diphtheria toxin in varying dosage on the platelet count in rabbits: (*A*) rapidly fatal dose; (*B*) smaller, but fatal dose; (*C*) sublethal doses.

Dr. S. H. Hurwitz, San Francisco: For a number of years investigators have been interested in the relationship existing between the formed elements of the blood and the factors of coagulation. Ever since the platelets were first recognized as distinct morphologic entities and not as disintegration products of leukocytes, the relationship of these elements to hemorrhagic diseases became a subject for investigation. Until recent years, however, we did not have methods available for studying the factors of coagulation and it was therefore difficult to find out what the relation of the formed elements of the blood to these factors was. At the present such studies have been made possible by the methods given us by Dr. Howell of Baltimore.

Stimulated by the observations on a patient with bleeding from the gums and purpura, with anemia and considerable reduction in the platelets, associated with a diminution in the circulating prothrombin, we attempted to reproduce this condition experimentally. Like Dr. Selling, we were able to produce by benzol injections in rabbits a picture of aplastic anemia with marked destruction of the marrow and a reduction in the formed elements, especially the leukocytes and blood plates. In some instances the blood platelets were reduced to 30,000 and associated with this drop there occurred a reduction in the circulating prothrombin. This observation is in harmony with the proof that blood platelets contain prothrombin, although it is unlikely that they are the only source of this factor. We were also able to follow the antithrombin and fibrinogen in these same animals. These two factors have been found to fluctuate little from the normal.

Dr. W. W. Duke, Kansas City, Mo.: The platelets surely must perform some very active function in the body, varying in number as they do under so many conditions. The observation of Dr. Webb that platelets contain opsonin is interesting indeed, and it would not be surprising if it were discovered that platelets play an active rôle in immunity. The observation of Dr. Hurwitz that blood in which the platelet count is reduced, contains less prothrombin than normal blood, is in line with what we might expect from the work of Morowitz and Bayne-Jones showing that platelets contain prothrombin. With these facts known, it is a little surprising to find that blood which is nearly free from platelets may clot with great rapidity. In a number of patients with purpura hemorrhagica and also in an animal with purpura hemorrhagica produced with diphtheria toxin, the platelet count varied from 10,000 to less than 1,000. The coagulation time of blood obtained from the ear was invariably normal. Platelets, without question, play an important rôle in stopping hemorrhage. It seems probable that they accomplish this through the rôle they play in the formation of thrombi. Platelets possess a property of rapidly adhering in masses to the wall of a blood vessel at points where the intima is injured, and these masses apparently form a nidus for the attachment of fibrin and the laying down of a thrombus. They do this, perhaps, by liberating their thrombin just at the point where it is most useful. Both platelets and fibrinogen seem necessary for the formation of thrombi, for if either is reduced nearly to a point of absence, bleeding from cuts is prolonged.

Dr. Webb's observation that the number of platelets may be increased by passive hyperemia is interesting and important. Dr. McKinley and I have tried this out in tuberculous patients at Dr. Webb's suggestion, and find as he did that the count can often be increased for a number of days in this way. It offers a very simple means for increasing the platelet count artificially. The Roentgen ray may be used in animals either for increasing or reducing the count. It is possible that some therapeutic application for this may be found.

THE INTESTINAL TRACT *

S. J. MIXTER, M.D.
BOSTON

Man's interest in the intestinal tract begins at birth and ends only with death. Through its long and tortuous canal pass the foods that supply the body, and here in its laboratory are carried on those complicated chemical and mechanical processes that allow these foods to be fitted for the use of the animal machine, and finally eject the unused portions. Anything interfering with any of these functions is a cause of discomfort, and even of death itself. Is it not natural, therefore, that those having the physical well-being of man in their care, should, from the earliest times, have sought to remedy bodily ills by medication applied to, or through, this channel, confidently hoping that all human disorders might thereby be cured. This hope and even belief still exists, filling the purse of the quack and "patent medicine" manufacturer, who today largely occupies the place of the sorcerer and medicine man of savage tribes.

Medication of some sort, then, was the only method for years, so far as we know, of treating the digestive tract. There were bold and not unskilful surgeons in the older civilizations, as witness the formidable operations on the skull and perhaps the brain, shown by the great number and variety of trephinings done with instruments of stone, found in Peru and elsewhere. These mummies and their bones have handed down their story through the centuries, and in them we can recognize the operative successes and failures as plainly as though these men were alive today, or perhaps on the necropsy table.

There is no such record, however, of operations on the intestinal tract; perhaps they were performed, but even in the mummy we find nothing to suggest it, though in the mummy have been found evidences of appendicitis. It is possible that in the prehistoric as well as in later days, torn or cut intestines protruding from a wound may have been sewed up and the patient cured.

The surgeon first operated on the beginning and the end of the intestinal tract, operations on the esophagus and rectum being done at a comparatively early date, but the peritoneal cavity was supposed to be such a dangerous region that few invaded it.

The real beginning of intestinal surgery was not more than fifty years ago, and step by step it has advanced until today there is not an inch of the canal or any of its appendages that has not been attacked. It may be well to briefly mention here some of the things that have already been accomplished.

Beginning with the esophagus, we find that the congenital or acquired malformations, like pouch, may be cured, sometimes by excision, sometimes without, strictures dilated, and malignant growths at least exposed to the view of the surgeon. Excision of such growths, however, is still in the early experimental stage and should not be attempted by the general surgeon. There is no organ more difficult to reach or more dangerous to operate on than the esophagus in the thorax. Some day, let us hope in the not distant future, excision of esophageal growths will be one of the recognized surgical procedures.

Certain surgeons who have had large experience in thoracic work, experienced in the technic of differential pressure, either by the use of the cabinet, or with intratracheal anesthesia, are working and experimenting in this field, and excision of the esophagus, in man, should be left in their hands for the present—enough has already been accomplished to show the probability of future success.

The stomach is certainly a most tolerant organ. For years it is generally either starved or overfed. It must receive and take care of all kinds of substances from milk to clay. It is tanned with tea, irritated by alcohol, tortured by drugs, alternately scalded and chilled, and yet it works on, doing its best though receiving the blame which should fall on its owner or the other organs. Some people complain of their "bad stomachs" all their lives, while in reality the poor thing is not at fault and is doing its best. Its great failing is that it is too sympathetic, reflecting the troubles of its neighbors.

It is also abused surgically without showing resentment. Being by nature a cleanly organ and not infested with the dangerous fauna and flora of the lower intestine, it is operated on with comparative impunity. Were this not true, the daily mortality from operative procedures, some good, some indifferent and many bad, would be enormous. It is cut into and cut out, it is stitched into faulty positions, puckered and drained, properly or improperly, but still the patient survives. Formerly, the would-be surgeon, just out of the medical school, began his operative experiments by amputating a breast, one of the most difficult of operations, by the way, if properly done, but now he is not satisfied until he has done something to a stomach.

In 1881 it was my great privilege to see Billroth do the first successful resection of the pylorus—that was really the beginning of gastric surgery as we know it today. Step by step it has advanced, until now there are few more brilliant results to be obtained by the skilful and judicious operator than in this field. Men are saved from years of suffering, invalidism and death itself by the surgeon who knows his business.

The question of the treatment of malignant disease of the stomach has been pretty thoroughly settled in the surgical mind, radical excision in early cases giving a fair percentage of cure with slight operative mortality. Excision of chronic ulcers is an accepted fact, and operations for pyloric stenosis, whether by the Finney operation or by gastro-enterostomy, give brilliant results. Duodenal ulcer has become a surgical disease in a great measure, the only question in the

---

* Read before the Section on Surgery, General and Abdominal, at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

choice of operation being that of excision or nonexcision of the affected area. In passing, mention should be made of the importance of a thorough examination of the gallbladder in all cases in which an operation is being done for pain or other symptoms in the right upper quadrant. We have all been disappointed after an apparently successful operation for well-marked duodenal ulcer to find on second operation that the symptoms were partly due to an inflamed "strawberry" gallbladder, or small, previously unrecognized, gallstones.

Having spoken of the gallbladder, whose troubles so closely resemble those of the intestinal tract itself, and for which they are often mistaken, I cannot forbear to touch on a question that has always interested me, namely, shall it be excision or drainage in cholecystitis. For years I advocated and practiced excision in the large majority of cases, until, persuaded by surgeons of larger experience than mine, I adopted drainage for a time, only to return with greater zeal to excision, feeling sure that my ultimate results would be better. The greater mortality of cholecystectomy is due, I am sure, to the fact that it has been done in the severer cases that could only be cured in that way. There is, however, no doubt that in inexperienced hands cholecystostomy is safer, and under such circumstances should be the operation of choice. Many of my former advisers today excise in a large proportion of their cases.

It should be borne in mind that in certain desperate cases of large perforations of the duodenum, when the condition of the patient is so bad that a prolonged operation will not be tolerated, simple drainage with gauze or a large tube, with no attempt at closure of the opening, will often save the patient's life, and the resulting fistula may close of its own accord.

With the small intestine the surgeon has less to do. Occasionally tumors are met, intussusception being one of the common ways of first disclosing their presence, but we may have that rare type of malignant growth, a lymphoid tumor, which may have become generalized before symptoms have called attention to its presence. Adhesions or kinks from acute inflammation are the chief source of danger in this region, and in acute obstructions above the cecum the question of gallstone ileus is always to be borne in mind.

Near the ileocecal valve, congenital or acquired peritoneal folds (the so-called Lane's kink), should always be looked for in operations in this region, for in the past many of the unsuccessful attempts to cure attacks of supposed chronic appendicitis were due to the failure to recognize this very common condition, which is so often the cause of severe ileal stasis.

And now we come to that much abused and vicious organ, the appendix. Probably more necessary operations on the appendix have been left undone, and more unnecessary operations have been done on it, than on any other organ in the body. The first symptoms of inflammation should be a reason for its removal, but too often are these symptoms mistaken. The retrocecal perforation of the appendix is often unrecognized until a rupture of the abscess causes a diffuse peritoneal infection, or, on the other hand, the innocent appendix is removed, and the offending fallopian tube, ureteral stone, gallbladder or Lane's kink is left behind. The surgeon should be careful and conservative in his diagnosis of the appendiceal trouble and radical in his treatment. It must always be remembered that the stomach is often blamed for trouble that really exists in the appendix.

The large intestine has been a fruitful field for much heated discussion and surgical adventure of late. Since the advent of the Roentgen ray, much has been learned and many mistakes have been made. It is safe to say that the old ideas of the positions of the abdominal viscera have undergone a great change in the last few years. Their positions and shapes are becoming better known, and what a short time ago were considered malpositions or malformations are now known to be but slight variations from the normal, if there is such a thing as a normal arrangement. The large intestine is a marked example of this rule; it never lies in the regular lines and curves as shown in the diagrams of the old anatomist. There are innumerable variations, due to congenital or acquired folds of the peritoneum, and many have too quickly decided that anything unusual must be a serious physical defect, and the cause of certain trains of symptoms. The rules for the treatment of malignant disease are well recognized, but it is in questions of abdominal plumbing, if we may use the term, that opinions differ most widely. Fecal stasis is recognized as an evil, and many operations have been designed and performed for its relief that are useless or do positive harm. The surgeon who looks on every such case as one whose faulty plumbing must be restored mechanically to a diagrammatic form is sure to make mistakes, having overlooked the real source of the trouble. Ptosis does not, or should not, always mean operation.

The interrelation of fecal stasis and the neuroses and autointoxications of all kinds are subjects that require further investigation and study, though day by day and year by year our knowledge is steadily advancing. The medical clinician, the neurologist, the psychologist, the bacteriologist must each do his part, and they should be aided, not overshadowed by the roentgenologist, whose mechanical findings may so often be misinterpreted. Viewed from the standpoint of any one of these, the observer sees but one part of the composite picture.

The relation of intestinal abnormalities and distortions to mental disease has always interested me. It is certainly a suggestive fact that a considerable number of cases of megacolon and giant sigmoid are seen in insane asylums. I have, by an operation for acute volvulus in such a case, restored a man to a normal mental condition, after he had been a frequent inmate of the asylum for a considerable number of years. In all these cases of suspected faulty plumbing, it is generally harder to decide which individual needs to be operated on and just which form of operation should be chosen, than to do the mechanical part of the operation itself. With the abdomen open before us it is not always easy to decide which fold or which adhesion is at fault, whether the intestine can be sidetracked or whether it needs excision, and all these factors enter into the subsequent cure or failure. The intestine is not a simple pipe that can be cut and soldered, or placed in what is considered the proper position and kept there, but it is a thin-walled affair in constant motion, always expanding or contracting, and changing its position with the position of the patient and the load it has to bear. We are apt to see only the collapsed intestine on the operating table and cannot picture to ourselves that same intestine distended, partially paralyzed after operation, and carrying its load of gas and fecal matter later. What we know already has been learned at the cost of many failures, and greater future knowledge must come from earnest, careful investigation and honest observation and study of the subsequent history of each individual case. We must try to find out why one case is a success and another, treated in the same manner, is a dismal failure. We must endeavor to recognize those bands or adhesions about the intestine which are of importance in operation and those that are unimportant. The less traumatism to which we subject the peritoneum the better.

We do not know why certain simple operations are followed by extensive and firm adhesions, while others much more extensive, or in the presence of sepsis, are free from these dangerous results. Gentleness in manipulation, and wet gauze instead of dry, leaving as few raw surfaces as possible, probably help. It is assuredly a fact that adhesions may in many cases be divided, and large raw surfaces left, without the formation of new, or the reformation of old adhesions. Until we understand the reason for this and the correct method to be followed to avoid them, we can never be sure of our ultimate results.

Great advances in the treatment of intestinal stasis have been made of late and many patients saved and made useful citizens by suitable operation on the large intestine, but cases should be carefully studied and selected before operating.

The large intestine is more frequently the seat of obstruction than any other part of the tract. An operation, to prove successful, should always be done early, and the cardinal rule is not to attempt too much, and an anastomosis or the temporary artificial anus will save many lives when the primary resection will prove fatal. Excision of a growth may be done later with much greater safety, and the removal of the disease, if it is malignant, can be much more radical. Never leave a patient with an artificial anus without his full knowledge of what it means, and his consent.

Diverticulis is one of the affections of the large intestine that is not infrequently met, and the choice of operation, or even of no operation, is often difficult. When there is a perforation there is of course no question, the abdomen must be opened and the abscess drained the same as an appendix abscess. We sometimes mistake the chronic or subacute cases for malignant disease and do a resection, our mistake in diagnosis being discovered only by the pathologist.

One meets undoubted cases of diverticulitis with recurring symptoms. These cases, as a rule, are relieved though not cured by thorough lavage. What are we to do in such cases? We know that the presence of the pathologic condition is a menace to the health and life of the patient and may be the starting point of malignant disease. On general principles we should remove the offending region, as we would remove a chronic appendix, but the operation is not a safe one and the mortality must be high, especially in those cases in which the lower end of a short sigmoid is involved.

The modern operation for cancer of the rectum gives such good results that radical extirpation should always be attempted in suitable cases.

Up to this point I have considered only the more important operations on the intestinal tract and their advisability, but now comes a more serious question—by whom shall these operations be performed? This applies to all surgery, but particularly to intestinal work, for any man who begins his experiments on man attains final success only at the expense of many lives and much unnecessary suffering. No man should ever attempt a serious operation until he has had a thorough training under a good master.

Throughout the country have sprung up thousands of small hospitals which mark a tremendous advance in the cause of human welfare, and in which is done an enormous amount of surgery, good and bad. In many of these hospitals the staff consists of all the reputable physicians in the town; in other words, any man who holds a degree, whatever his surgical experience, can send his patients there and operate on them. Many of these men have had no suitable training and their work can be imagined, but it is seldom described. The establishment of the American College of Surgeons is a step in the right direction, but only a step. It is perhaps impossible at present, but in time the rule may be made that no man shall practice surgery until he has served a term as an intern at some good hospital and has had a chance to observe and assist competent operators.

Medical education is constantly advancing, and greater efficiency is the aim always before us. At present, large numbers of practitioners, young and old, visit the different famous surgical clinics of the country, and then go home and try to repeat the operations that they have seen performed so easily by the master hand. Such observation and experience, to the man not properly trained, only renders him more dangerous to the community in which he lives. For intestinal work especially, it is unusually dangerous for a man to operate on a human being until he has performed many operations on living animals. Until he has the necessary skill and technic, he is bound, unless possessed of unusual ability, or more often luck, to have many failures, and a failure means a human life.

A witness before a parliamentary committee in England once said: "Gentlemen, with or without the sanction of the law, vivisection must and will continue, surgery cannot stand still, and is it not better that vivisection be done on the lower animals rather than on you, your wives or your children?"

I once assisted a famous surgeon who was performing his first intestinal anastomosis, in the days of Senn's plates. I suggested that his first knot was not drawn tightly enough, but he was sure it was all right. At necropsy he found that he was wrong; had he operated on animals before operating on a man the result would probably have been different. One cannot do these things by seeing them or reading about them. We all make mistakes enough; let us not add to these, unnecessary ones for want of proper preparation.

American surgery today is in the foremost rank, but let us not be content with that; a famous future can be ours, but it must be achieved by constant work and study. The standard must be raised still higher and surgeons must be trained more thoroughly for their work; graduate schools of surgery, large clinics where men can live and work long enough to acquire some of the art and skill of the master, more operations on the lower animals, both in the medical school and hospital laboratories, and greater observation and practice in the after-treatment of surgical cases, all these must be within the reach of the would-be surgeon. Technical skill in the surgeon is important, but of greater importance is surgical judgment. Many a man is, or can become, a skilful operator, but he needs to be something more. In operations on the intestinal tract, often more depends on knowing when to operate and what to do, than in any other part of the body. Of what advantage is it to the patient that a successful excision of the large intestine, for instance, or an anastomosis to side track it be done, if it does not improve his condition, having been performed when it was useless or unnecessary. The man of sound surgical judgment will save more lives and benefit humanity more, even though he be clumsy, than the man who is quick and dexterous but devoid of that essential requirement. The ideal surgeon possesses both qualities, and it should be the aim of every man who claims to be a surgeon, to perfect himself in every side of his art. Much has been written about intestinal surgery, but there are many problems yet unsolved, and it is the trained surgeon who must find the solution.

This subject is a live one which is being carefully studied and worked over. There is still work ahead, for no question that is open to discussion can be considered as settled.

180 Marlboro Street.

CHENOPODIUM IN THE TREATMENT OF UNCINARIASIS

PRELIMINARY REPORT

WILLIAM A. BISHOP, M.D.
AND
O. T. BROSIUS, M.D.
Resident Physicians, Santo Tomas Hospital, Panama City
ANCON, C. Z.

In an article on the treatment of uncinariasis with the oil of chenopodium, Levy[1] has reported a number of cases in which he has had excellent results, and has given a detailed account concerning the toxicity of the drug, assuring us of the little danger connected with its administration. His article appeared subsequently to a thorough report of 1,457 cases presented by Schneffner and Vervoort in which results were sought comparatively with other vermifuges, and the following percentages of comparative efficiency were presented: oil of eucalyptus, 38; betanaphthol, 68; thymol, 83; oil of chenopodium, 91.

At the present time, there is perhaps not a field in existence better given for further investigation in lines of hookworm and other parasite therapy than Santo Tomas Hospital. Its location is tropical; its patients (numbering seldom less than 500) are drawn from many nationalities, among which the native poor Panamanians and the West Indian negroes chiefly predominate, and extremely poor sanitary conditions unfavorable to hookworm extermination still exist throughout the interior of the Republic of Panama.

The West Indian negroes mentioned are those poor discharged laborers from the Canal Commission whom Panama still harbors within her boundaries, and many of these, not able to obtain employment, live in the interior of the republic in the most deplorable poverty — shoes, as with most of the Panamanians living in the interior, being a luxury not often possessed by them. Both of these peoples, with few exceptions, when the cause and nature of their maladies and the measures necessary to produce a cure have been fully explained in simple language, will in most instances yield honestly and cooperate with the physician. With the chenopodium treatment it was far easier to accomplish this than with thymol, because of the simpler method of its administration, and the less drastic results following its ingestion. The oil is put up in capsules of 8 minims each, and we have administered two capsules to the dose, including three doses to the treatment, given two hours apart. Each treatment was followed in four hours by 2 ounces of castor oil. In the plan of the treatment laid down and recommended by Dr. Levy in his article, 50 minims of chloroform were added to the castor oil for the purpose of enhancing the efficiency of the vermifuge; but in the form of treatment which we adopted and followed throughout, we purposely omitted this, intending thereby to give the drug under investigation a fairer trial.

In contrast, the accepted routine treatment of uncinariasis with thymol at Ancon and Santo Tomas Hospitals is as follows: At 4 p. m. calomel is given, the supper is restricted to liquids, and at 8 p. m. 2 ounces of magnesium sulphate are administered. The following morning the patient receives 60 grains of thymol in three doses of 20 grains each at the hours of 4, 5 and 6, respectively, and at 9 o'clock 2 ounces of magnesium sulphate, the diet being resumed at noon if the bowels have moved well.

The dosage of both chenopodium and thymol, in the treatments outlined, is that for adults; we have followed Young's rule in the treatment of children. It may be safe to say, however, that 1 drop of the oil of chenopodium may be given for every year of the child's age, and that this dose should be repeated twice, two hours apart, and followed by oil to constitute a treatment as hereinbefore outlined. The oil can well be given to children with sugar.

It must be evident to all who have had experience in the treatment of uncinariasis that such a method of administering a vermifuge, provided it be *efficient,* is to be preferred. It is attended with much less inconvenience and discomfort to the patient than with thymol, there being no dietetic restrictions and no excessive purging. The matter of dietetic restrictions insisted on by others has been in our experience entirely unnecessary with chenopodium, the oil being given at night merely to facilitate obtaining and examining morning specimens.

The treatment of hookworm disease, and any determination of a removal of infection with either thymol or chenopodium necessarily are expensive from several standpoints: First there is the cost of the drug: Here there is no great variation between the two. The Health Department of the Isthmus pays $2.40 a pound for thymol. Sixty grains constitute one treatment. Levy gives jobbers' prices in the States as from $2.50 to $3 a pound for chenopodium. A treatment consists of 48 minims, but it will be proved later that the average case requires fewer treatments to constitute a cure with chenopodium than with thymol. The other important consideration is the length of time required to effect a cure. In that a great many cases of uncinariasis require several courses of treatment to overcome the infection, it is obvious that the sooner courses of treatment can be repeated, the sooner can the patient be discharged

---

[1] Levy, R. L.: Oil of Chenopodium in the Treatment of Hookworm [illegible] 1914, p. 1946.

With thymol the effects of [illegible] the drug on the patient practically [illegible] in less than five or six days. With chenopodium we have often repeated treatments at intervals of three days, and we have never seen the prostration and weakness which is often occasioned by thymol.

The oil of chenopodium is not a new drug. Hare states that the oil is distilled from the fruit of the *Chenopodium ambrosioides*, or American worm-seed, and that its anthelmintic properties have long been known in the treatment of ascariasis. Levy has dealt with great detail in the pharmacology and chemistry of the drug, but as far as we are able to ascertain, no active principle has been isolated therefrom. It is claimed for the drug that it acts as a paralysant on the parasite, causing it to loosen its hold on the intestinal mucosa, enabling the purge to sweep the worms from the intestine.

As concerns the toxicology of the drug, Levy has surveyed the literature on the subject and has collected twelve authentic cases of poisoning, nine of which ended fatally and seven received an overdose. One of his conclusions is that "in therapeutic doses it is nontoxic." In the 108 cases in which we have administered this oil thus far, we have never encountered any manifestations of toxicity. Of the twelve cases mentioned by Levy, eight occurred in children under the age of 13. While most of our experience has been with adults, we have thus far definite record of six cases in children of ages ranging from 3 to 14 years, and none of these have ever shown any ill effects from the drug.

Believing in the nontoxicity of the drug, we have not hesitated administering it to all patients regardless of other conditions, with the exceptions of those suffering from hyperpyrexia and acute inflammations of the gastro-intestinal tract. Accordingly, during the course of treatments, we have had some deaths, all of which went to necropsy and, as will be seen, in none of these, despite careful investigation, were there any evidences of chenopodium poisoning being a factor in the cause of death.

Our methods of observation of treatments administered were as follows: The stool specimen having been microscopically examined and found positive for uncinariae, the hemoglobin was taken, and the first chenopodium treatment given, after which the first whole stool obtained following the administration of castor oil was washed and examined and the hookworms counted in order to determine, in a measure, the success of the therapeutic procedures applied. Then for five successive days a stool specimen from the patient was examined microscopically every morning, and at the end of this time the chenopodium treatment was repeated. If during the examination of these morning specimens one of the first was found to be positive, we frequently repeated the treatment before the series of five was completed. And so we continued, repeating the treatment as long as any one of the specimens showed even as much as a single hookworm egg, and also keeping count of the worms expelled after each treatment. Some there were who received in accordance with this, our routine course of therapy, as many as seven and eight such courses of treatment; and some of these patients, needless to say, yielded very reluctantly to further treatment after the fifth or sixth administration of their medication. In some, though probably not more than two or three, the patients absolutely refused more treatment, and their records unfortunately could not be completed. Our requirements for a cure were, that all morning specimens for at least five or six or more successive days must be negative for uncinaria eggs, and then the treatment having been repeated, the whole stool must be negative for hookworms. After this the hemoglobin was again taken and compared with the first reading. We have had occasion to examine the stools of patients thus treated and considered cured by us, as long as two and three months after the prescribed course of treatment had been completed, and found that the stools were still negative for uncinariae. The hemoglobin estimation also showed a distinct rise in these patients from the time of their cure.

In our series of treatments we also included a number of patients treated with thymol, just as an approximate comparison and with no intention of establishing any definite ratio between the two drugs for, as already stated, this feature of percentage efficiency among vermifuges has already been more or less definitely determined. In a few cases we have also followed thymol treatments by chenopodium, and accordingly have also followed chenopodium by thymol treatments, but this being only a preliminary report, our observations thus far have not been extensive in this respect.

To date we have records of treatment in 168 cases of hookworm disease of both the Old and New World varieties. Thus far we have administered oil of chenopodium to 108 patients, and of these, ninety-two received throughout their treatments chenopodium alone, the remainder having been given alternate treatments of chenopodium and thymol or thymol alone.

With the desire to ascertain approximately the efficiency of chenopodium as a vermifuge in uncinariasis, it was necessary to adopt some method of comparison with thymol, the accepted anthelmintic for this condition. We decided that as good an indicator as any would be a comparison of the average number of hookworms expelled in the first whole stool from equal numbers of unselected and previously untreated cases. The cases in which thymol was given and the first whole stool obtained were sixty, and the average number of hookworms expelled was seventy-six. The first sixty cases treated with chenopodium gave an average of ninety-nine hookworms. Among more recent treatments there have been so much better results that the average of ninety-nine in the first sixty chenopodium cases has increased to 131 in ninety cases. In one instance there were expelled 1,379 uncinariae in a first whole stool.

It was impossible at times to complete courses of treatment instituted for various reasons, such as the patient demanding his discharge, intervening death, or inability to obtain the whole stools, often because of the patient's failure to cooperate. The number of cases at the present time, in which we consider our records complete and the patient as cured, total twenty-four in which thymol only was given, and thirty-five for chenopodium. It will be interesting to note the average number of treatments which each drug required to effect a complete cure, according to our standard as stated above. In the twenty-four instances of a cure with thymol, forty-nine courses of the drug were required to obtain the results. In the first twenty-four cures with chenopodium, only thirty courses were required, and for the total of thirty-five cures, forty-two treatments were needed.

Since beginning this work with uncinariasis, the opinion has grown with us that the oil of chenopodium is a vermifuge which will act more quickly and more efficiently than thymol. The comparison of the number of courses necessary to effect cures with the two drugs, we believe, shows this to be true. Desirous of testing the action of the drug further, we decided to alternate them in the same case. As yet the number of these trials is too few to furnish statistics, or do more than suggest that further investigation will confirm our supposition.

Case 1.—The patient received thymol, after which the first whole stool was negative. Several days later a chenopodium treatment caused the expulsion of seven hookworms in the first whole stool following.

Case 2.—Whole stool after thymol showed twenty-nine hookworms. A week later chenopodium expelled forty-eight hookworms. A second chenopodium treatment gave a negative result.

Case 3.—Thymol whole stool was negative. Chenopodium a few days later expelled eleven hookworms. The next chenopodium treatment was followed by negative whole stool.

Case 4.—Thirteen worms were expelled by chenopodium following a negative result from a thymol treatment.

Case 5.—First thymol result showed seventeen hookworms, after which the third daily stool specimen showed ova. Thymol was repeated with a negative result, after which the fifth morning specimen again showed ova. Thymol was again given with a negative result. Then chenopodium was given; six hookworms were expelled, and five successive morning specimens were negative for ova.

In the many instances in which chenopodium was primarily given, and thymol subsequently administered, the thymol results never exceeded those of the preceding chenopodium treatments.

Most of our patients were admitted to the hospital with conditions other than simply uncinariasis, this infection being discovered through the routine stool examination of all new patients. Some of these patients, dying of the accompanying diseases, gave us the opportunity of observing at necropsy the absolute results of our treatments, and we will cite the following cases in this respect:

Case 6.—The patient had been given three thymol treatments in which the whole stool results were not observed. At this time he was very anemic, and the ova still persisted in the stool. He was then given chenopodium treatment, but the whole first stool was missed. This was followed by five successive negative morning specimens, and the chenopodium treatment was repeated with the result that twenty-five uncinariae were expelled. The hemoglobin was 20 per cent. at the time of beginning the chenopodium treatments. At necropsy the small intestine, especially the duodenum and down near the cecum, were literally filled with hookworms, which were embedded deeply in the mucosa of the valvulae conniventes. All organs were extremely anemic. Nothing else was found to be abnormal save for a chronic nephritis which was not very severe, and a mild bronchopneumonia, probably terminal. The cause of death was attributed to hookworm disease with secondary anemia. The patient died on the day following the last chenopodium treatment.

Case 7.—The patient received two chenopodium treatments with expulsion of but one hookworm. Four morning specimens were negative. The patient died some time after treatment, the cause of death being septic endocarditis, the patient having not received treatment during the time of persistent fever. At necropsy, the intestine was entirely free from hookworms. The septic endocarditis had most probably developed after this treatment had been begun.

Case 8.—The patient was tuberculous. Chenopodium expelled fourteen uncinariae. Five daily stool specimens and the second chenopodium treatment gave a negative result. We had considered him, therefore, cured of uncinariasis. Necropsy, some time later, showed pulmonary tuberculosis as the cause of death. Although the intestine showed two large diverticula and many small ones in the ileum and jejunum (the two large ones being in the jejunum), no uncinariae were found anywhere.

Case 9.—Eighty-seven hookworms were expelled after the first chenopodium treatment, and five successive stools were negative. A second chenopodium treatment expelled two uncinariae. Necropsy revealed, as the cause of death, general septicemia, with ulcers of the leg as a primary focus. Here also the intestinal tract was free from hookworms.

Case 10.—Boy. Hemoglobin was 10 per cent., with no increase during treatment or during stay in hospital. A first thymol treatment expelled twenty-nine uncinariae, and a subsequent chenopodium treatment, forty-eight uncinariae. A second chenopodium treatment was negative. Necropsy showed a complete removal of the parasite and gave the cause of death as congenital syphilis.

Chenopodium has long held a place in the pharmacopeia, being employed chiefly as a vermifuge in ascariasis. In many of our hookworm cases, several other types of intestinal parasites were also present, and our experience has confirmed its efficiency in roundworm infections but absolutely no effect on *Strongyloides intestinalis*, *Trichocephalus dispar* or trichomonads was noted, these parasites often persisting after many treatments. With the *Balantidium coli* the data are too limited to permit conclusions, as this infection is not very common.

That hookworm infections are sometimes very stubborn and resistant to all treatments is illustrated in the following cases:

Case 11.—The patient received thymol and expelled eleven hookworms, but the following specimens contained ova. Chenopodium was then given, but the whole stool was not received; the following specimens contained ova. The third treatment consisted of chenopodium, and gave a negative result. The fourth treatment was also chenopodium and was negative, but stool specimens were still positive. The fifth treatment of chenopodium was negative. The sixth treatment consisted of thymol, and gave also a negative result. The seventh and eighth treatments were with chenopodium, and similarly gave negative results, after which specimens were still positive, and the patient demanded his discharge.

Case 12.—Thymol case. Seven courses of treatment were required before a cure was effected.

Case 13.—Thymol case. Six treatments established a cure.

Case 14.—Hemoglobin was 43 per cent. Uncinariae and ascarides were present in the first specimen. The first treatment with chenopodium expelled 552 uncinariae and eleven roundworms. Positive specimens followed. The second treatment with chenopodium expelled ten uncinariae, and still positive specimens persisted. Four uncinariae were expelled after the third chenopodium treatment (at this time the hemoglobin had risen to 52 per cent.). Five negative specimens followed. The fourth chenopodium treatment gave a negative result. It will be interesting to note that ten days later, uncinaria ova again appeared in the stool, and a fifth chenopodium treatment was given, causing the expulsion of 120 hookworms and one roundworm. The sixth treatm consisted of thymol, and a negative result followed. six successive morning specimens were negative. (Th was here introduced because our supply of chenopo became exhausted.) The hemoglobin had risen to 85 per c Two stool specimens examined five and six weeks later w still negative.

Case 15.—Hemoglobin was 18 per cent. The first treat of chenopodium expelled 1,379 hookworms. The second ment of chenopodium expelled 1,304 hookworms. The result of the third chenopodium treatment, unfortunately, was not received. The fourth treatment, consisting of thymol, expelled thirty-five uncinariae. The fifth treatment of thymol gave a negative result. (Hemoglobin at this time was 27 per cent.) The sixth treatment of thymol expelled two uncinariae. The seventh treatment of thymol expelled two uncinariae. After this there were six negative specimens, followed by a negative chenopodium treatment. (Hemoglobin now had risen to 61 per cent., and the patient's entire appearance was wonderfully improved.) This total of 2,722 hookworms in one patient is the heaviest infection we have ever encountered, with the possible exception of the case cited above which we examined at necropsy.

Such resistant cases, however, are rather the exception than the rule, and in many instances a rapid and permanent cure was obtained. The following cases illustrate some of the gratifying results which attend the successful treatment of hookworm disease with chenopodium:

CASES 16-18.—The patients were a mother, aged 33, with two children, aged 3 and 6, respectively. The hemoglobin was: mother, 32 per cent.; younger child, 50 per cent.; older child, 48 per cent. The stools of all were positive for uncinaria ova, and all received chenopodium treatment, after which the mother expelled 201 hookworms and one roundworm; the younger child expelled sixty hookworms, and the older child expelled twenty-two hookworms. A second treatment with chenopodium gave the following results: The mother expelled twenty-five uncinariae; the younger child expelled ten uncinariae, and the older child expelled nineteen uncinariae. A third chenopodium treatment gave negative results in all three cases. The hemoglobin tests at this time were as follows: the mother, 55 per cent.; the younger child, 60 per cent.; the older child, 68 per cent. Six weeks later, two separate stool specimens were examined from each, and all of these were negative. The hemoglobin tests at this time were as follows: the mother, 74 per cent.; the younger child, 102 per cent.; the older child, 100 per cent.

In all of our hemoglobin tests, the same instrument (a Dare hemoglobinometer) was used.

SUMMARY

1. The method of administration of chenopodium is simple, and is attended with less inconvenience and discomfort to the patient than with thymol. This would give the drug an important place in the field work in uncinariasis.

2. Chenopodium can be given at shorter intervals than can thymol, and a cure can thereby be more quickly established, which gives it a greater economic value.

3. Chenopodium is nontoxic in therapeutic doses.

4. Chenopodium is a more efficient vermifuge than thymol in the treatment of uncinariasis.

Equality Not Biological.—"All men are born free and equal," it is asserted, but *such equality* is political only. It can not be biological. In every race are certain strains having capacities not attainable by the *mass*. There should be equality of start, equality before the law, but there will always be differences of attainment. The *gifts* of potentiality, unit characters of the germ-plasm, are *not shared* by all people of the same race. The average status of one may be below that of another, and the highest possibilities of one type may be greater than that of another. In general, the highest range of possibilities in every field has been reached by the "blonde races" of Europe. Groups of less *individual* or of less aggregate achievement may properly be regarded as "lower."—David Starr Jordan in *Popular Science Monthly*.

CREATIN AND CREATININ EXCRETION DURING THE PUERPERIUM AND THEIR RELATION TO THE INVOLUTION OF THE UTERUS *

ARTHUR MORSE, M.D.
Assistant Professor of Obstetrics and Gynecology, Yale Medical School
NEW HAVEN, CONN.

The retrogressive changes which follow pregnancy restore the mother's body approximately to the condition which existed before conception took place. The restorative process, as it affects the uterus, includes an autolytic phenomenon known as involution, which rapidly reduces the weight of the organ from about a kilogram to 50 or 60 gm. Histologically, the decrease in mass depends on the atrophy of the muscle cells forming the walls of the uterus, and the metabolic end-products which thus arise are eliminated in the urine.

Since it is generally admitted that following labor catabolic changes predominate in the metabolism of the uterine muscle cells, it seemed reasonable to suppose that this fact explained the presence of creatin and of a relatively large amount of creatinin in the urine of puerperal women. Indeed, the anatomic and physiologic facts regarding the involution of the uterus accorded so satisfactorily with the urine findings that for a long time no one challenged the hypothesis which held that the one was the cause of the other. Lately, however, Mellanby[1] has questioned this doctrine and declares as his opinion that activity of the breasts is fundamentally concerned with the excretion of creatin. It was this uncertainty regarding the part played by the involution process which led us to accept the opportunity to study several patients whose metabolism promised to throw additional light on the problem.

Our conclusions are based on the observations of four types of cases, namely, (1) a normal labor; (2) a conservative cesarean section at the end of normal pregnancy; (3) a conservative cesarean section in a case of pre-eclamptic toxemia, and (4) two cases of cesarean section with removal of the uterus. A material so varied has enabled us to learn in the first place that the creatin and creatinin metabolism is practically identical after normal labor and after cesarean section, provided the uterus is not removed, and the pregnancy has not been complicated by a toxemia. And, in the second place, we have been able to compare the excretion of these substances in cases in which the uterus was undergoing involution with others in which the uterus had been extirpated.

With two exceptions all the patients were the subjects of metabolic observations during pregnancy, but the results to be reported in this communication relate exclusively to the puerperium. The observations were continued without interruption for a period of two weeks or more after the delivery. The diet was creatinin and creatin-free. The urine was obtained by catheterization as long as there was risk of contamination from the vaginal discharge. It was collected over twenty-four-hour periods, was preserved with chloroform and analyzed daily. All determinations were made in duplicate. The total nitrogen was estimated by the Kjeldahl method; the creatinin and creatin by the Folin method.

[1] Mellanby: The Metabolism of Lactating Women, Proc. Royal Soc., London, Series B, 1913, lxxxvi, 88.

The results of the Kjeldahl determinations indicate a notably smaller output of nitrogen in case hysterectomy was performed. This phenomenon has been previously observed by Slemons,[2] who demonstrated that during acute puerperal involution the average daily nitrogen excretion attributable to uterine autolysis varied between 2 and 3 gm.

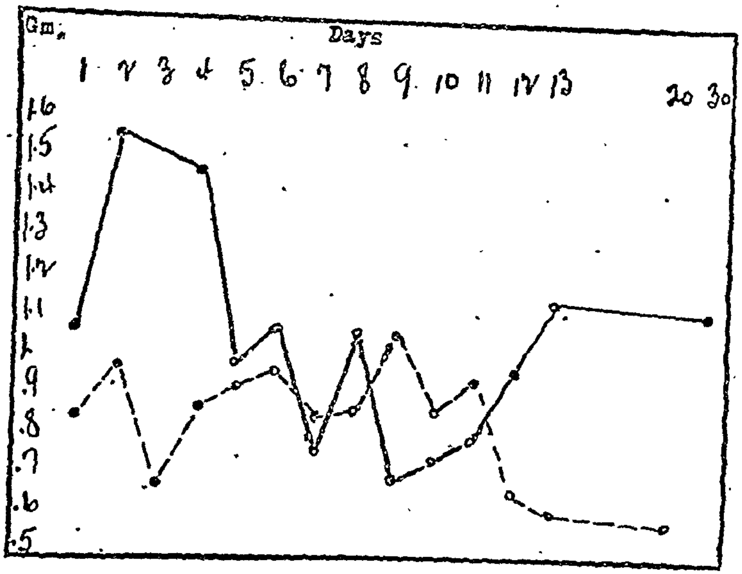

Chart 1.—Contrasting the preformed creatinin of the urine after conservative cesarean section and after the Porro operation. Solid line represents the excretion in the case in which the uterus was not removed; broken line that of the case in which it was removed.

In its behavior the creatinin elimination resembles that of total nitrogen; larger amounts are excreted in case the uterus is undergoing involution. In Chart 1 the creatinin excretion of two patients is illustrated. In both cesarean section had been performed, but in one the uterus was removed and in the other not. During the first thirteen days of the puerperium the mean average daily output of creatinin was found to be 1.09 gm., in two cases in which the uterus was undergoing involution, and .897 in two cases in which the uterus had been removed. Therefore, during this period it appears that approximately 2 gm. less of creatinin is excreted by a puerperal patient, if hysterectomy has been performed. Later in the puerperium the excretion of creatinin has always been lower than during the first two weeks.

An increase in the excretion of creatinin during the puerperium has frequently been demonstrated and has generally been attributed to the involution process, but Heynemann[3] thought additional causes for the phenomenon existed in the muscular effort incident to childbirth and in the restricted diet generally employed thereafter. It would seem, however, that these factors are not essential, for we have observed the phenomenon though the patient was delivered by operation, before the onset of labor, and though she received from the third postoperative day a diet the caloric value of which was quite adequate for the individual.

After bleeding animals, Patterson[4] found the creatinin excretion was increased. If this factor played a rôle in our cases we are unable to estimate it, but in spite of such an influence a lower excretion was invariably found in case the uterus was removed. We are convinced, therefore, that an increased output of creatinin during the period of convalescence following cesarean section without hysterectomy, and also during the normal puerperium, is largely, if not entirely, due to the involution of the uterus.

Soon after Folin[5] devised a satisfactory clinical method for the estimation of creatinin and creatin, the presence of the latter in the urine was sought in a great many different pathologic conditions. Not infrequently during the course of disease creatin was found, but in health it was learned that the urine contained no creatin, or amounts too small for measurement. In the case of women during the period of convalescence from childbirth, however—a borderland between sickness and health — creatin was demonstrated to be a regular constituent of the urine. This observation made in 1908 by Schaffer[6] has been amply verified; but the hypothesis he offered, which attributed the creatinuria to the involution of the uterus as we have said, has been called into question. In these circumstances it is instructive to compare the excretion of creatin in four cases of cesarean section, in two of which the uterus was removed and consequently the involution of this organ could play no part in the metabolism of creatin.

In all the four cases the urine contained a large amount of creatin during the early part of the puerperium. For the first thirteen days of this period the average daily excretion was .207 gm. and .167 gm., respectively, in the two cases in which the uterus was in situ; the corresponding figures for the cases of hysterectomy were .285 and .329 gm. Thus it appears that the removal of the uterus did not modify the creatinuria. As a matter of fact, in the cases in which the involution of the uterus was in progress, smaller amounts of creatin were present than in the cases in which the organ was removed irrespective of the surgical procedure.

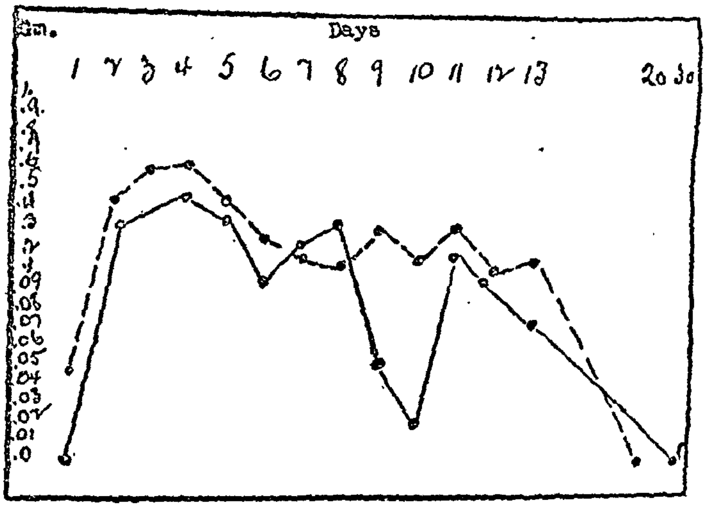

Chart 2.—Contrasting the creatin of the urine after conservative cesarean section and after the Porro operation. Solid line represents the excretion in the case in which the uterus was not removed; broken line that of the case in which it was removed.

The curve representing the daily excretion has generally been of the plateau type. On the day following the operative delivery there begins a notable rise in the output, the maximum is reached about the fourth day, and except for an occasional irregular drop the curve remains high for approximately two weeks. The urine was free of creatin in the cases of hysterectomy on the twelfth and twentieth days, respectively. In one of the cases in which the uterus was not removed, creatin was present on the fifteenth day, when observations were interrupted, but was not found subsequently from the thirtieth to the thirty-fifth days. In the other case of a conservative cesarean convalescent from a toxemia of pregnancy, creatin was still present on the twenty-third day postpartum (.057 gm.). For the first thirteen days of the puerperium the total excretion of creatin in the four cases was as follows: The uterus in situ and involuting, 2.17 and 2.48 gm.; the cases in which the uterus was removed, 3.71 and 4.27 gm. Such results clearly indicate that the creatinuria which always occurs during the period following childbirth is not dependent on the involution of the uterus.

[6] Schaffer: The Excretion of Creatinin and Creatin in Health and Disease, Am. Jour. Physiol., 1908, xxii, 1.

The facts learned regarding the excretion of creatinin and creatin in these patients have a significant bearing on the question in general of the metabolism of these substances. On the one hand, the quantity of creatinin eliminated depends on the involution of the uterus; on the other hand, there is no relation between this process and the elimination of creatin. And it is also true in these cases that the excretion of the one substance bears no direct or reciprocal relation to the excretion of the other. For these reasons it appears that at least during the puerperium the metabolism of the two substances is independent—a fact which accords with the recently announced views of Folin[7] and of Klercker.[8]

The explanation for the creatinuria of the puerperium is doubtful. Our observations not only make untenable the involution hypothesis of Schaffer and of Murlin,[9] but they also fail to support Mellanby's hypothesis attributing the phenomenon to a failure of excretion of the creatin through the milk. Our cases showed marked creatinuria even though the breasts were functioning normally.

To recapitulate: From observations made on four cases in which cesarean section was performed, in two instances without removal of the uterus, and in two instances with hysterectomy, the following conclusions may be drawn.

1. A lower total nitrogen output is observed in case hysterectomy is performed, and the higher output of nitrogen observed when the uterus is left in situ is explained by the involution process.
2. A lower creatinin output occurs in case of hysterectomy and at least 2 gm. of this substance excreted during the puerperium arise from the involution of the uterus.
3. Creatin in large amounts regularly appears in the urine following childbirth. The creatinuria is independent of the involution of the uterus, and it is also independent of the creatinin metabolism.

ELEMENTARY BUT VITAL FACTORS IN THE EFFICIENCY OF SMALLER HOSPITALS *

L. W. LITTIG, A.M., M.D., M.R.C.S.
DAVENPORT, IOWA

To add to my personal knowledge of the hospital situation, I sent a rather exhaustive questionnaire to the leading medical men of one of our western states, hereinafter known as "Mid West." The response was most generous. No effort is made to classify the answers, but it is a fair assumption that they represent the general situation, especially in hospitals of from forty to 150 or 200 beds, and they are conclusive evidence that the medical profession is not satisfied with existing conditions, and is fully alive to the pressing need for improvement. Not only is the medical profession fully and painfully cognizant of the many shortcomings in hospital management and service, but the public, already skeptical in regard to the medical profession, is rapidly learning that many hospitals are not as efficient as they might be; and that a palatial operating room does not always mean careful diagnoses, good beds, well-trained nurses, and faithful bedside attention. The public is learning to discriminate between the good and the indifferent. It is only by putting the house in order that the latter all too common type of hospital can escape severe but well-merited criticism. The hospitals that are first to read and heed the signs of the times will spare themselves the rude but belated and unpleasant awakening to the fact that very desirable and financially able patients are seeking better managed and more efficient institutions.

I am, further, convinced that the present efficiency of many of these open hospitals can be doubled, increasing their annual budget, and with much more satisfactory results in every department.

The great majority of the hospitals in "Mid West" are "open." Every physician or surgeon bringing a patient is admitted without question. One of these hospitals has fifty beds and 100 members on the staff. My informant seriously assured me that this was a "closed" hospital, although he was unable to mention the name of a single practitioner of medicine within a reasonable distance who is not freely and probably gladly admitted. He compromised by insisting that the hospital is "not wide open."

THE ATTENDING STAFF

In not more than 5 per cent. of the hospitals in "Mid West" is there anything but a nominal staff; usually there is no staff. When a so-called staff really exists, it "does not meet at all," or it "meets once or twice a year," or "once in a decade," or it "meets when a fight is on," or "everything is hit or miss." Compare this warping, withering, dwarfing, disintegrating situation with the stimulating and invigorating practice in vogue in the oldest and one of the most progressive hospitals in America, located in a great metropolitan city. In this hospital the attending staff meets one afternoon each week, to study and discuss interesting cases; it has one business meeting each month, held just before the monthly meeting of the hospital management; and once each quarter the staff

---

* Read before the Section on Hospitals at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

and the management have a conjoint business meeting with a dinner.

The attending staff usually sets the pace for the hospital. With an active, progressive, united and cooperating staff, the hospital must be good, because such a staff will make it good. With a staff the reverse of the foregoing, the hospital cannot be good, unless the hospital has an unusually well-organized and efficient nursing staff, with a few unusually strong men on the attending staff.

If there be one special characteristic of the usual attending staff, it is a woful lack of harmonious cooperation, and a great surplus of petty jealousy and bickering. It may be conceded, I think, that the management of a private hospital has the right to select the members of its staff, has the right to say who may enter, and who must remain away. If the hospital management would stop at this point, much would be gained. But the management of some hospitals assumes the right to appoint staff committees or to insist that certain men constitute all or a part of the executive committee of the staff. Unfortunately, in many instances, the management of the hospital is not a good judge of professional efficiency; the wily self-seeking politician, "cowering low with blandishment," receives a much more attentive and willing ear than patient merit that frankly speaks the truth. As a result, incompetent men are too often appointed on such committees. The employees of a great industrial concern have the right to organize as they see proper. How a hospital management can presume to inflict a committee on men whom it invites into the house, to divide with it a great responsibility, or how men can accept such a situation, is beyond comprehension. A staff dominated by an incompetent committee, appointed by the management, is a hopelessly disorganized staff, and not only will the hospital suffer, but also the staff members individually. A staff must be left free to organize as it sees fit, and to select its own officers and representatives. I have seen several attending staffs sadly disorganized because the management insisted on selecting or appointing an unfit committee, although in each instance there was in the staff a group of splendid progressive men, several of whom had seen high-grade intern service, who were in every way deserving of the confidence of their fellow members and of consideration by the management. It is a mistake for the hospital management to appoint even the best men on a committee, as such men will be far more efficient if selected by their fellows.

The right to seek advice and council when and where it will cannot be denied the hospital management. It may invite one man or a group of men to act as its privy council, and in this choice consult only its own pleasure. This is quite a different thing from appointing a staff committee, to dominate the staff, to represent the staff, or to misrepresent the staff, as the committee sees fit. A staff so dominated or controlled can never raise itself to the high level outlined in this paper. The date of its birth and demise are the same, so far as serving a useful purpose is concerned.

What is the chief function of a hospital staff? The answer is very simple. The chief function of a hospital is to educate itself, individually and collectively, to better discharge the duties and obligations incurred by its members in accepting a staff appointment. To serve its purpose, a staff must hold frequent meetings, at which not only hospital problems, but more especially medical problems must be discussed, interesting cases must be presented for consideration, pathologic specimens must be studied, that all may be benefited. As failures are often even more instructive than successes, the former also should be reported for free discussion. It is especially important that the causes of "accidents" be thoroughly investigated and the responsibility fixed. Staff members should make frequent visits to medical centers, and every member making such a visit should bring back with him, for the benefit of his fellows, whatever seems to him worthy of presentation. The operating room should be open to staff members at all times, and all operations should be bulletined. As many members as possible should be invited to study interesting cases in the wards. Necropsies should be bulletined. In this way the experience of each staff member will become very considerable. It might be well for the staff to organize itself into a current medical literature club, to better keep abreast of the times, and also to have its members present synthetic reviews on this or that topic, thus taking an invoice of knowledge in stock. All staff members ought to take an active part in medical society work. With the improvement of the staff individually and collectively as the prime motive in staff organization, increased staff and hospital efficiency, and better service to the patient will be sure to come. *All* of this is very elementary and self-evident, yet I failed to find one open hospital in "Mid West" in which the staff either realized its opportunities or profited by them, along the lines suggested. Failure to recognize this important function, more than anything else, is responsible for the very general spirit of unrest and dissatisfaction at present existing in the hospital world. Its recognition and exercise must be the first step in the solution of many hospital problems.

With the right kind of attending staff, requests addressed to the hospital management will always be reasonable, in the interests of all concerned, and will receive respectful consideration. To keep the men pushing all at the same time, and in the same direction, will surely bring better things.

THE TRAINING SCHOOL AND THE NURSING STAFF

It need not be said that the members of the attending staff are under serious obligations to the training school, and that it is their duty to cooperate with the head of this department to give the young women in training a proper course of instruction, both theoretical and practical. Such a course must include the necessary laboratory work in selected medicochemical subjects, and in practical becteriology. A nurse cannot grasp the important facts in infection, or understand the all-important rôle of bacteria in surgical work, unless she knows something of bacteriology, and her knowledge must be practical as well as theoretical. Too often the obligation as instructors of nurses rests very lightly on staff members, who do not appreciate the responsibility they assume when they accept the invitation to teach.

The object of the training school is, or should be, primarily, to fit young women for the very responsible duty of properly caring for sick people. Judging from the practice in vogue in some hospitals, the management considers the training school an effective means to reduce the hospital expenses, or even a source of revenue. The management is ever ready to assign a pupil nurse to a special case, charging the patient for this service from $15 to $20 per week. I have known girls still on "probation," and not infrequently nurses in the third or fourth month of training, to be assigned to special cases. To pay a nurse $6 or $8 per month, and have her earn $20 per week, seems a not unprofitable arrangement, but in reality is short-sighted and ruinous. Such service cannot be profitable. The patient pays for and has a right to expect skilled service. It is unfair to the pupil nurses, because special duty often lays on their shoulders responsibilities for which their youth, lack of training, and inexperience entirely unfit them. It is unfair to the doctor because he has a right to assume that his patient, while in the hospital, is under trained and skilful eyes, not always the case in some hospitals. In fact, the question is often forced, "Would the patient not be much safer in his own home, in charge of a selected graduate nurse?" Some training schools expect members of the attending staff constantly to excuse and cover the shortcomings of untrained inexperienced girls; one is expected to become a party to a system which is as dangerous to the patient as it is unfair to the nurse, and which in the end is sure to be disastrous to the reputation of the hospital.

Young nurses ought to be under the direct, Argus-eyed supervision of older nurses, and ought to be in training at least eighteen months before they are assigned to special duty, even in mild cases. They ought to have completed two years of their course in training before they are assigned to special duty in serious cases. The head of the nursing staff ought not to assign pupil nurses to special duty at all, if by so doing the nursing staff is depleted, and the nurses remaining "on general" are overworked and unable to care properly for their patients. This practice is exceedingly bad even from a business standpoint. One patient with a "special" may leave the hospital fairly well satisfied, but a much larger number of patients "on general" leave the hospital feeling that they have not received the attention to which they were entitled. If the head of the nursing staff cannot provide special pupil nurses without overworking the nurses "on general," it is a far better policy to invite graduate nurses into the house for special duty. For obvious reasons a few mercenary hospitals insist that all special nursing in the house shall be done by pupil nurses. Some hospitals even assign a pupil nurse as a companion to a patient able to pay $20 per week. To be an agreeable companion to a "difficult" patient may be an accomplishment of some value, but of such experience a nurse has quite enough, without wasting time that should be devoted to acquiring real useful information. Besides, the nurse is not assigned to this post for her benefit, or for the benefit of the patient, but for $20 per week. Some hospitals assign entirely too many patients to one nurse, as many as six or seven or more patients in private rooms in charge of one nurse being not uncommon. But even with this great pressure on the nurses "on general," there is always one more pupil nurse for special duty, a most short-sighted policy.

Absolutely essential to good work by the nursing staff is management and discipline. I have said that the one special characteristic of the usual attending staff is a woful lack of harmonious cooperation. In a like manner the chief characteristic of many nursing staffs is a woful lack of efficient organization. The nursing staff must have a single, efficient, responsible and fearless head. This head must admit trainers, reject them if unfit; she must have the power to dismiss any nurse in the hospital. Head nurses on the floors of the wards must be just as completely under her authority as the youngest "trainer." In some hospitals, it occasionally happens that head nurses on the floors or in the wards, in length of service or in age, rank the head of the nursing staff, and hence do not take kindly to suggestions or advice. Sometimes these head nurses are not responsible to the head of the nursing staff, but to the same authority to which the head of the nursing staff owes her appointment. I must speak plainly on this all-important point. In community hospitals it very often happens that the head nurses on the floors or in the wards are members of the community and have occupied their positions for years. A younger member of the community, or an efficient lay nurse, is made head of the training school, or head of the nursing staff. This arrangement is entirely inconsistent with high-grade work, as the head of the nursing staff never has that authoritative control so necessary to efficient service. Far better to retire the noble well-intentioned women that have long since earned their crown, and put in their places well-trained, tactful and capable young women, graduate nurses if possible; but far better than the veterans would be the picked members of the third year class of "trainers." To be appointed head nurse on the floor or in a ward would be a much sought-after distinction, and such head nurses would respect and carry out the wishes and ideals of the head of the nursing staff.

If a community has one member competent to act as head of the nursing staff, that member must be put in control, in complete control, of all the departments of the nursing service; she must have the authority to dismiss any nurse regardless of age, position, length of service, or date of affiliation. If a community hospital is unfortunate in not having one such competent member, one must be developed or secured in some way. A thoroughly competent head of the nursing staff will get along in some way, and with great credit to herself and to the hospital, if given a free hand, even without very active cooperation on the part of the attending staff. An inefficient head of the nursing staff makes high-grade service impossible.

With a good attending staff, and with a competent, unfettered head of the nursing staff, there remains but little to add; all else will follow, and the work of the hospital will be high grade.

I wish briefly to refer to the practice in vogue in many of the medium-sized open hospitals: that of having every nurse graduating from the training school serve a short period at the instrument table. Smooth operating room work is not possible with such service. Worse still is the practice which one sometimes sees of having an older nurse, during the operation, act as instructor to the younger nurse at the instrument table. Nothing so loudly and so unfavorably advertises the shortcomings of the operating room service as this thoroughly amateur practice. I should very much prefer the untried nurse, green as she is, than the combination of teacher and pupil at the instrument table, a new nurse being introduced just as soon as the one becomes somewhat proficient. The impossibility of making every graduate an operating room nurse has long been recognized, and the best interests of the patient and of the hospital demand that the attempt to do so be discontinued. Work at the instrument table, as head nurse on the floor, or in a ward, must not be a part of the nurses' curriculum, but a distinction reserved for those especially capable.

AN EFFICIENCY EXPERT

There is no place where an efficiency expert can be more valuable than in the average open hospital. An expert of this kind ought to be employed for short periods, and as often as may be necessary. A report ought freely to criticize the hospital management in all its details, from the dean of the attending staff and the head of the nursing staff, to the orderly in the wards. Every one at all familiar with the ordinary hospital knows how much time is wasted by members of the attending staff and by nurses, and this needless waste of time is not confined to any particular department. It is found all through the house, from the minute the patient enters, until the nurse, with a "bon voyage," passes her into a departing taxi: the great distance nurses travel — travel is the word — to get a drink of water for a patient, or to journey to the chart room to fill in the records, the time that is lost in serving meals, the hours that are lost by the members of the attending staff in waiting for dressings, or because the operating room is not in readiness. An efficiency expert would see many time-saving opportunities that entirely escape notice, not only by those who have been long in the service, but also by the more or less critical causal visitor. In fact, those long in a service are the very last to see the weak points of such a service; they have become a part of the system, and the system a part of them, and too often they are both deaf and blind to its imperfection. The efficiency expert would note also the character of the bedside attention, whether prompt, gentle, tactful, and skilful, or whether dilatory, rough, irritating and crude.

CONCLUSION

A high-grade hospital must have a conscientious, progressive, united and cooperating attending staff, integrated to educate and improve itself, and to discharge its duty alike to patients and to nurses in training.

It must have a nursing staff under the guidance and control of a single, efficient, capable and authoritative head.

It must have a general management which, hard pressed though it may be by financial considerations, remains ever sensitive and responsive to the best interests of its patients.

In such a hospital, responsibility can always be fixed, untrained and poorly supervised girls are not assigned to special cases, the number of patients under the care of one nurse "on general" never exceeds a certain fixed minimum, there is not an unending chain of inexperienced girls at the instrument table, and an efficiency expert is rarely needed. This hospital will fulfil its high mission as an educator of the profession and the community in which it is located.

ABSTRACT OF DISCUSSION

Dr. I. D. Webster, San Diego, Calif.: I am new at the hospital business. It has fallen in my lot to have charge of the San Diego County Hospital. We had a county physician in that county who did not agree with the county medical society or any of its fellows, and the hospital was closed to the medical profession of the community. The county medical society took the matter up and through the board of supervisors I was appointed county physician. I immediately called on the county medical society to furnish the visiting staff. As far as I know the very close relationship that we have established between the county hospital and the county medical society is perhaps somewhat unique. I asked the county medical society to appoint a so-called hospital committee, of which they made me a permanent member, with two other members from the county medical society, and it rests with this hospital committee to choose the visiting staff at the hospital. We had about forty volunteers seeking to get on the staff, and the present situation is that there are a great many who would like to be on the staff to whom we cannot give places. We have four general surgeons, two gynecologists, one orthopedic surgeon; one man who does nothing but pathology and has charge of the laboratory, one on nose and throat and one man who does nothing but the eye. There is a three months' service for each individual through the year and I believe there is some dissatisfaction at that. We are trying to figure out some way to make their services continuous through the year. In regard to the training school, it was a two years' school and the graduates were not eligible for registration. We changed it to a three year course and we were told by the registrar of nurses that our school made the greatest progress of any school in the state. It is about two years since we made this change.

Dr. William H. Walsh, Philadelphia: I am forcibly opposed to nurses giving anesthetics, for I consider the administration of an anesthetic a very important function of the practice of medicine, and under this assumption, from both a professional and a legal standpoint, it would seem perfectly logical to assume that a nurse has no more right to give an anesthetic than she has to open the abdomen. While it is becoming quite common to find that almost any nurse considers herself a competent anesthetist, it is a well-known fact that very few nurses ever become competent in that highly specialized work, and then only after the most painstaking instruction and long and varied experience—experience that is necessarily acquired at the expense of the patients. The examination of a patient before the administration of an anesthetic is a vital part of the duties of the one who gives the anesthetic, and it is quite beyond my comprehension to understand how a nurse can perform this part of her duties with the limited amount of medical knowledge at her command. Finally, the administration of an anesthetic is the function of a physician, and I believe that if the question were ever brought before the higher courts it would be definitely decided that the administration of these drugs was in fact practicing medicine.

With regard to the point emphasized by Dr. Littig concerning the selection of the officers and the committees of the hospital staff, it is a question in my mind whether it is not sometimes better for the board of managers to pick out certain live, wide-awake, progressive members of the staff and make them the officers thereof rather than permit the staff to go on year after year electing the same old reactionary members as their officers, without the courage even to propose others for fear of offending the overlords. This evil tendency forms what has been called by Dr. J. Chalmers DaCosta the "system." It means that certain of the older members of the staff improperly and unjustly acquire sufficient influence and power to further their own selfish interests at the expense of the hospital and public welfare. Under such domination, even a good hospital superintendent is often thwarted in his attempts to do what he knows is for the best interests of the hospital, and in spite of the protests of the regularly appointed authority, these men get more than they deserve. Their opinions on vital questions are often accepted, and they become highly indignant at the attempt of the hospital administrator to suppress the abuses that they foster. With such a staff in full sway the abuses accumulate with great rapidity and neglect is tolerated and excused in those who belong to the "system," but for others the best efforts and most brilliant accomplishments are censured. New appointments to the staff are handled much as is the common garden variety of ward politics, the question of fitness being of little importance, personal reasons being the deciding factor. Again, in the words of Dr. DaCosta, "On one side we see the suffering poor; on the other the foul, loathsome rule of the 'system.' Everything is passed on to the men higher up. If I had my way I'd strike that thrice accursed 'system' dead." I should be pleased to assist Dr. DaCosta when he gets ready to strike. On general principles it would be the best plan to formulate a rule in every hospital that staff officers shall not hold office longer than a period of two or three years, and by this procedure it might be possible to break up the "system."

With regard to the question of continuous service, which has been so ably handled by Dr. Littig, I think it is generally conceded by all close observers of hospital work that both from the standpoint of the medical treatment of the patient and the administration of the hospital, it is a far better plan to have continuous service in preference to any other arrangement. The first consideration in any hospital should be the proper and efficient care of the patients treated therein, and there can be no sound argument against the proposition that the patient is better treated if one physician or surgeon attends him throughout his stay in the hospital. This fact is particularly applicable to the orthopedic service of a hospital, it being particularly desirable that the man who operates in such a case should not only supervise the after-treatment, but should prescribe the proper brace, approve of its adjustment and indicate the changes necessary as the child grows. When the individual patient treated in the hospital becomes the most important consideration in that institution, continuous service will be adopted in all cases.

DR. L. W. LITTIG, Davenport, Iowa: I wish to say that is what we hope to accomplish, to have some of these somnolent gentlemen retire. A staff that does not meet for six years is moribund; it is better to have its inactive leaders retire and more progressive men elected to their position. The question of anesthesia does not trouble us much in the Middle West. We have good anesthetists, usually young practitioners that make a specialty of anesthesia, and really do very well. We have but few resident physicians, probably in not more than six hospitals, and in two of these hospitals the anesthetic is administered by students, under the direct supervision of an expert anesthetist. We never have nurses give anesthetics, although the fact has been demonstrated that nurses do make splendid anesthetists. I do not think it is essential that every nurse graduating from a hospital should serve a course at the instrument table. After graduating, nurses have very little work of this kind to do unless they take up hospital work, when an additional course in training should be taken. It is certainly dangerous practice to have every nurse that graduates serve a short term at the instrument table. This is not done in any of the large clinics. The average nurse can pick up all she needs to know by careful observation as assistant to the first operating room nurse.

Tuberculous Metatasis.—It is a sound assumption, that general metastasis in its worst form of tuberculous meningitis is an accurate index of the tendency of any procedure, whether surgical or therapeutic, to mobilize tubercle bacilli infesting tuberculous lesions in various parts of the body. Again and again it happens that in mobilization of tuberculous joints, after necessarily imperfect surgical operations on tuberculous joints or bones or mucous membranes (rectum), or in lymphatic glands, metastasis has been followed by fatal tuberculous meningitis. In these operations, which frequently involve scraping and other crude methods which inevitably open up afferent venous and lymphatic channels by which material elements, such as tubercle bacilli, may be carried into near and distant parts by these channels, tubercle bacilli find their way into the general circulation, and, if in sufficient numbers, may lead to tuberculous meningitis. In some cases, the tuberculous meningitis may be independent of this local injury of tuberculous tissue, but in many cases the tuberculous meningitis is the direct effect of the damage to the tissues around the tuberculous focus.—W. Camac Wilkinson, M.D., *Practitioner*, October, 1915.

THE BLIND DENTAL ABSCESS*

HENRY LUDWIG ULRICH, M.D.
MINNEAPOLIS

At the University of Minnesota Hospital, in an effort to correlate oral sepsis with systemic lesions, particularly in patients exhibiting rheumatoid conditions, special inspection of mouths was made for pyorrhea, gingivitis, caries, and by means of the Roentgen ray, for apical abscesses. We were struck by the frequency of apical abscesses in these cases. Routine work was extended to all patients in the hospital in the medical service. Further search was made for apical abscesses by studying the roentgenograms of the mouth in a medical Roentgen-ray laboratory, the purposes of the roentgenograms in many instances being remote from that of ours. The findings are as startling as they are of significance. A little over 68 per cent. of all artificially devitalized teeth were found with apical abscesses, and the total number of abscesses, on 1,350 dead teeth, including those found on pulpless teeth due to caries or accident or to proximal fillings was 83 per cent. (Tables 1 and 2).

TABLE 1.—DENTAL ABSCESSES FOUND IN FIVE HUNDRED CASES

Number of cases	Number of dead teeth	Number of dead teeth with root canal fillings
500	1,350	976
Number of these teeth abscessed	Nmber of abscesses on pulpless teeth due to caries or accident	Total number of abscesses
669, 67.5%	439, 32.62%	1,108, 83.42%

TABLE 2.—DENTAL ABSCESSES FOUND IN EIGHTY CHARITY AND THIRTY-SEVEN PRIVATE PATIENTS*

CHARITY PATIENTS

Number of cases	Number of dead teeth	Number of dead teeth with root canal fillings
80	241	111
Number of these teeth abscessed	Number of abscesses on pulpless teeth due to caries or accident	Total number of abscesses
82, 73.87%	130, 53.5%	212, 88%

PRIVATE PATIENTS

Number of cases	Number of dead teeth	Number of dead teeth with root canal fillings
37	131	102
Number of these teeth abscessed	Number of abscesses on pulpless teeth due to caries or accident	Total number of abscesses
76, 74.7%	29, 22%	105, 80%

* In 117 cases divided into poor and rich patients little difference is shown in apical infections.

---

* From the Department of Medicine of the University of Minnesota.

* Read before the American Association of Immunologists, Washington, D. C., May 10, 1915.

One hundred and fifty-nine of these cases with apical abscesses have had bacteriologic review. Henrici[1] reports 107 cases from the University clinic of which 100 gave the *Streptococcus viridans*. Fifty-two are from my private clinic, fifty of which gave *S. viridans* or *S. hemolyticus;* occasionally *S. mucosa* was recovered. Thus, 150 of these 500 cases gave evidence of streptococcus, either in pure culture, or as the dominant organism. Occasionally the *Staphylococcus aureus, or albus,* or the *Micrococcus catarrhalis* was also observed in conjunction with streptococcus. The bacillary growths were considered contaminations. Gilmer and Moody[2] report streptococci, both *S. viridans* and *S. hemolyticus,* and other organisms, such as *S. aureus, Micrococcus catarrhalis,* the *Bacillus fusiformis,* and in two instances diphtheroid bacilli.

Hartzel and Henrici[3] find in 162 cases that 150 yield streptococci. They report inoculation of twenty-four rabbits with *Streptococcus viridans* isolated from apical abscesses. Heart lesions were found in five, kidney lesion in seven, those of the aorta in three, and of the joints in two.

In the light of the doctrine of focal infections the prevalence of these abscesses, with their flora and its pathogenicity, takes on added significance. To me the apical abscess is merely another evidence of a focus of streptococcal focal disease, just as the lesions found in the heart, the mucosa of the stomach, the articulations or the kidneys are evidences of secondary deposits. In other words, it is hematogenous in origin.

Rosenow[4] remarks:

> It would seem, therefore, that focal infections are no longer to be looked upon merely as a place of entrance of bacteria, but as a place where conditions are favorable for them to acquire the properties which give them a wide range of affinities for various structures.

At the time of devitalization of a tooth apical trauma occurs with its subsequent area of lowered resistance, and possibly lowered or changed oxygen pressure, thereby forming an ideal nidus for streptococcal growth. This is possibly the explanation of all apical abscesses with the probable exception of those capping pulpless roots following caries. Under preexisting conditions of caries I can readily see that infection may travel along the canal, producing direct infection of the alveolar bone. It is an interesting commentary that those who have written on this subject, Billings, Rosenow, Gilmer and Moody, and Hartzel and Henrici have still the old habit of thought in looking on the mouth as a primary territory apart from the rest of the body. The suggestion first made by me[5] that these foci are not primarily dental, but secondary deposits, that is, hematogenous in origin, has produced stormy discussions among dentists. One group has accepted the suggestion, while the other claims that these abscesses are due to dental technic, that is, a matter of poor root-canal filling. It seems highly improbable to me that out of 159 possible infections, 150 should turn out streptococcal in origin if there were not some broad biologic law, such as the selective and mutative activity of this group, to account for such results.

Experimental evidence as to the mode of origin of these abscesses has not been secured. Their pathogenicity and their relation to other concurrent foci have had ample clinical verification. There are four striking forms of evidence for this judgment:

First, acute exacerbation of systemic symptoms takes place following their removal; in other words, focal reactions occur, owing to auto-inoculation at the time of their reduction.

Second, acute new systemic symptoms have followed reduction of these areas; in other words, other foci were established.

Third, improvement and sometimes total recession of other focal areas followed the extirpation of these sites.

Fourth, local and focal reactions occurred with vaccines prepared from infected apical areas.

Seventy-six cases were analyzed clinically in which a streptococcus was isolated from apical pockets.

In a recent study, "Streptococcicosis,"[6] they were classified for convenience into:

First, a rheumatoid group in which the special feature of the cases consisted of arthritis deformans, rheumatoid arthritis, neuritis and myositis, with or without cardiac involvement (38 cases).

Second, a cardiovascular group exhibiting in the main feature heart lesions or hypertension without any appreciable rheumatoid manifestations (6 cases).

Third, an asthenic group closely allied to Group 1, showing joint, periarticular pains, nerve or muscle pains, but in which the main feature is one of asthenia, mild anemia, albuminuria, and occasionally myocardial weakness. Visceroptosis is a common finding in this group (18 cases).

Fourth, a gastro-intestinal group exhibiting gastroduodenal ulcers, gallbladder or pancreatic symptoms, and acute enteritis (4 cases).

Fifth, a genito-urinary group allied to Group 1 in having at times rheumatoid pains with renal, bladder, prostatic or vesicular involvements (2 cases).

Subgroup 1, streptococcus focal infections superimposed on tuberculosis, syphilis, primary anemia or vice versa (8 cases).

A striking feature of this analysis is the diversity of clinical manifestations for which streptococcal focal disease is responsible. The diversity of symptoms is so marked that I have proposed the term "streptococcicosis" for streptococcal focal disease. Under such an etiologic name various branches of the profession could approach this diverse problem with much more clarity and unity.

Of the more striking foci or symptoms in these groups we have manifestations of rheumatoid conditions, 51 per cent.; heart lesions, 47 per cent.; blood (that is, secondary anemia), 43 per cent.; tonsils, 40 per cent.; pyorrhea, 25 per cent.; kidneys (albuminuria and nephritis), 34 per cent.; caries, 15.8 per cent. (Table 3).

Although the tonsil is represented by 40 per cent., a certain number of these patients presented themselves with tonsils removed; or in the early efforts at correlation, the inspection of the tonsil was not so close as it is at present. The tonsil or pharyngeal ring is the commonest focus and possibly the primary portal of entry. Experience with alveolar infection in which systemic symptoms were present has made us very cautious concerning the apparently innocent looking tonsil. Invariably the same tonsil on closer inspection, and particularly after it had been removed, under protest, by the throat specialist, has proved our suspicions correct.

To us who are attempting active immunization against disease, the blind dental abscess has a very practical significance; the apical abscess may be the only focus left, evacuation of which will permit the reestablishment of renewed integrity to all parts. It may hold the balance of power in the struggle of the body for complete sterilization. Thus the discovery of such a focus is important in the prognosis of any given case.

TABLE 3.—NUMBER OF TIMES CLINICAL MANIFESTATIONS OR SYMPTOMS WERE NOTED IN SEVENTY-SIX CASES OF STREPTOCOCCICOSIS WITH ALVEOLAR ABSCESSES

Rheumatoid conditions	39	Gastric ulcer	4
Cardiac lesions	36	Cystitis	3
Secondary anemia	33	Pharyngitis	3
Chronic amygdalitis	30	Ascites	2
Pyorrhea	20	Glucosuria	2
Albuminuria	19	Prostatitis	2
Caries	12	Conjunctivitis	2
Visceroptosis	10	Primary anemia	1
Adenopathy	8	Enteritis	1
Neuritis	7	Syphilis	1
Bronchitis	6	Iritis	1
Hypertension	6	Emphysema	1
Nephritis	6	Exophthalmic goiter	1
Tuberculosis	6	Rhinitis	1
Leukocytosis	4		

In every case of streptococcal focal infection, its presence or absence must be established. I can look back on my attempts at vaccine therapy in middle ear, accessory sinuses, and chronic bronchial cases, and now see a possible explanation for some of the puzzling reactions and failures I achieved.

In every case of focal infection due to streptococcus, the presence of this focus may aid us in obtaining material for the preparation of vaccines. Much trouble and disappointment in attempting cultures from glands and tonsils can thus be avoided.

It is difficult, if not too early, to judge of the value of vaccine therapy in streptococcal focal disease. It is our custom to make a vaccine from a root pocket in every possible case, although the major number of these patients are relieved by the reduction of foci alone.

Ten cases with subacute or chronic rheumatoid conditions were treated with autogenic vaccines made from blind abscesses, all streptococcic in type.

Two cases with acute exacerbations of violent character were quickly relieved. In five cases of chronic arthritis, the patients were much improved. In two cases of arthritis, one of sixteen years' duration, the patients are still under treatment and are undergoing steady improvement. One patient with marked arthritis deformans has stopped treatment with no manifest improvement of the joints. Experience has taught us that small doses of vaccine, 5 or 10 millions at about five-day intervals, give the best results.

HEMOLYSIS AND AGGLUTINATION IN TRANSPLANTATION *

CHARLES GOODMAN, M.D.
Fellow of the American College of Surgeons; Professor of Clinical Surgery, University and Bellevue Hospital Medical College
NEW YORK

In studies of the conditions incident to the cause of autolysis and the dissolution of the transplant, we devoted especial attention to the influence of hemolysis and agglutination on transplants. No question is more timely than that concerning the causes of their absorption.

Most authors lay great stress on the importance of eliminating the two great dangers in blood transfusion — hemolysis and agglutination. We must consider blood transfusion not only as an infusion of a certain quantity of fluid, but also as a transplantation of a definite mass of tissue represented by the cellular elements of the blood.

Accordingly, before transplanting the thyroid, we first made hemolysis and agglutination tests, and operated only when these reactions were absent.

Owing to difficulties in obtaining and in handling the blood (which have since been obviated to some extent by a new method), we are thus far able to report results in only seven instances.

HEMOLYSIS AND AGGLUTINATION

Date	Donor	Host	Hemolysis	Agglut.	Remarks
1/22	179	180	Negative	Negative	In this instance there was autolysis and absorption in three months.
2/3	190	191	Partial	Negative	Thrombosis of the artery set in in six weeks.
2/17	201	202	Negative	Negative	The results were good after eight days.
3/10	224	225	Negative	Negative	The results were good after three weeks.
3/12	228	229	Negative	Negative	Hemorrhage set in in two weeks.
3/20	215	239	Negative	Negative	
4/9	281	282	Negative	Negative	

Before the employment of these tests, we were unable to obtain any results from homotransplantation. But since the importance of these reactions came to be more clearly appreciated, we have in two instances, at least, obtained a satisfactory preservation of the transplant for one and three weeks, respectively. While our experiments have been few in number, we feel justified in concluding from results so far obtained that the hemolysis and agglutination tests to a certain extent are some indication of the tolerance of the tissues of one animal for those of another. Such a hypothesis is given some support by the fact that in blood transfusion these reactions are now largely depended on as clinical indicators. May they not therefore be reasonably expected to be of equal significance in the transfer of the less liquid tissues from one organism to another?

FACTITIOUS DERMATOSES *

OLIVER S. ORMSBY, M.D.
CHICAGO

The object of this paper is to record a group of cases of self-inflicted dermatitis, which have occurred during the last several years in the practices of the late Dr. James Nevins Hyde, the late Dr. Frank Hugh Montgomery, and myself.

Much confusion exists concerning the dermatitis herein described, and the physician who is originally consulted in these cases rarely is able to recognize their character, commonly on account of prejudice, through personal acquaintance with the patient or family. It is on account of this failure to appreciate the possibilities in these cases that it has been thought worth while to record this group of thirty-four cases.[1]

Opinions differ among men who recognize these, and some able observers have recorded cases as being of spontaneous origin, in hysterical persons, which later have proved to be factitious. That there are some cases in which a spontaneous origin can hardly be doubted, there is no question. Yet the large majority, according to most observers, have an associated, though often unrecognized, factitious origin.

In public practice, paupers and others are not infrequently seen who inflict injuries for the purpose of securing financial or other aid. In Europe, the professional malingerer is not uncommon, and the degree of skill exhibited by these people in imitating disease is at certain times high. In this country this class of cases is uncommon.

There is another class in which existing skin diseases are aggravated by irritation, and prolonged by the patient for various reasons. All of these types are excluded from this paper.

The major portion of the patients recorded here were women and poor girls of a highly neurotic temperament, and showing distinct stigmata of hysteria. As will be noted from the case histories, the lesions occurred on accessible parts of the body, such as the breasts, abdomen, and limbs; all were areas accessible to the right hand. The right arm was commonly exempt, except in left-handed individuals. The lesions occurred suddenly in all cases, and usually developed during the night, when the patient was alone; and several of the patients were able to predict the exact spot where a lesion was going to develop, much to the astonishment of their friends.

An interesting feature, in a large number of cases, was the fact that the disease was initiated through accident. This may have been trifling, and the dressing employed in the treatment gave the suggestion to the patient as to how to carry out the deception.

The symptoms in the cases vary from a simple erythema to vesicular, bullous, gangrenous and ulcerating lesions, with their sequels.

A number of cases are on record, and there occurs one in this series, in which tissue destruction has been marked, and amputation of fingers, the whole hand, and even the arm has been performed, with the full consent of the patient.

The methods employed by these patients are varied, and are at times exceedingly difficult to detect. A long list of animal, vegetable and mineral substances is included in this category. Those most commonly used are phenol (carbolic acid), croton oil, cantharides, mustard, various acids and alkalies, including lye, tartar-emetic ointment, cresol and compound solution of cresol. Other methods employed have been burning with matches, with pieces of hot metal, or with bottles containing very hot water, and friction with the fingers, sandpaper, and other rough substances. In one patient whom I saw, intense dermatitis was aroused by rubbing tobacco briskly into the skin of the genital region. The character of the lesions and the intensity of the inflammation depend not only on the agent employed, but also on the strength of the solution, the duration of the application, and the tissue resistance.

ETIOLOGY

The cause of these peculiar actions in the individual must be sought in derangement of the nervous system. All the intricate processes concerned in hysteria could be brought forth to explain the condition here. In some cases there is exhibited a desire on the part of the patient to escape from disagreeable duties or surroundings; in others, to gain attention, sympathy, interest or pity, or to achieve notoriety. In some instances, no possible explanation can be given, and it may be, as suggested by Pernet and Towle, that in a certain proportion of cases there is a dual personality, or a subconscious state, in which the lesions are produced, while in the normal condition the patient has no recollection of the acts performed in the other state.

Towle[2] explains the production of these lesions from the standpoint of hysteria, on the ground that the initial wound which occurs in numbers of cases serves as a suggestion to the patient, who afterward enters into a somnambulistic state, in which he is powerless to control the suggestion of producing wounds by any means at hand. On emergence from this state, the patient has no memory of the somnambulistic period or of the production of the wounds, and honestly believes the wound appeared of itself.

Pernet[3] concludes that in some instances there is an altered personality, whereby the self-infliction of wounds is not remembered by the patient at the time they are examined. In all these cases hysterical stigmata can be found.

Galloway[4] states that the more these cases are investigated, the less probable does their spontaneous origin become.

Jelliffe,[5] in a discussion of hysteria, states that the various cutaneous manifestations occurring in hysteria, such as bullous dermatitis and other lesions, are, in the vast majority of cases, artefacts; yet there remain a few in which this factor cannot be proved.

In the major portion of recorded cases the factitious element is present, though it has not been proved in many of them, for various reasons. Many cases of

pemphigus gangrenosus of supposedly spontaneous origin have been proved to be factitious by the discovery of the materials used, and later by confession of the patient. That spontaneous cases do occur is strongly supported by Van Harlingen.[6]

Corlett[7] reported a case having lesions of this type. The patient was a hysterical girl, aged 15. This case was recorded as one of spontaneous gangrene.

White[8] recorded a case of recurrent, progressive, bullous dermatitis in a hysterical subject. This case was well studied, and in the opinion of the reporter was one of spontaneous occurrence. In the discussion which followed the reading of the paper, opinion was divided as to its spontaneous or factitious origin.

Illustrating the difficulties encountered in arriving at conclusions on this point, may be mentioned a case recorded by Shepherd.[9] This is the record of a patient, aged 20, who had suffered with a recurrent bullous eruption of the face for four years. After much study, the reporter concluded that the eruption was feigned. The possible connection of this eruption with the menstrual epoch was discussed. The interesting feature was its localization on the face alone.

An interesting case of factitious origin was described by Stelwagon.[10] This is the record of a female patient, aged 19, who had produced lesions on the forearms and legs, over a period of several months, by constant rubbing with the finger. The object of the patient was not to create sympathy, but there was an irresistible impulse to rub the skin, which apparently created an agreeable sensation.

Another instructive case was recorded by Weber.[11] This patient, a woman aged 37, was suffering with hysterical functional nervous affections, and was also a malingerer. The lesions consisted of bullae, with superficial ulceration, and were located on the front of the abdomen. Their duration was seven months. A starched bandage was applied, in order to detect deception. The bandage, however, became loosened, probably by deflating the abdomen, by means of which the patient was able to introduce her hand under the upper anterior portion. In this area bullae developed, and on examination some dark specks were detected in the raised epidermis over the bullae. These specks proved to be powdered cantharides. In spite of the finding, the patient would not acknowledge the deception.

Weber also reported a patient who produced spurious Roentgen-ray ulcers by means of hydrochloric acid. In this patient an appendectomy had been performed, as well as three other abdominal operations. On account of menorrhagia, she was treated with Roentgen rays, and later developed ulcers which spread over the whole abdomen, and which were produced as stated above.

Shepherd[12] recorded four cases which are instructive:

1. Gangrenous patches on the skin of the arms, in a woman aged 30, produced by some heated object. No hysterical stigmata.
2. Woman, aged 44, suffering with a bullous dermatitis, produced by some blistering agent, probably cantharides, phenol, acetic or other acid; the object was to avoid disagreeable work.
3. Woman, aged 28, hysterical stigmata present. Bullous lesions produced by cantharides. Object, to excite sympathy and interest.
4. Woman, aged 24; no hysterical stigmata. Gangrenous patches on foot and leg. Agent used not discovered. Original lesion due to an accident, subsequent ones to design.

Pernet[13] recorded two cases of trichotillomania, associated with other factitious manifestations. These occurred in young women aged respectively 20 and 22.

Illustrating each side of the contention are cases recorded by Wende.[14]

> The first case, in a young woman aged 17, had its beginning following the application of phenol to a wart situated on the back of the right hand. Subsequent to this, gangrenous areas began to develop on other parts of the body.
>
> In the second patient, aged 18, the disorder followed an accident sustained while sleigh-riding, the first lesions appearing as a group of vesicles on the nates. In this case, the recurrences were always confined to the original area. The peculiar location of the lesions, in a situation hard to reach by the hand, and the character of the lesions, placed the case, in the mind of the reporter, beyond the possibility of being factitious.

Two affections described under other titles should be mentioned here. Under the title "Zoster gangrenosus atypicus," Kaposi[15] described two cases of cutaneous disease occurring in hysterical young women. He later described others, making a total of eleven.[16] In these cases, recurrent lesions appeared, consisting of grouped vesicles and papules, followed by crusting. In some cases, by coalescence, large areas of gangrene were produced, which, after the sloughs had separated, were followed by cicatrices, which often showed keloidal developments.

Rona[17] (Budapest) stated that in 1889 he reported a case of zoster gangrenosus atypicus, and attempted to solve its etiology. Since that time his views had radically changed. In four of the five cases under his observation there were definite hysterical stigmata; in four, the lesions followed a trauma, two from a needle wound of the finger; one followed operation; one followed abortion. In two of the cases, caustic soda was found secreted. That all the cases were identical with those described by Kaposi he believed there was no doubt, and that the differences in the descriptions of the disorder are due to the different chemical substances used in their production, and the concentration, mode and place of application.

Recently, a group of cases has been described under the title "dermatitis symmetrica dysmenorrhoica," by Matzenauer and Polland.[18] They report six cases, occurring in persons of unstable mentalities. The lesions were usually linear, and developed rapidly. The authors set up a hypothesis explaining the spontaneous occurrence of these lesions on the ground of some change in the internal secretions.

Kreibich[19] discusses the same subject, but proposes the term "gangrenosa neuroticum dysmenorrhoica."

Friedeberg[20] describes a case, under the title "dermatitis symmetrica dysmenorrhoica," of a woman, aged 30, who suddenly developed bullous lesions on the cheek, which in the course of a few days became crusted and healed without scarring. At the next menstrual period, a similar process occurred on the trunk.

Mathes[21] discusses the etiology of these cases.

Török[22] (Budapest) discusses the cases of dermatitis symmetrica dysmenorrhoica, and concludes that the most probable explanation of these cases is the presence of a factitious element.

DIAGNOSIS

The diagnosis is usually not difficult to one familiar with cutaneous disorders, since the lesions, though of a simple inflammatory nature, are different from those of any recognized disorder. The most important points are the following:

The lesions occur within reach of the patient's hands, and are usually most numerous on regions easily accessible to the right hand. These include the anterior surface of the body, the left arm, forearm and hand, the lower extremities, and the right side of the face and neck. As a rule, the palms and soles, eyelids, mouth, nose, ears, scalp, and genitals are spared.

The lesions are always sharply outlined, and of unusual, often fantastic, shape. They appear suddenly, at irregular intervals, usually one or two at a time, and run a fairly rapid course. When fluid caustic is used, it frequently happens that one or more drops run down the skin from one of the lesions, leaving a characteristic streak, which is usually lighter in color and shows a more moderate degree of inflammation than the patch from which it depends. When the caustic is applied with a needle or pin, as is frequently the case in gangrenous areas, the border shows a finely jagged or serrated edge, made by the numerous punctures in the advancing border. When gangrene is present, it is usually very superficial, and is separated from the normal skin by a narrow, vivid red line. The fingers, nails or some article of clothing are often stained by the agent employed.

Subjective sensations, usually pain and burning, may be greatly exaggerated by the patient, who will cringe or jump at the slightest touch during the examination, and will complain bitterly about the distress caused by the simplest and lightest of dressings. On the other hand, some of the areas are largely anesthetic, and some of these individuals like to exhibit their ability to endure pain. Many of the patients enjoy mystifying their medical attendants by predicting, from twelve to twenty-four hours in advance, the exact areas on which new lesions will occur, claiming that during this period they experience in these areas a sense of heat and burning and other abnormal sensations.

The impulse one has is to confront the patient immediately with *the charge, and there are several* who advocate such procedure. While occasionally this terminates happily, in the majority of cases it probably would fail, in which case it would work an injustice on the patient, her friends and the attending physician. A plan which I pursue is to instruct the patient in methods of treatment, and during the instruction impress her with the idea that there is no question whatever as to what has produced the lesions, and that if she will faithfully apply the remedies suggested, and as faithfully avoid using anything else, she will make a prompt recovery. Then have the patient watched with care, using at a later date, if necessary, fixed dressings; that is, dressings which cannot possibly be removed without detection; or, if driven to extreme measures, take the patient to a hospital, where she can be kept under strict surveillance, both day and night, when, by complete disappearance of the lesions and the nonappearance of new ones, the diagnosis is proved. This, however, does not reveal the causative agent. In an intelligent patient, the appeal to her pride and self-respect has weight. In certain of the cases no impression is made by such an appeal. It may be that a number of these patients belong to the group described by Pernet and Towle, those who really do not know *that they have inflicted the injuries.*

Further aids to the diagnosis may be found in the general characteristics of these patients, the unusual history of the disorder, the discovery of anesthetic areas, especially of the fauces and conjunctiva, and other evidences of hysteria.

CASE REPORTS

Case 1.—The patient whose lesions are shown in the illustration was being attended in one of the hospitals of the city for ulcerated, gangrenous lesions occupying the entire length of the left hand, forearm and arm. I saw her in consultation at the hospital. She had been examined by a number of physicians, and apparently was much pleased at the prospect of having another examination. There were several physicians and hospital attendants in the room when the patient was examined. During the undressing of the arm, the following history was elicited: At the beginning, an apparently serious lesion occurred on one finger. A physician was called, who dressed the lesion and stated that he would redress it the following morning. On the second *visit, a similar lesion was found immediately above the* bandage. This was dressed, and, either daily or on each alternate day for several weeks, new lesions continued to appear immediately above the bandage. They were painless, occurred *suddenly, always developed during the night,* and the first lesion seen by persons other than the patient was a bulla. The bulla would soon become dark, gangrene would follow, and either deep or superficial ulceration result. At the moment of examination, lesions varying *from superficial* scars to deep ulcers, through the various stages, were present. They were irregularly shaped, and varied in size from that of a split pea to that of a silver dollar. During the time the dressings were being removed, the lesions were carefully examined, but no questions were asked the patient. She, however, was apparently enjoying the situation and attention. When the dressings were all removed, with no preliminaries, the patient was informed that the lesions were due to the application of phenol made by herself. She was so surprised that before she could master her emotions she admitted the deception, and finally stated that by accident she had learned how to produce the lesions with phenol, and continued the process, as it relieved her from the disagreeable duty of practicing at the piano.

Case 4.—Miss I. V., aged 22, of nervous temperament, had had the cutaneous disorder one and one-half years. The history obtained from the patient and her mother was as follows:

In the beginning, a finger was burned with nitric acid. The lesion remained open for some time. Three months later an ulcer appeared in the same area. Six months after the beginning, curettage was performed and necrotic tissue removed. One month after the curettage, an incision was made into the hand, after which the lesions disappeared, excepting a small spot. Two months subsequently, the record states, the patient was in good condition. One month later lesions began to reappear. New ones occurred still another month later, and two months subsequent to this they began to appear higher up the arm. The lesions all occurred suddenly and began as blisters.

---

[20] Friedeberg: Arch. f. Dermat. u. Syph., 1913, cxiv, 173.
[21] Mathes: Arch. f. Dermat. u. Syph., 1913, cxiv, 185.
[22] Török: Arch. f. Dermat. u. Syph., 1913, cxiv, 185.

On examination, the following was noted: The dorsum of the left hand was erythematous, and showed scars from old incisions and lesion relics. One active lesion was present on the side of the face. This was irregular in outline and covered with a brownish eschar. The entire arm and forearm, left side, showed superficial atrophy and scar formation, in irregular areas.

The mother was informed of the diagnosis, and was good enough to cooperate in trying to determine what was being used. Her physicians were also informed, but were skeptical as to the possibility of the disorder being self-inflicted. Eight months afterward, one of the attending physicians reported that, after compound solution of cresol had been found in the patient's stocking, she confessed that the lesions had all been self-inflicted. Following this disclosure, recovery ensued.

Case 5.—Miss F. R., aged 15, had had the cutaneous disorder seven months. The patient was of a highly neurotic temperament and showed marked evidence of hysteria. The disorder began as an abrasion on the left hand, from which lesions spread up the forearm. The early lesions were vesicles filled with semipurulent material. Each new attack was accompanied by marked elevation of temperature, the family stating that it reached as high as 108.5.

Bullae continued to appear from time to time. The day before the patient was examined, a new lesion appeared on the forehead, at which time a temperature of 106.5, as recorded by the mother, was reported. There were never any lesions in the mouth. The patient vomited considerably, but had no nausea. She frequently had spells of fainting; these always occurred when she was with another person.

The patient was right-handed, and was apparently normal mentally; there was no pharyngeal reflex; the corneal reflex was much reduced.

On the forehead a dime-sized, irregular, pigmented, superficial burn was present; healed lesions were present on the left arm; there were irregular hypertrophic scars, with similarly shaped and circular, well-defined, superficial, dried, burned areas on the right arm, in various stages of healing.

Temperature taken at time of examination was normal. Leukocyte count was 8,000. Visual fields were normal and equal.

The diagnosis of factitious dermatitis was made and forwarded to the patient's attending physician. A letter received from the latter some months later reported that under the care of a competent trained nurse the diagnosis was confirmed, that phenol was found to be the agent used, and that the patient had made a complete recovery.

Case 7.—A strong, healthy, Scandinavian girl, age 22, presented a peculiar eruption occupying the anterior surface of the right arm from the wrist to a short distance above the elbow. Three weeks prior to examination, she had pricked her finger with a pin; it became sore and painful, and her physician feared blood poisoning. A few days after the accident, she fainted in church. Fearing serious complications, she was taken to a hospital, where she remained two weeks. A day or two after entering the hospital, a small red area, more or less covered by blisters, appeared, which darkened in color and resulted in a few days in superficial necrosis. Several of these areas appeared on the forearm while the patient was in the hospital.

Examination showed the anterior surface of the right arm (the patient was left-handed) to be occupied by about seven separate rectilinear areas of altered integument. These were placed with their long axes in a transverse direction. Roughly estimated, their size averaged from 2½ to 3 inches by 1 to 1½ inches. Each was separated from those adjacent by a strip of normal skin. The borders were well defined, but in places irregular and frayed out. The lesion nearest the hand, opposite the carpal joint, was practically healed, leaving a scar; the uppermost band was the most recent. The lesions from above downward showed the various stages of evolution and involution of a dermatitis due to the application of a solution of phenol. She had evidently first made an application to the wrist, and, being ignorant of the power of phenol, had used enough to cause a fairly deep burn, which resulted in superficial necrosis and ultimate scarring. While lesion No. 1 was under treatment, she caused No. 2 to appear just above the bandage. No. 3 was produced above the bandage which included No. 2, and so on up the arm. The later lesions were noticeably less severe than the first.

It was learned later, from the girl's history and her conduct, that she was a degenerate. She and her sister had the same lover, and, thinking that her sister was receiving too much attention from him, she had taken this means of attracting his interest and sympathy. The lover departed, and no more lesions appeared.

Case 10.—The patient, Mrs. J. H. W., was 30 years of age, and fond of society. She had been married twelve years, but had never been pregnant. Her husband, who was 25 years older than she, was a minister and circuit-rider, his work taking him away from home a large portion of the time. She was a well-nourished woman of average weight, with some tendency toward hysteria, her physician stated. In December, 1905, she had a hemorrhage from the uterus, which examination showed had come from an ulcer of the uterine wall. Diagnosis of adenocarcinoma was made and the uterus curetted.

The patient stated that the first skin lesion appeared, simultaneously with the hemorrhage from the uterus, as a small pinkish patch on the face. This appeared suddenly. The color gradually deepened for two or three days, then slowly faded out, leaving a stain, which eventually disappeared entirely. Later, numerous patches appeared from time to time on different parts of the body. During a year and a half she had rarely been entirely free from them for more than a week or two at a time. On the body, many of the later lesions had been of rather severe type, the redness being followed by the appearance of numerous small vesicles, or larger bullae. The contents of these bullae, if allowed to flow over the sound skin, produced new lesions.

On examination, the face showed a number of irregularly shaped but sharply outlined areas of erythema, in varying stages of involution. There were no scars on the face. On the body, especially over the breast and on the left arm and forearm, were numerous sharply outlined areas of irregular, and occasionally fantastic, shapes in varying stages of evolution and involution, including acute erythema, vesicles and bullae on hyperemic bases, superficial necrosis, pigmentation and, finally, a few scars.

She had been in the hands of a dozen or more physicians, and stated that she was generally known in her section of the country as "the medical puzzle." She said she always knew from twelve to twenty-four hours in advance, from certain burning sensations, exactly where the lesions would appear; and that the drawing of a blunt instrument over her skin, as had been done by several physicians to test the reaction, was always followed, in from twenty-four to thirty-six hours, by a new lesion. She was frankly told what the trouble was, but denied all knowledge of how the lesions occurred. Six months later, we learned that there had been no recurrence of the lesions.

Case 12.—A woman, aged 19, married two months, applied for treatment of peculiar lesions which had appeared on her breasts, left upper arm, neck and face. They had been coming, one or two at a time, for five weeks. The first one followed an accidental scratch, to which she had applied an antiseptic liquid given her by a druggist.

On examination, the lesions were seen to be chiefly small, irregular, sharply defined patches of erythema. On the breast were several small bullae surrounded by a narrow hyperemic zone. Subsiding lesions were followed by pigmentation, but no scars were visible. From the under margin of a triangular hyperemic area on the breast there extended downward an irregular band from one-eighth to one-quarter inch wide and 1½ inches long. The inflammatory process forming this band was less severe than that on the area above, and was undoubtedly produced by a drop of liquid escaping and running down over the skin.

The woman had always lived in the country, had never been away from home before, and had come immediately after her marriage with her husband to the city, where they had no friends or acquaintances. He was busy with his work all day, and she was, in consequence, very lonely. The nature of the condition was explained to the husband alone, and he very sensibly recognized the situation and generously stated that he did not blame the girl. He sent her home for a few weeks, and a year later reported that everything had come out all right, and he was greatly obliged for the advice given.

Case 20.—A girl, aged 18, apparently in good general health, reticent, at times almost sullen, in association with her companions, was a probationer in a Sisters' hospital. While assisting in dressing a patient with a number of ulcers on the skin, she pricked her finger, and it became infected. The lesion was later incised and curetted, and probably healed. Six months later, the tip of the finger became inflamed, and in two or three days turned black. With hot fomentations, the lesion cleared up. During the next six months, the occurrence was repeated several times, until the first phalanx appeared to be entirely gangrenous and was amputated. Two months later, the second phalanx of the same finger became involved in the same manner and was amputated. Following this, she remained well for three months, when the remaining phalanx of the finger became gangrenous, and was amputated by the same physician. Three weeks later, gangrene began to spread over the back and sides of the hand. On account of the rapidity of the process, the surgeon contemplated removing the hand at the wrist, an operation which the patient begged him to perform to save her life. Before the operation was performed, however, a consultation was held. On examination, the gangrene was found to be superficial, and was bounded by a narrow red line. The advancing border showed a finely jagged or serrated edge, in which the marks of individual punctures could be detected. There was slight anesthesia of the fauces and conjunctiva, and the general condition of the girl suggested hysteria.

The patient denied having made any application herself, but under fixed dressings made a complete recovery, and later confessed to the Mother Superior that she had produced the trouble herself with a needle and pure phenol.

Case 23.—Miss A. Y., a girl aged 17, in good general health, was the eldest of nine children, and, on account of the death of her mother two years previously, had had charge of the entire household.

Six weeks previous to the examination, her finger was scratched on a barbed wire. The skin turned black three days later, and blisters appeared on the hand and arm. These began as pimples, which became dark in three days, and gradually became larger.

On examination, there were seen on the outer surface of the left forearm and on the wrists and hands eight or ten irregularly shaped patches, from 1½ to 2 inches in diameter. There were two acutely inflamed areas, with an irregular, finely jagged or serrated outline, thickly covered with pinhead or slightly larger vesicles. These were of but two or three days' duration. Other similar areas were covered with black, gangrenous crusts, surrounded by a narrow red line. There were two rather thick, irregular, pigmented scars. The tissue destruction was deeper than that seen in most of these cases.

On confrontation, the patient admitted that she had produced the lesions with a pin dipped in lye. A letter received some months later from her family physician stated that the patient returned home and made a complete recovery.

Case 26.—Mrs. J. M. W., a married woman, aged 33, and apparently in good general health, had been seen by many physicians, a number of whom were impressed by the fortitude with which she bore pain. She was equally impressed by the fact that none of her physicians had discovered what the trouble was.

Two and a half years prior to this examination, which was made by Dr. Montgomery, she had all the symptoms of pregnancy up to the seventh month, when suddenly the whole thing disappeared.

The cutaneous disorder was of two years' duration, and had begun in the breast. A month later lesions appeared on the nose. The trunk soon became involved, and finally the limbs. The lesions were accompanied by burning and itching sensations. On the body they began as a blister on the sound skin, or on a slightly reddened area. Frequently, her face had been nearly well. The lesions always appeared suddenly.

On examination, there was found a superficial dermatitis of the nose and cheeks, in irregular, sharply outlined areas, covered with a thin edge of scales or crusts. On the upper surface of the breasts and above them were numerous irregular, sharply defined, erythematous spots, one-quarter to three-quarters inch in diameter. Some of these spots showed slight vesiculation or a superficial necrosis. Areas were seen in all stages of healing and of resulting pigmentation. They were most numerous over the breasts, the abdomen and the left arm. On the breasts were two small areas of erythema, from the lower border of which extended the characteristic streaks caused by the dropping of the fluid over the skin. There were several lesions about the umbilicus, others in the groin and on the inner surface of the thigh.

Her attending physician was informed of the nature of the trouble, and after using fixed dressings for a time he discussed the matter with her. The patient agreed that she would do as he directed, but she promptly put herself in the hands of another physician.

Nearly a year after this examination, I saw the patient in a clinic given before a medical society, when the diagnosis of factitious dermatitis was independently made. The difficulty in making the diagnosis at this time lay in the fact that the patient had become more skilful and was now producing perfectly circular, regular areas, and was not spilling any of the fluid. At least six or eight members of the society discussed the hysterical manifestations seen by them in this case, and all were agreed as to the factitious origin of the lesions.

Case 29.—The record of this patient, Miss M. B., aged 27, includes four or five visits to the Presbyterian Hospital, one or more to the County Hospital, and the attendance of several physicians.

About May, 1910, the patient received an injection of tuberculin in the left arm above the elbow. Three days later, the arm swelled, and the patient was sent to the dispensary for treatment. A salve containing phenol was applied, and the patient returned home. Shortly after this, lesions began to occur, extended down on the arm, later appeared on the left leg, and subsequently, as time went by, on the entire trunk, right arm, and all parts of the body within reach of the hands.

I saw the patient shortly after the onset of the trouble. It was evident that the original phenol salve had given her the idea and the material with which to carry it out. She was hysterical, almost always moderately deaf, sometimes entirely so, and was capable of marked imitation. During the years she had been under observation, the type of the lesions had changed. It is likely, therefore, that the materials used had been modified.

Monday, Nov. 4, 1910, the patient was seen in the clinic at which time the lesions were present on the left arm, the trunk, the foot and the lower limbs, the right arm being free. Up to that time she was supposed to be deaf. In the clinic the case was demonstrated, and attention was called to the absence of lesions on the right arm. November 7, three days later, the patient again attended the clinic, and entered the hospital on the same day. At this time she had a number of lesions on the right arm, which apparently showed evidence of suggestion. The house physician, Dr. Tope, made these notes on that day:

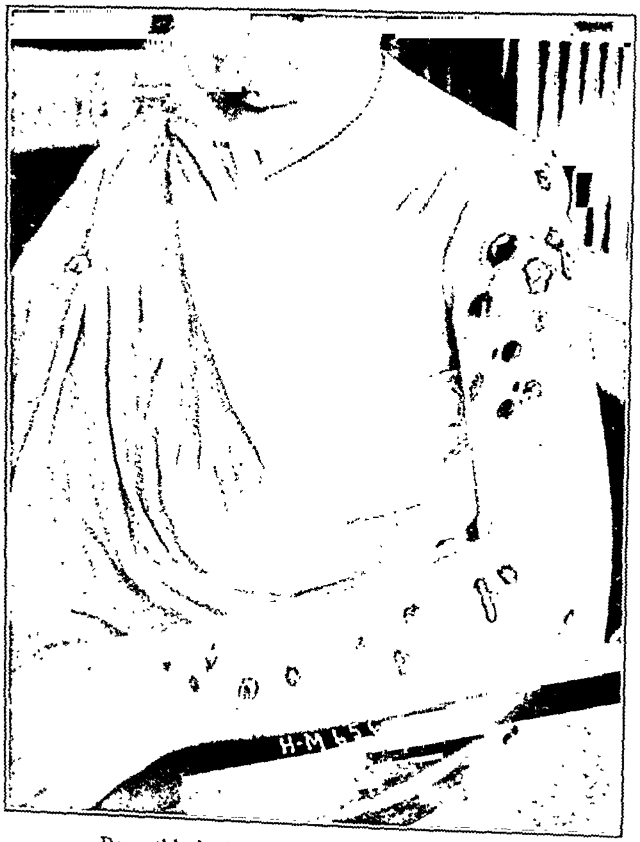
"Lesions situated on both arms, from shoulder to wrist. They consist of open ulcers, gangrenous areas, some covered with dirty-gray sloughs, other ulcers that are healing, and many scars, some of which are keloidal. The patient professes ignorance as to the cause or duration of the lesions;

professes to be deaf, but can hear much better than she admits. Speaking in ordinary tones to her, she not only hears but understands. If asked if she understands, she says 'No.'"

Nov. 1, 1912, when the patient was again in the hospital, Dr. Pincoffs, the house physician, wrote a description of the cutaneous lesions much as given above.

The record further states that the patient mentally was at first in an antagonistic attitude, but during her stay at the hospital she became more cheerful and went about the ward conversing with other patients. Deafness and blindness were complained of, but these later disappeared. The question of a certain amount of true deafness was not definitely settled, but the amount varied from day to day.

During one of her temporary visits at the County Hospital, she saw numbers of syphilitic lesions in inmates of the same ward. After leaving the hospital, many of her lesions assumed the peculiar circinate outlines which she had witnessed at the hospital.



Dermatitis factitia, induced by phenol (Case 1).

She was examined as to her mental state by Dr. Bassoe, who discovered marked evidences of hysteria. There were no other neurologic changes.

The patient had been under the care of Dr. Mackey during the greater part of this time, and it was the observation of all that during her residence in a hospital the lesions always cleared up. Immediately on her release they would recur. As they were always produced at home, and as we had had no assistance while she was there, we had no means of ascertaining the agent employed, except the one originally suggested, phenol.

SUMMARY

Of the thirty-four patients described above, thirty were females. Fifty per cent. were under 22 years of age. Trauma preceded the lesions in twelve cases. Of these, two had been burned with acid, two had had antiseptic applications made by a druggist, and two had been treated with phenolized salve. Of the thirty-four, thirteen confessed and made an immediate recovery; one case was proved under the care of a nurse, and three under fixed dressings; one patient completely recovered after being confronted. Of the total number, twenty-five made complete recovery, three disappeared, one was a degenerate, two gradually recovered after a long time had elapsed, and in two cases the lesions continued. One patient never had lesions while under observation in the hospital, but continued to have them outside.

Of the thirty-four, it was proved that fourteen used phenol, four probably used phenol, one used compound solution of cresol, one phenol and other substances, one croton oil, one lye, one sandpaper, one tobacco, one the electric needle and unknown but liquid applications, six entirely unknown substances, and three unknown liquids. It is interesting to note that several patients recovered after being confronted with the materials they had used, even though denying their use. Change of scene in one case induced recovery, and in another the departure of the person whose presence had irritated the patient. In only four of the group was the diagnosis not positively proved, either by confession or by complete recovery of the case under fixed dressings or constant supervision. In the four, however, the evidence was so strong that there was practically no doubt as to the diagnosis.

CONCLUSIONS

First, it seems probable that the major portion of cases described as pemphigus gangrenosus are in reality examples of factitious dermatitis. That the major number of cases recorded under the title "zoster gangrenosus atypicus" (Kaposi) are of the same type, and also those more recently described under the title of "dermatitis symmetrica dysmenorrhoica," seems probable.

Second, while the disorder is comparatively rare, it probably would appear more common if recognized more generally. As stated in the beginning, the family physician will generally, on account of personal acquaintance with the patient, refuse to admit even to himself the possibility that this particular patient would produce such lesions.

On the recognition of the disorder, the admission of the patient as to its cause, and the cessation of the practice, immediate recovery generally takes place; if not, careful attention to the measures detailed above should be employed, when the desired result is accomplished. Treatment is a simple matter, and requires only the application of the various remedies indicated by the stage of dermatitis present. The only difficulty in any case is to prove the diagnosis.

25 East Washington Street.

ABSTRACT OF DISCUSSION

Dr. Howard Morrow, San Francisco: I have had five or six of these cases in the past ten years. They have all been in women. The majority of the patients have been over 30 years of age. I can recall two who were to me of great interest: One was that of a telephone operator. She disliked her work and stayed away by producing a phenol burn on the arm. Her family had sympathy for her and she was kept at home. She applied the phenol as a compress and produced deep sloughs. Another girl was seen in consultation with Dr. Buckley some time back. She applied phenol to different areas on her leg. She told her folks she was run down and would have to take a trip to get rid of them. After she returned from the trip, these lesions disappeared. After a time they started again. I suggested zinc oxid paste, as the patient cannot remove that, and reapply it. Each day after the application of the paste, new lesions would appear in the neighborhood. After this was done four or five times, Dr. Buckley became annoyed at the patient and he said to her, "You do this yourself and it must be discontinued, or I will report it to your family." She at first denied this but afterward admitted it. No more lesions occurred.

Dr. Lasher Hart, Los Angeles: Dr. George Henry Fox had a case in his clinic. Dr. Fox took the patient into a room and said, "What have you been doing here?" She admitted that the lesions which she had on her forearms had been caused by rubbing salt into them, and that she was seeking sympathy from her employer. Dr. Fox confronted these patients at once with the idea that he knew the diseased areas were self-inflicted, and I have always followed out that idea in my own practice since then.

Dr. George M. MacKee, New York: As bearing on possible etiologic factors, we had in Dr. Fordyce's clinic a few months ago a case of neurosyphilis with lesions of factitious dermatitis on the chest, arms and shoulders. The interesting question was whether or not the neurosyphilis had so altered the nervous system as to produce a malingerer. As is well known, cases of malingering are at times exceedingly difficult to diagnose, and are not infrequently confused with other diseases. I recall a case in which the first ulcer developed on the back of the hand; later numerous ulcers occurred on the forearm. The case was investigated for the possibility of sporotrichosis, syphilis, tuberculosis, etc., but later the patient was proved to be a malingerer.

Dr. A. J. Markley, Denver: During the last six or seven years I have had the misfortune to observe a number of cases of this kind and believe that, as Dr. Ormsby has done, it is necessary carefully to distinguish between the two types of individuals in which this occurs; that is, the malingerer and the neurotic. In the malingerer, if the patients definitely know that you are familiar with the manner in which the lesions are produced, they may be frightened off. On the other hand, hysterical and neurotic individuals are less easily dealt with, and when accused of inducing these lesions themselves, are often led by their neurotic tendencies into practices of more serious kind. Such cases belong definitely in the hands of the neurologist. Of this type, a girl in an orphanage in Denver had become a serious charge to the good Sisters who took care of her. She had disfigured herself with some form of caustic, sparing no part of her body which was accessible to her right hand. The only part which she had been unable to reach was the scapular region of the right shoulder. When confronted with the charge of self-infliction of these lesions, she ceased to produce them, but other stigmata of hysteria occurred, and only when she had been placed under proper neurologic care was any permanent benefit obtained.

Dr. Richard L. Sutton, Kansas City, Mo.: I envy Dr. Ormsby the long list of cases which he has had opportunity to observe. The character of the lesions, the region involved, and the fact that the affected areas were usually readily accessible to the right or left hand are also suggestive. I recall a recent case in Kansas City in which a patient, a woman student, had burned herself with nitric acid. The lesions healed, but new ones speedily appeared. The superintendent of the school was a very religious woman, almost excessively so, and she would not believe it possible that a girl placed under her care would do such a thing. It was only when the matter was thoroughly sifted and the diagnosis verified beyond the shadow of a doubt that the girl was sent home as utterly unfit for the training she had taken up. So one must be as careful as possible in approaching the patient as well as her family, if the treatment is to be ultimately successful.

Dr. Oliver S. Ormsby, Chicago: In one of the illustrated cases which I intended to read, the question of autosuggestion arose. It has been thought that sometimes by autosuggestion lesions may be produced spontaneously; that is, a patient is able to bring out a lesion on the body by fixing the mind on it. These, however, are often factitious, and may be illustrated as follows: In a clinic on a certain Tuesday there was a patient who was supposed to be deaf. The lesions were all placed in regions readily accessible to the right hand, on the left side, and I called this fact to the attention of the assistants. On Friday, when the patient returned, she had lesions on the right side, including the right arm and forearm. At a later date, when in the County Hospital, she observed cases of syphilis in women having that disorder, and some months later she began to have lesions which were circinate in outline, and these lesions were supposed by several to be of syphilitic origin. The question of suggestion is sometimes important.

ROENTGEN STUDIES AFTER GASTRIC AND INTESTINAL OPERATIONS *

JAMES T. CASE, M.D.
Assistant Surgeon and Roentgenologist, Battle Creek Sanitarium;
Roentgenologist, St. Luke's Hospital, Chicago; Professor
of Roentgenology, Northwestern University
Medical School

BATTLE CREEK, MICH.

Through my institutional connections I have for a number of years enjoyed special advantages for the roentgenologic study of patients after gastric and intestinal operations. My colleagues have extended many much appreciated courtesies in arranging for the postoperative studies on which this paper is based Results both good and bad have been included, the patients studied representing the work of a number of different surgeons, some of the cases coming from the most famous clinics of this country. Many of the patients had no complaint, the postoperative condition being satisfactory, at least subjectively. Others were

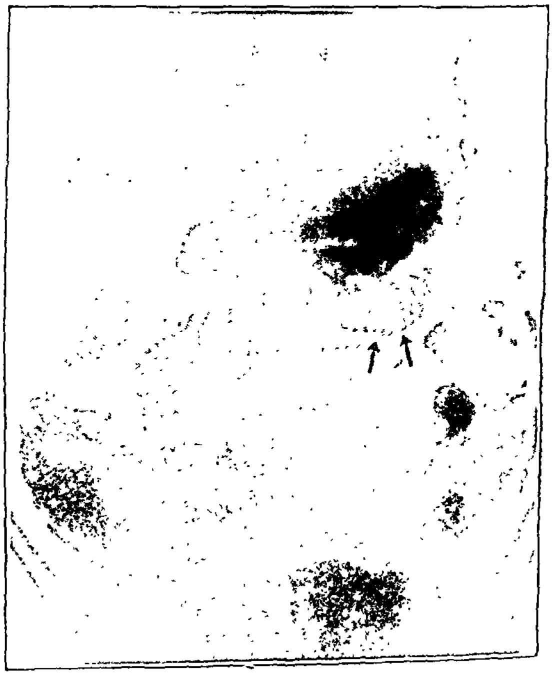


Fig. 1.—Gastro-enterostomized stomach, five hours after eating. Note the delay in the jejunum opposite the stoma. After complete clearance of the stomach, this residue in the jejunum persisted for several hours. This case is typical of the findings in a large percentage of gastrojejunostomies.

* Read before the Section on Surgery, General and Abdominal, at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June. 1915.

* Because of lack of space this article is abbreviated in The Journal. The complete article appears in the Transactions of the Section and in the author's reprints. A copy of the latter will be sent by the author on receipt of a stamped, addressed envelope.

referred for postoperative convalescence, and the opportunity was improved to make the postoperative roentgenologic observations. In the majority of the cases reported in this paper, the examination was advised in the hope that it would assist in ferreting out the cause of untoward symptoms. I would not insinuate that, because the majority of the cases included in the series studied have been unsatisfactory, referring especially to colonic operations, the majority of such cases with operation show similar late results; I merely report my findings on account of their obvious importance. The untoward results have been particularly frequent after operations for the relief of intestinal stasis, real or supposed.

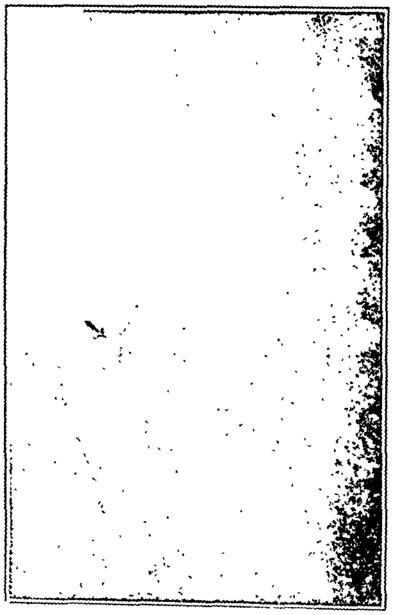

Fig. 2.—The small rounded residue often seen at the site of the appendix stump following appendectomy; also sometimes seen about the base of a diseased appendix before removal. In some of the cases showing such a residue after the barium meal, the operation had been performed years before.

ACUTE SMALL BOWEL OBSTRUCTION

Our experience during the last five years has convinced us of the value of the Roentgen examination in the diagnosis of postoperative acute small bowel obstruction, with special reference to the decision as to the advisability of surgical interference. Having accumulated the evidence in a sufficient number of cases of suspected obstruction following operation, it has seemed warranted to urge strongly the value of the Roentgen study in all such suspected cases with special reference to the existence of an obstruction, the degree of the hindrance, the location and perhaps the nature of the lesion, and whether or not the obstruction is progressive. If nonsurgical treatment seems preferable at first, the progress of the case under treatment may be observed roentgenologically.

Emphasis should be laid on the fact that it is not necessary to administer any barium or other opaque material in pursuing these studies, the observations being made possible by the gas distention of the intestine. There is, therefore, no delay incurred; and no objection can be raised to the Roentgen study of these patients on account of possible danger through delay or through the introduction of new food material into the digestive tube in the presence of possible obstruction. A Roentgen study should be required in every case of suspected postoperative obstruction.

Given a patient on the third day after operation, presenting symptoms suggestive of acute intestinal obstruction, he should be transferred to a carrier, conveyed to the Roentgen-ray department, a 14 by 17 inch plate with intensifying screen placed under him, and a flash exposure made. It must be short enough so that the patient can hold the breath during the exposure. The plate is then removed and the patient returned to his room and bed without further manipulation or inconvenience than is required to lift him onto the stretcher and back to bed again. No preparation of any kind is required; dressings are not removed. The plate is then developed and the findings may be noted as soon as it is taken from the fixing bath. Not more than twenty minutes need be consumed in the entire process.

The developed roentgenograms will reveal at once whether there is any gas distention of the bowel, and if so, whether the distention occurs in the small or in the large intestine. Acute postoperative dilatation of the stomach may be at once ruled out. Small and large bowel may be distinguished by the characteristic outlines of the gas areas. In acute colonic obstruction, the haustral markings as well as the peripheral distribution of the gas along the course of the colon are sufficiently characteristic to identify the large bowel. Equally characteristic is the appearance of the gas-distended coils in acute obstruction of the small bowel; the coils are more or less parallel and the caliber of the small intestine is increased to 1½ or 2, and sometimes 3 inches. It is seen that the distention is not confined to a short segment of the intestine but involves one or more feet of the small bowel, usually many feet. A certain amount of postoperative distention of the small bowel is frequently noted where there are no symptoms suggestive of obstruction, but in the serious cases the degree of distention is at once apparent and suggestive. The serrated contour of the bowel is characteristically different from the contour of the colon due to the markings of the haustra coli;

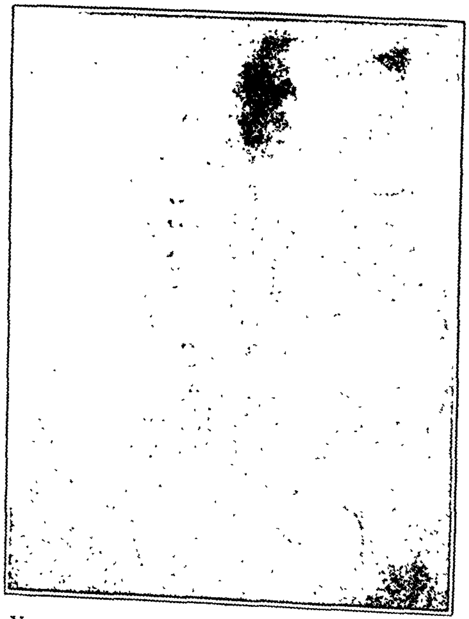

Fig. 3.—Very marked distention of the colon with gas in a case thought to be acute small intestinal obstruction. The gas distention was relieved by washing out the colon, and the administration of pituitary extract. The distribution of the gas and the characteristic markings of the bowel outlines indicate colon rather than small bowel.

so that we are at once able to recognize and differentiate acute postoperative gastric dilatation and obstruction in the large or small intestine.

Observation of the cecal region is especially helpful, for if the cecum contains gas, it is not likely that the obstruction is in the small bowel. If the gas collections, as above described, are seen to occupy the middle of the abdominal shadow while the flanks are gas free, it is probable that the obstruction is in the lower ileum, though not so low as the ileocecal region. When the gas areas occupy the true pelvis and the middle of the abdominal shadow, one may suspect the ileocecal region. Intussusception may be discovered by colonic injection with an opaque material. Early physical findings in these cases are very difficult to demonstrate with surety, whereas the roentgenologic findings may be demonstrated much earlier, and gain in surety as the gas distention progresses.

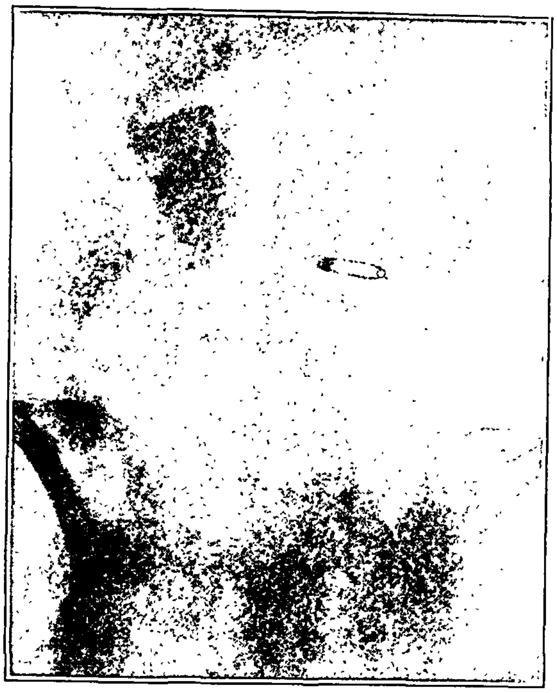

Fig. 4.—Acute obstruction high up in the small intestine, somewhere near the junction of the jejunum and the ileum. Note the absence of gas-distended coils in the lower half of the abdominal shadow.

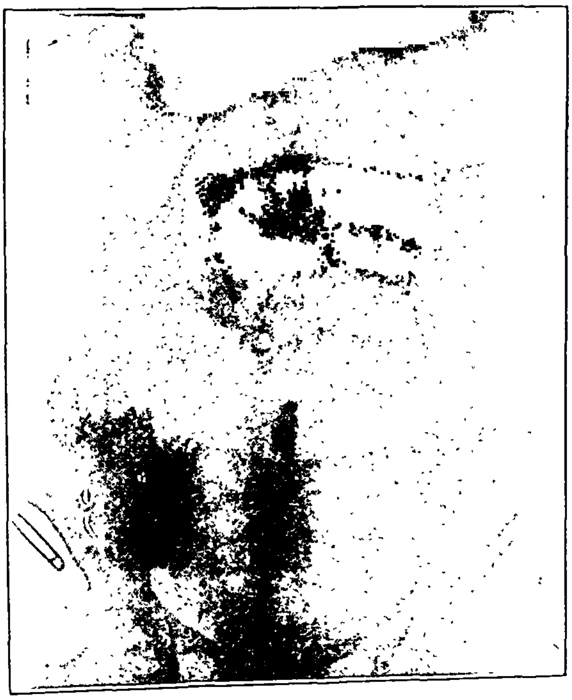

Fig. 5.—Marked gastric dilatation. Acute obstruction low in the small bowel, yet a little distance above the ileocolic junction. One determines this by the distribution of the gas-distended coils. The trace of barium in the cecum remained there from a preoperative barium meal study.

If the observation of the gas-filled bowel (without the ingestion of barium) does not make clear the location of the obstruction, time will be saved by proceeding at once to the administration of the barium enema to rule out colonic obstruction. If the entire colon fills, it is then recognized that the obstruction must exist in the small bowel. If the findings thus far are still indecisive, and the clinical symptoms are not yet clear, with the permission of the surgeon a small amount of barium sulphate, say half an ounce, may be administered by mouth in any medium which the patient will take. These cases are usually also so doubtful from the clinical standpoint that final decision as to operation is postponed in any case, and there is ample time for some of the barium to pass on into the small intestine. After a little experience, however, it is quite unnecessary to administer any barium at all by mouth, the decision being rendered on the appearance of the abdominal shadow with reference to the character and distribution of the gas areas which it may present.

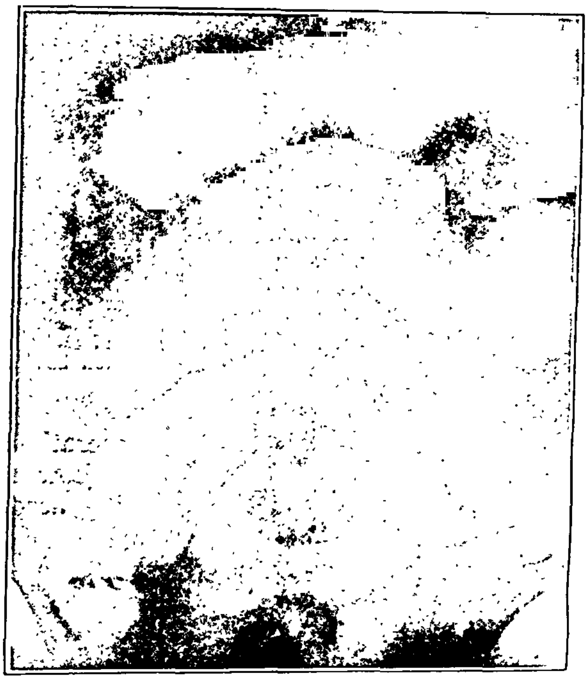

Fig. 6.—Very high grade of acute obstruction near the ileocolic junction. The dilatation of the entire small bowel in this case was extreme.

GASTRO-ENTEROSTOMY

To Cannon belongs the credit for some of the earliest Rœntgen studies on gastro-enterostomized patients. Until a few years ago gastro-enterostomy was looked on as a drainage operation, and it was the effort of surgeons to make the anastomosis as near as possible to the lowest point of the stomach. This idea was based on the conception of the stomach as a passive reservoir from which food was discharged more or less under the influence of gravity. Cannon's studies on the movement of food after gastro-enterostomy were very carefully carried out and constitute a classic to which no exceptions can be taken.

There are, however, two new points to which I should like to direct attention. It will be recalled that Cannon and Blake from their experimental work concluded that the stoma should be fairly large and near the pylorus—that conditions which stretch the stomach should be avoided, and that several centimeters of distal intestine should be attached to the stomach to prevent kinking in the jejunum. But when pyloroplasty was possible, these authors thought it was the operation of choice. They found that the rapid exit of food from the stomach was prevented by the formation of rhythmically contracting constriction rings in the duodenum. They believed that this activity replaced in part the function of the pylorus and also served to mix the food with the pancreatic juice and the bile. I have observed this phenomenon in two out of four cases in which a Finney operation had been done. It is interesting that analogous phenomena were noted in a large number of cases in which the ordinary gastrojejunostomy had been performed, namely, a sort of sphincter action established in the jejunum at a point varying from 3 to 6 cm. below the gastrojejunal opening. This was at first interpreted as a spastic contraction of the circular muscle of the jejunum; but in the light of Cannon's observation on rhythmic contractions of the duodenum after pyloroplasty, it seems reasonable to conclude that this contraction ring in the jejunum is purposive, serving somewhat as a sphincter.

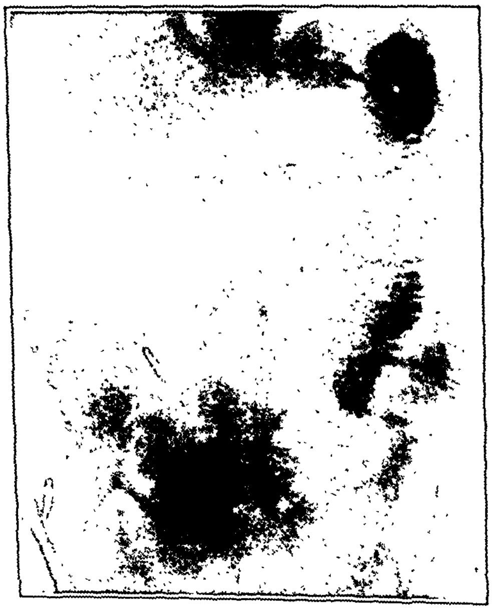

Fig. 7.—Acute obstruction in the small intestine in which the decision to operate was not made until the *second* examination, six hours after the first. Meanwhile a small amount of barium had been given, and the characteristic appearance of the small bowel visualized.

Kocher years ago made the statement that the gastro-enterostomy opening developed a sphincter action and actually underwent rhythmic contractions. It seems possible that the formation of a contraction ring in the jejunum below the site of operation may well simulate the normal action of the pyloric sphincter. Under the fluorescent screen, one sees a small fingerlike shadow gradually build down behind the gastric silhouette, simulating very much the formation of pseudopodia in the ameba. This fingerlike shadow projects farther and farther until it is suddenly constricted off an inch or two below the stomach, the pinched-off bolus passing onward into the distal small bowel, the proximal portion remaining and gradually assuming larger proportions until the distal portion of it is again pinched off by succeeding contractions. In other words, this action has in a certain degree seemed to take the place of the rhythmic contraction normally occurring at the pylorus.

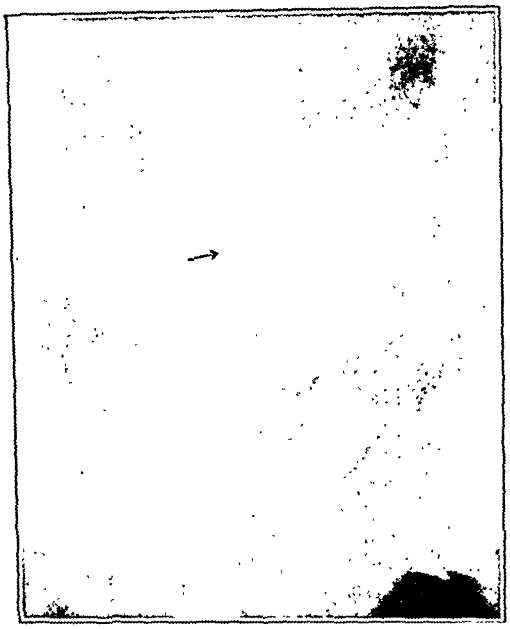

Fig. 8.—Three years after ileosigmoidostomy. The arrow indicates the site of the anastomosis. Appearance of the colon forty-eight hours after barium meal. The colon is filled by material carried backward from the rectum by retrograde peristalsis. *This retrogression of food* residues often forms large cecal tumors

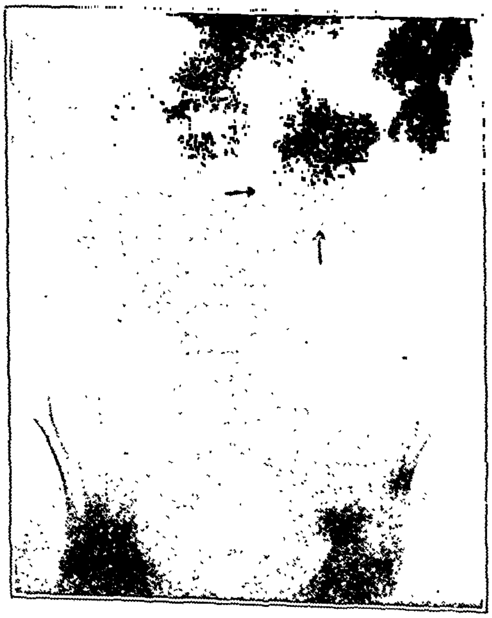

Fig. 9.—Even after removal of the right half of the *colon*, including the first third *or half* of the transverse colon, there is a tendency to the formation of a tumor in the proximal end of the remaining large intestine. In this case the barium-mixed residues in the stump are shown on the ninth day following the meal, forming an easily palpable tumor.

A second new point relates to a stagnation of food in the jejunum at or near the site of the gastro-enterostomy. Cannon, with F. T. Murphy, made intestinal resections in animals, uniting the severed intestine either by end-to-end or by lateral anastomosis. After lateral anastomosis, there occurred a more or less complete blocking of the canal by undigested detritus at the opening between the opposite loops. Necropsies on animals proved that the stasis was not due to previous accumulation of undigestible waste, but that the two apposed coils did not cooperate to propel the enclosed food, and that after an ordinary meal, food was stagnant in the region of the anastomosis. It has seemed to me that the same phenomenon is also observed after gastro-enterostomy. Especially toward the end of gastric clearance, there occurs a stagnation, apparently in the small bowel, at the site of the anastomosis, this stasis being accounted for by the inhibition of onward peristaltic activities at this point (Fig. 1).

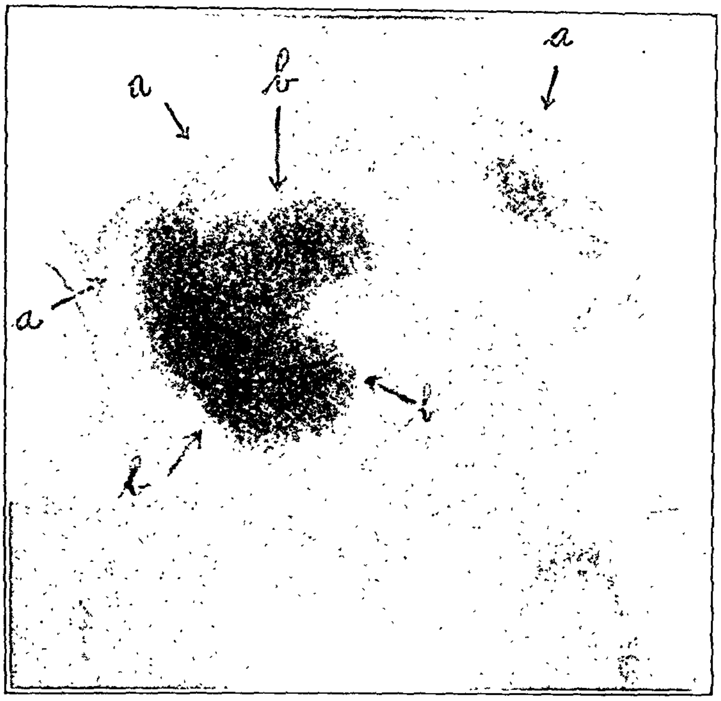

Fig. 10.—This backing up into the short-circuited colon takes place constantly, and begins immediately after food reaches the rectum. This roentgenogram, twenty-six hours after eating, shows at *a* the backed-up material in the transverse colon and cecum, and at *b* a large residue still remaining in the terminal ileum. The bowels had meanwhile moved satisfactorily (?) several times. (See Figure 11.)

APPENDECTOMY

A common cause of cecal stasis is adhesions, usually associated with disease of the appendix. It is also a fact that immediately following recovery from the operation of appendectomy, there is in the majority of cases a considerable degree of cecal stasis. The cecum retains portions of the barium meal for from two to four days, and sometimes more, although the remainder of the colon may clear itself normally. Following the attempt to expel the barium enema it is seen that the cecum has failed to contract, the propulsive ring peristaltic waves which evacuate the large bowel commencing at or above the ileocolic junction instead of at the tip of the cecum. Even at a remote period after the operation, several years later, a certain degree of cecal stasis persists in a considerable number of cases, a rounded residue of barium the size of a 25-cent piece remaining in the cecum after the colon has otherwise been entirely cleared of the barium meal. This is especially likely to occur where the patient complains of a tenderness over the cecum. Sometimes this cecal stasis was present before the operation, as shown by the preoperative Roentgen records; but that it often exists after operation where it did not exist before is convincingly shown by our series. I believe that the rounded barium residue, above referred to, occurs at the site of the stump of the appendix, and that it has some relation to the invaginating suture by which in the technic commonly employed the stump is buried. The coincidence of a point of localized tenderness on pressure with this rounded residue at the site of the appendix stump would suggest the desirability of including the least possible amount of cecal muscularis in the invaginating suture.

ILEOCOLOSTOMY

I have been especially fortunate in having been able to study a large series of cases after ileocolostomy performed for adhesions, ileal stasis, Lane's kink of the ileum, and other nonmalignant lesions. Forty such cases have been examined very carefully, operation in most of them having been performed according to the technic advocated by Lane, one of them by Lane himself. Not all the patients in this series were clinically failures, though the majority of them were examined for the cause of an unsatisfactory result. In most of them, during the early months following operation, the result was apparently worth while, and in a few striking instances the operation had seemed to work like magic; but sooner or later, usually within a year after the surgical procedure, the symptoms have begun to recur and the patient's last state is worse than the first. It should be remembered that this series of cases represents the work of more than a dozen different surgeons, most of them of national reputation—work which I believe to be on the whole representative of the best in technic which this country affords. The unsatisfactory results can, therefore, hardly be attributed to poor technic.

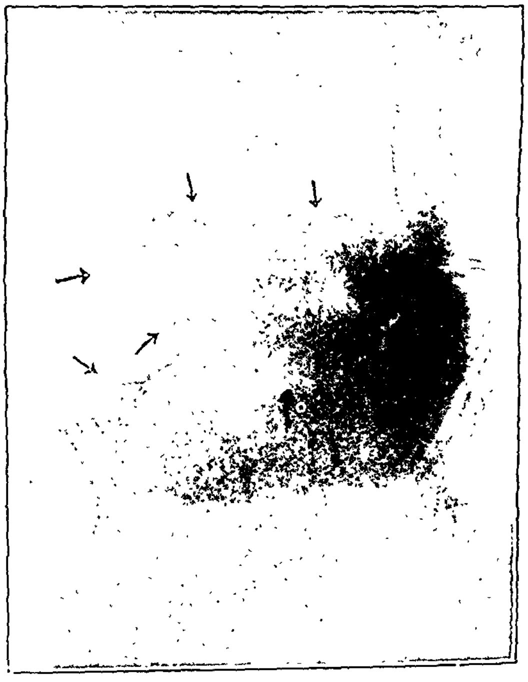

Fig. 11.—(See Figure 10.) The very marked distention of the coils of terminal ileum attending the marked ileal stasis in some of these cases is illustrated by the colon injection. Same case as in Figure 10. The arrows point to distended small bowel, the seat of stasis in Figure 10.

Excepting only those cases in which an artificial ileocolic valve has been formed, all cases have shown incompetency of the ileocolic stoma permitting the enema to flow back into the small bowel as well as retrogradely around the colon to the cecum or as far as the stump of the colon in those cases in which partial colectomy had been performed. The small bowel thus visualized has displayed a variable caliber.

not much enlarged in the recent cases, but frequently so large as to be confused with the colon itself in patients examined two or three years after the operation. In some of the roeitgenograms it is impossible to tell definitely from the roentgenogram alone which shadows are colonic and which are ileac. Of course, it is recognized that the test by enema reverses the usual order of progress of the food column, but there is also noted in many of these cases a regurgitation of *ingested* food. There is a very definite ileal stasis in most of the older patients (operation performed a year or more before the examination). It is not uncommon to find at the twenty-sixth hour a large mass in the terminal ileum simulating a colonic residue in size and caliber of the coils. The worst cases of ileal stasis, judged by the retention in the ileum of a mass of ingesta, are those cases which, when tested by the enema, show the greatest ileal dilatation and the most extensive ileal filling by the passage of the enema through the anastomotic opening. This incompetency of the stoma to enema and the ileal stasis should both be prevented by the formation of an artificial ileocolic valve by Kellogg's method. In one case reexamined three years after the operation just referred to, the artificial valve still prevented the reflux of the enema, and there was no ileal stasis.

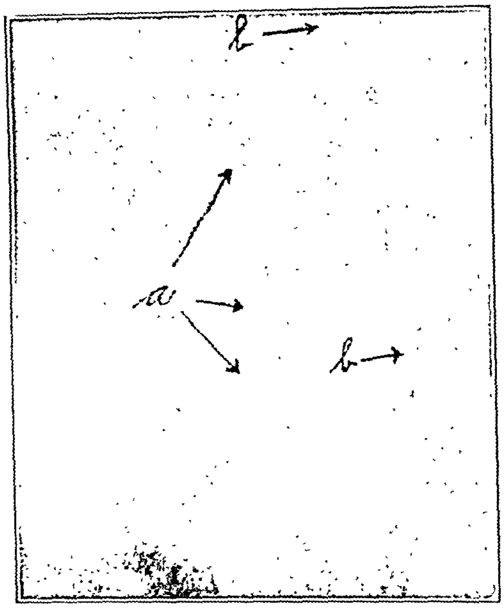

Fig. 12.—Another case two years after ileosigmoidostomy. Colon injection. Note the very marked dilatation of the small bowel shown at *a*, whose caliber equals that of the neighboring colon shown at *b*. There was marked ileal stasis in this case, shown after the barium meal. In cases of ileosigmoidostomy examined shortly after the operation, there is noted a similar insufficiency of the ileocolic orifice, but the coils of terminal ileum do not exhibit the same degree of dilatation until later.

Following the barium meal, there has been noted in every case, without exception, retrograde peristalsis carrying barium oralward as far as possible from the rectum. This regurgitation commences immediately after food reaches the rectum, and the head of the backed-up column has usually reached the splenic flexure by the tenth or twelfth hour. This retrograde movement of ingested material persists in spite of repeated enemas and in spite of repeated bowel movements, so that by the end of the twenty-sixth or even the fiftieth hour, the residues are banked up in the proximal colon, from which it is very difficult to dislodge them. I have seen a large barium-mixed mass in the cecum on the fourteenth day forming a tumor in the right inguinal region, easily palpable and visible on inspection of the abdomen. Hauchamps has recently reported a case of a nervous woman of 26 years, who had suffered all her life from obstinate constipation. To give relief some surgeon made an appendicostomy, to facilitate colonic lavage. Later the patient was reoperated, the appendix being removed and the right kidney being anchored. Still later, the patient failing to improve, ileosigmoidostomy was performed. A month after the last operation the patient was given a barium meal. There occurred evident retrograde peristalsis with the formation of a large barium-mixed fecal mass in the right inguinal region, which was still visible both on inspection of the abdomen and roentgenologically on the thirtieth day, although no opaque salt had been administered meanwhile. This stasis in the excluded colon is usually attended by the formation of distressing amounts of gas, which sometimes distend the colon to enormous proportions, resisting all efforts to dislodge it. Gas distention of the colon after ileosigmoidostomy often distorts the stomach in such a way as to produce a pseudohourglass appearance. Efforts to prevent the retrograde procession by making a kink in the sigmoid just proximal to the anastomosis result only in greater stasis and greater difficulty in dislodging the stagnant material, which is only slightly delayed in its regurgitation.

It thus appears that in a very considerable percentage of cases in which the operation of ileosigmoidostomy is performed for the relief of intestinal stasis, particularly ileal stasis, the end-result is infinitely worse than if the patient had not been operated on, at least so far as the ileal stasis and the patient's comfort are concerned. As before suggested, there is often a period of improvement, sometimes marked; but ultimately the majority of the patients under our observation exhibit a recurrence of the stasis.

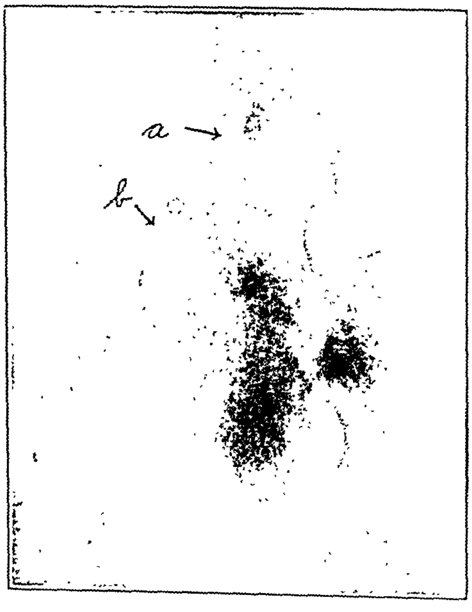

Fig. 13.—In performing the operation of ileosigmoidostomy, it is possible to make an artificial valve at the new opening, by Kellogg's method. In the case here figured, the right half of the colon had been removed, the ileum being inserted into the sigmoid with the formation of an artificial valve. The enema failed to enter the ileum. There was no ileal stasis following the meal. There was marked stasis in the blind portion of the remaining colon; *a*, stump of transverse colon; *b*, site of ileocolic junction.

To avoid a recurrence of the ileal stasis, Kellogg has endeavored to make an artificial ileocolic valve, hoping to prevent the regurgitation of food residues back into the ileum and to lessen the ileal delay. This operation, which results in the formation of a valve-like invagination of the terminal ileum into the colon in a manner resembling the formation of the normal ileocolic valve of the pig, is accomplished by a modification of the ordinary technic for end-to-side ileosigmoidostomy. In twelve cases the valve thus formed has worked satisfactorily in seven, the five failures occurring early in the series. Even in those cases in which the effort to make an artificial valve failed, the patient was no worse off than if the ordinary anastomosis had been performed. When ileocolostomy must be performed, it seems distinctly worth while to attempt the production of an artificial one-way valve, simulating the normal ileocolic junction.

To obviate the retrogression of rectal contents back into the excluded colon in these cases of ileosigmoidostomy, a number of surgeons conceived the idea of resecting the right half of the colon, including the cecum, the ascending colon and a part of the transverse colon. This operation preserved the omentum and saved the patient much of the shock likely to attend removal of the colon down to the sigmoid. In all the cases thus operated in which the patients have come to me for postoperative study, there has been demonstrated the same retrogression of colonic contents with the formation of an obstinate residue in the blind end of the stump of colon, this residue in several cases forming a palpable and visible tumor, persisting many days. In one case this tumor persisted longer than nine days, in spite of repeated daily enemas and the use of laxatives. The severity of the stasis in the stump of the colon has a relation to the length of time which has elapsed since the performance of the operation, becoming progressively worse as the months go by.

The operation of cecosigmoidostomy was also proposed as a procedure which would obviate the distresses attending the retrogression of materials up the colon under the influence of antiperistalsis. This operation appears to me an illogical and unreasonable procedure in these cases. In one instance in which it has been impossible to secure a reexamination by means of the Roentgen ray, the reports from the patient are fairly satisfactory; but in the other cases examined at some interval after the operation (three cases), there has been seen a double procession of food residues, one column traveling up the ascending colon in the normal direction and the other up the descending colon, the two columns tending to meet near the middle of the transverse colon. My friend, Dr. L. T. LeWald, who has studied such a patient two years after operation, has kindly communicated to me his Roentgen findings:

> The intra-abdominal distress and the constipation were relieved for a time, but the symptoms recurred within two years and the constipation became extreme. The bowels never moved without enema, and the gas distention of the abdomen was very distressing. Roentgen studies after a barium meal showed most of the meal going in the direction of the hepatic flexure and transverse colon instead of through the cecosigmoidostomy opening. At the end of twenty-four hours the transverse colon was filled, only a little having passed from the cecum through the artificial opening. By the end of the second day only a trace of the meal had been eliminated, the greater part remaining in the cecum, ascending colon and the transverse colon. Seventy-two hours after the meal and after repeated enemas, it appeared that the elimination of the barium-mixed residue was almost impossible, the appearance suggesting a definite vicious circle. As some of the barium passed down the descending colon and began to enter the sigmoid, it appeared to enter the cecosigmoidostomy opening into the cecum, and thence through the ascending colon back into the transverse colon. Only a small portion remained in the rectum and was voided.

The next class of cases includes those in which it was not deemed advisable to subject the patient to an extensive colectomy, and yet radical treatment was demanded. It was finally decided to make an ileocolostomy with partial colectomy, that is, resection of the right half of the colon followed by insertion of the ileum into the transverse colon as near as possible to the stump. In our Roentgen studies as well as in our clinical observations in these cases, this type of operation has given the most satisfactory results. Thus far, it would appear, both clinically and from the Roentgen findings, that this type of operation is preferable where any operative procedure at all seems indicated for stasis in the right half of the colon. Of course, for a lesion in the pelvic colon such an operation would not be likely to afford any improvement of the condition.

It would thus seem that when for any reason it appears necessary to resect a portion of the colon, making a new ileocolic junction, the ileum should be implanted as near as possible to the proximal end of the remaining portion of the colon, and an effort should be made to produce an artificial ileocolic valve. Exclusion operations are invariably followed by stasis in the excluded intestine, and blind ends, as after ileosigmoidostomy with or without partial colectomy, always sooner or later become the seat of stasis, usually with the formation of distressing amounts of gas which cannot be dislodged without great difficulty. The production of a serviceable artificial ileocolic valve by Kellogg's method is quite feasible, and in the majority of cases it is successful.

THE USE OF PLASTER OF PARIS IN MOUNTING GROSS MUSEUM SPECIMENS

WITH SPECIAL REFERENCE TO PARASITIC WORMS AND SERIAL TISSUE SLABS *

FRED D. WEIDMAN, M.D.
PHILADELPHIA

For several years I have had more or less to do with the mounting and maintenance of gross morbid museum specimens, a large number of which were especially prepared for student-instruction purposes in large medical schools.

Suspended in the usual way by ligatures on glass frames, and after handling several times in the course of a year by instructors and students, these specimens have suffered, entailing much loss in time and some of material in repair. If of soft texture (liver), the threads have torn out, if necrotic the detritus has fallen out, and the glass frames are sometimes broken by shaking when the specimen is handled by students. If the mounting medium has become turbid, a more or less thick layer of nontransparent material

---

* From the McManes Laboratory of Pathology, University of Pennsylvania.

intervenes between the eye and the specimen. Or, where the specimen is small (parasitic worms) and fastened to a glass slide by gelatin, the latter has in time lost its adhesion and the specimen dropped to the bottom of the jar.

Of late, therefore, I have aimed in the first place to prepare all specimens so that the important feature to be exhibited will appear on a broad plane surface, and will fit snugly or tightly into the container. This end is most easily accomplished when dealing with slabs of tissue (liver, spleen, tumors) which can be cut to almost any desired shape, and where a variety of variously sized and shaped containers is available. Under these circumstances, no special backing is needed. If, in the second place, the specimen has a flat surface, but is much thinner than the container, it may be held against the face of the container by some special backing, and it is with the preparation of such backings that this communication has especially to deal. Of course there are many specimens which will not permit such treatment because it might hide important features on the opposite side of the specimen, and here the older methods have to be used.

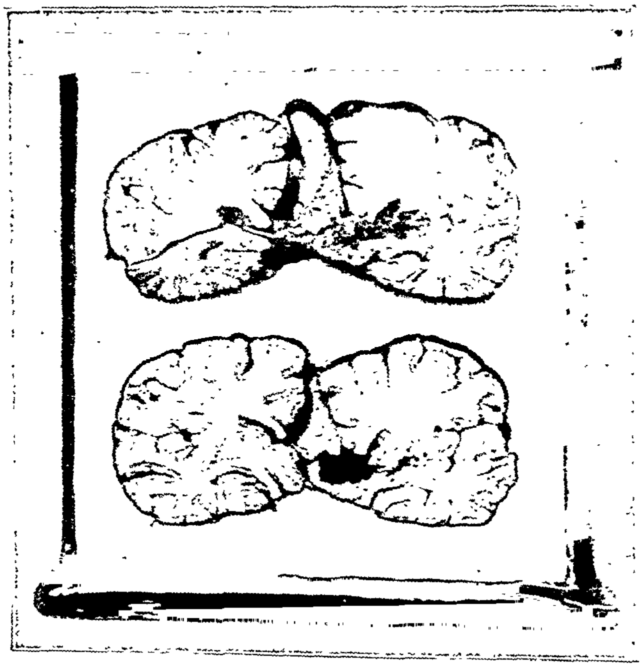

Fig. 1.—Consecutive slabs of brain, largely embedded in plaster of Paris, showing position and extent of cerebral hemorrhage.

The merits of this method are obvious. In bringing the specimen close to the eye, no fluid is interposed to become turbid or distort (especially in cylindric containers) the specimen. It matters not, indeed, so far as the specimen is concerned, if the mounting medium does become turbid. The specimen, furthermore, is held rigidly, permitting marking of the face of the container to indicate special points, and preventing the loss of soft necrotic parts. It is especially valuable in supporting (and partially embedding) slabs of brain.

The choice of an appropriate backing material is most important. Absorbent cotton has been used for a long time and is often most satisfactory. It has the disadvantage of not giving a rigid support unless very tightly packed, and then it is not sightly.

In my hands, plaster of Paris, while not ideal, has proved of great value.

Where the tissue is soft and will not stand pressure (serial slabs of brain are especially amenable to this method) it is arranged face downward on a smooth soaped surface. A wall is built around it enclosing a space about 1 cm. larger than the inside dimensions of the face of the container, which must be rectangular for the proper use of this method, and the inside of the walls now also soaped. Plaster of Paris is poured over the specimen until it is of depth equal to the narrowest anteroposterior dimensions of the container. As soon as the plaster has hardened, which ordinarily occurs in from fifteen to thirty minutes, the walls are torn down and the slab of plaster, with contained specimen, lifted from the glass. While it is still moist the edges are neatly trimmed with a knife until the slab slips snugly into the container. It is allowed to harden further, say for several hours, a moistened cloth, if necessary, being kept over the face of the specimen to prevent undue drying out. The whole is then gently slipped into the container and covered by mounting fluid. It should not be at once sealed, since bubbles will accumulate for several days, and these must be brushed off with a feather before final sealing. In the course of a year the tissue may slightly shrink from its embedding walls, but this is of no moment since it is held in place by the face of the container anteriorly and is always supported below by a plaster base. Indeed, it may be considered an advantage, permitting the inspection, though very limited, of the sides of the tissue slab.

When the tissues are firm, they need not be thus embedded, but are pressed against the face of the container by a plaster backing acting against the back of the specimen. On account of the formation of bubbles on the plaster, it has been found advisable to make up a number of containers holding their backings and keep them in stock in weak formaldehyd (2 per cent.) until needed, the bubbles being meanwhile removed from time to time.

Either rectangular or cylindric containers may be used. Most rectangular ones, however, are unsatisfactory on account of their irregular interiors, commonly flaring out toward the bottom, which quite prevents subsequent removal of the backing. This is sometimes also the case with round containers, especially the ones with necks. Where this is the case, a layer of plaster may be poured in until the "flare" is filled and allowed to harden. The backing may then be made as though there were no flare. The most suitable containers are cylindric ones (though necked ones may also be used), for then the backing may be later removed from the container, neatly trimmed, and the specimen be exactly arranged on it. This is especially desirable with long slender worms like filariae or numerous small worms like hookworms.

The containers receive about one quarter to one third of their capacity of thin plaster-of-Paris cream. It is aimed to insert such an amount that, after the container has been laid horizontally, about one third of the circumference will be covered by plaster. Where there has been a basal flare which has been filled previously by plaster, it is necessary first to soap its surface before pouring in the backing. In the case of necked containers which have ground stoppers, the stoppers (soaped) are now inserted and the containers laid horizontally. In the case of cylindric ones with loose-fitting lids for cementing, cork or rubber stoppers are inserted (also soaped), which will reach well (about 5 mm.) below the point to which the lid will reach. If this distance is not allowed, fluid will later pass by capillarity from the backing to the lid and interfere with sealing. As soon as the plaster has hardened sufficiently (from fifteen to thirty minutes), the stoppers are removed and the containers set upright. If the margins of the backing are uneven, they may be easily corrected now while the container is full of water, and after a few hours the backing may be easily pried or will spontaneously fall away from the face of the container. It is well to mark the original position of the backing by applying a label at its base, for after loosening it will slip freely around the jar, and it is desirable on account of the irregularity of the jar to be able to return the backing to its original position. This is not an important point when dealing with larger worms, but when they are small and delicate they may fail to be nicely gripped between the backing and the face if the two are not thus accurately adapted. It is between the convex surface of the backing and the concave interior of the face that the specimen is to be placed and then held there by pressure, the pressure being given by packing cotton behind the backing.

Since a dark background is often desirable, a rectangular piece of black photographic paper is fitted over the convexity of the backing sufficiently large to cover it well and hide it, and the whole stood away in weak formaldehyd until needed.

If the specimen is dark, the black paper is withdrawn and discarded, the glistening white backing affording a splendid background. If pale, the paper is brought over the label marking the original site of the backing. In either case the backing is brought over the label, and a pledget of wet absorbent cotton gradually pushed behind it to the bottom of the container, sufficiently large to push the backing snugly but not tightly forward to the face and anchor it. The introduction of excessive quantities of air bubbles with the cotton should be guarded against.

While the cotton anchors the lower end of the backing, the upper end is pulled away from the face of the container, thus producing a (curved) wedge-shaped space between the backing and the face of the container. Into this the worm (or other specimen) is introduced and adjusted in the desired position on the background, the thickness of the wedge being adjusted to the size of the worm by packing cotton behind the backing. After the worm has been oriented, more cotton is inserted to fix the specimen securely, the fluid reduced to the level of the upper end of the backing, and the jar closed.

It will be readily seen that this manipulation is much easier with cylindric containers than with necked ones. When the latter *must* be used or several rather small specimens (hookworms) are to be mounted, it is advisable first to coat lightly the (wet) paper backing with hot gelatin outside the container, and quickly and lightly press the worms into the desired positions. After cooling, the paper is adjusted as before on the backing. When the specimens are sufficiently small this background may be made very small, say 2 by 1 cm., appearing on a white background as a black paper window on which the white worms in turn appear.

The foregoing method is especially applicable in mounting all kinds of worms, except the thicker soft ones, such as the Amphistomidae. The latter should be mounted, as are also larval insects and other thick, soft specimens by the following modification: A cylindric jar must be used, from which the backing can be slipped. This done, a cavity is made in the backing which will take the specimen snugly and will be deep enough to receive the whole specimen. If it is pale, a black paper background may be fastened to the depths of the cavity with hot gelatin. The specimen is placed in the cavity, and the backing slid over the face of the container into position and then held there tightly by cotton as before.

If an especially presentable mount is desired, one or two strips of black passe-partout paper may be wrapped on the outside of the container at the top and bottom to hide the water level and the ends of the backing or background.

This method has possible disadvantages. It is possible to pack the cotton so tightly as to flatten the specimen unduly, and it is possible that the paper may lose its deep black color in time. Black celluloid has been substituted for paper, but a sufficiently thin grade is not on the market to permit the nice adaptation to the irregularities of the glass necessary in mounting very small specimens; but it can be used with larger worms like ascarids. The test of time has not as yet been applied to these two materials for color fastness. Attempts have also been made to color the backing by mixing lampblack or coal dust in the plaster while wet, but quantities sufficient to give a deep black impair the cohesion of the plaster so seriously that it spoils the mounting medium. Portland cement is a most unsatisfactory substitute for plaster. It does not give a good black, sets slowly and cannot be easily fashioned.

Special advantages obtain when the method is applied in mounting worms. They are not damaged by immersion in an adhesive or ligating material, and

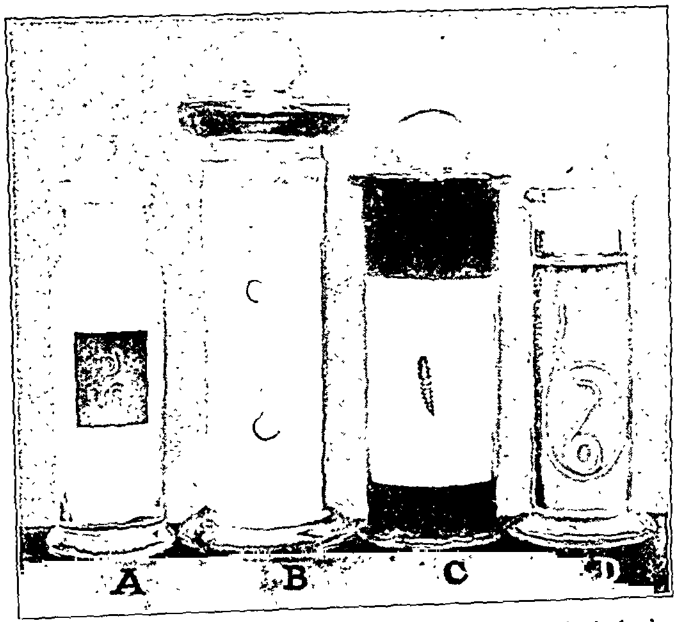

Fig. 2.—Parasitic worms mounted against plaster-of-Paris background: *A*, hookworms shown against a black paper "window," which in turn is supported by a plaster-of-Paris backing. Shows use of necked container. *B*, whipworms mounted against plaster-of-Paris backing. C, insect larva mounted in depression. Passe-partout tape wound around container above and below, to give finished appearance. *D*, filariae mounted against black paper background, in turn supported by plaster backing.

can be removed easily at any time for microscopic examination.

In conclusion, a word may be said in regard to the use of plaster of Paris. This is purchased, "quick setting" and "slow setting"; the former sets in about five minutes, the latter in twenty. Setting may be hastened by adding salt, retarded by adding a little gelatin. In mixing plaster, it should always be sprinkled on the surface of the water, never adding so much that the surface of the mixture becomes dry. Water should never be poured into dry plaster. The plaster should be allowed to settle from five to ten minutes, during which time a layer of water appears on the surface. This is poured off and the mixture *gently* stirred. These precautions are taken to prevent lumpiness and the formation of bubbles, which result from much stirring. Prepared in this way, the plaster is of the proper consistency for pouring, and is free from bubbles.

JUVENILE DEFORMING OSTEOCHONDRITIS OF THE HIP*

GEORGE J. McCHESNEY, M.D.
SAN FRANCISCO

My reason for presenting a paper on this subject lies, first, in the newness of knowledge concerning it, only two years having elapsed since Perthes' article before the German Congress of Surgeons; and secondly, in the importance of recognizing the disease, and of saving our little patient from a wearisome course of treatment for tuberculosis of the joint, to which, in its early stages, osteochondritis shows a close resemblance, but in its later stages, a vast difference.

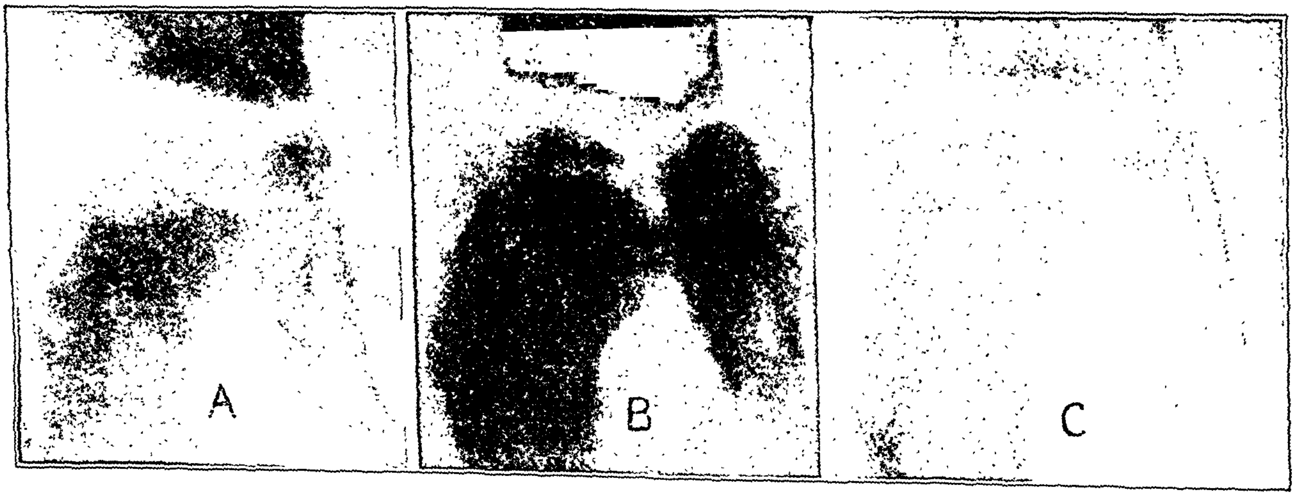

Fig. 1 (Case 1).—*A*, roentgenogram taken at first visit, showing very slight flattening of the epiphysis; *B*, ten months later; *C*, nine months later than *B*, showing fragmentation as well as flattening.

To define briefly, juvenile deforming osteochondritis (the name given by Professor Georg Perthes of Tübingen) is a progressive destruction and crushing, principally of the upper femoral epiphysis, characterized by a slight limp, mild subjective symptoms, a fairly constant limitation of abduction, and a benign course with complete recovery under little or no treatment.

ETIOLOGY

A history of limping by parents is only occasionally elicited, and would hardly seem to have any significance. The disease appears when the child is in good health, and is not especially concerned with any specific trauma, although in two of our three cases, mild injuries were associated with the onset.

Quite constantly boys are affected in the second five years of life. No explanation has been offered for this phenomenon, although one might presume that the strenuous exercise of the male animal at this time of his life might produce a constant strain and tend to a breaking down of the structures in consequence, when no one tissue was at fault.

SYMPTOMS

A slight limp is the obvious symptom. This occurs early and persists till late, becoming more and more intermittent, and is accompanied by slight or no pain. The limp may last from two to four years, says Perthes, and then lessens, in spite of greater destruction of the epiphysis, as seen in successive roentgenograms.

The symptom next in importance is the elimination of abduction, seen constantly, and persisting much as the limp does. It is marked at first, and is due to alterations in shape of the epiphysis and acetabulum, according to Perthes, although he admits that limitation of abduction may be well developed when the flattening of the epiphysis is slight. Under narcosis he could overcome the limitation to a great degree, although not altogether, showing that muscle spasm played an important rôle. This was done in one of our cases with a similar result.

Also rather constantly is reported a limitation of in or out rotation to a slight extent. Other motions are said to be unimpaired, although in two of our cases we found limited hyperextension.

Slight shortening and atrophy are occasional symptoms of lesser note.

Pain is almost a negligible factor, and in these three cases none was elicited by our examinations. There was an occasional complaint of spontaneous pain in the early stages.

PATHOLOGY

According to the studies of Perthes, including an arthrotomy, in which the joint was inspected and specimens removed for microscopy, there is a delay in ossification of the cartilage of the epiphysis, and to a lesser extent also in the juxta-epiphyseal cartilage of the neck and isolated areas in the acetabulum. This forms what he calls "cartilaginous isles," or defects in ossification. He also notes calcareous nodules or dark spots on the ossific nucleus of the epiphysis. As a result we have flattening or crushing of the epiphysis, because cartilage persists in places where bone is needed to bear the increasing weight of the growing child and withstand the traumatisms of a boy's rough play. Its shape also is a factor in this connection, for Quain says, "The epiphyseal cartilage in the young bone is not a flat plate situated at the junction of the head and neck, but an arched lamella, which at the summit of its convexity lies near the center of the articular head."

---

* Read before the Section on Orthopedic Surgery at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

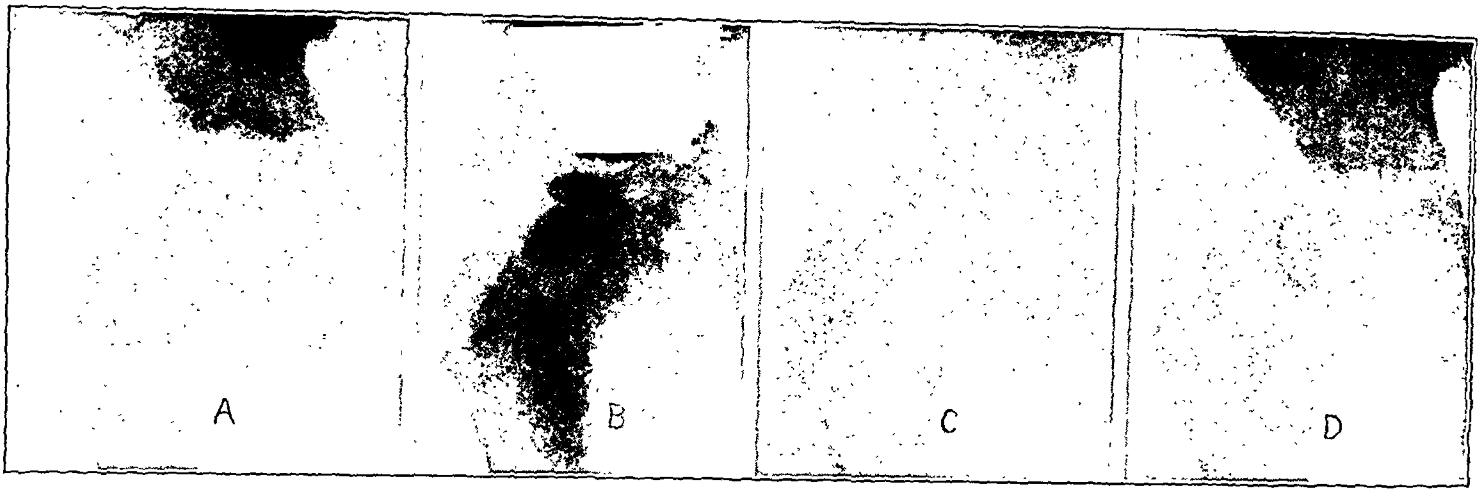

Fig. 2 (Case 2).—*A*, condition at first visit; flattening well marked; *B*, five months later; continuation of process; *C*, six months later; fragmentation appearing; *D*, seven months later; fragmented sections fusing to diaphysis.

Later the flattened epiphysis breaks into two or three pieces, and finally unites to the neck, which has become much shorter and thicker than normal, although still preserving the normal angle.

ROENTGEN-RAY FINDINGS

These are so distinctive that Delitala,[1] in an exhaustive review, asserts that a Roentgen examination alone is sufficient for the diagnosis.

The flattening or crushing of the epiphysis is the salient feature. This is progressive, being slight at first, and increasing till the epiphysis, instead of being a rounded outline, is reduced to a flattened plate or disk, often divided into two or three parts. Later these appear to fuse, and the whole finally unites to the diaphysis. The cartilaginous isles mentioned above as appearing in the juxta-epiphyseal line and in the acetabulum are sometimes seen in good roentgenograms.

DIFFERENTIAL DIAGNOSIS

Here we must consider tuberculosis, juvenile deforming arthritis, polyarticular acute arthritis or rheumatism, coxa vara and osteomyelitis.

To distinguish it from tuberculosis we can place considerable reliance in the von Pirquet test, in the clinical examination showing the principal limitation of motion in abduction, a little in internal rotation and none in other directions, as opposed to tuberculosis, which usually shows some limitation in all directions. The lack of pain or joint spasm is another point, while the roentgenogram, showing none of the general rarefaction of tuberculosis in the early stages, in the later offers conclusive differences in the shape of the epiphysis.

Juvenile deforming arthritis is accompanied usually by joint crepitation, the pain is quite severe, and there is considerable stiffness and marked limp. The von Pirquet test should help, and the roentgenogram sometimes resembles Perthes' disease closely as to the crushing of the epiphysis, but often shows osteophytes or spurs, which osteochrondritis does not. Furthermore, the joint cartilage is intact, a point emphasized by Perthes.

In coxa vara the roentgenogram and the von Pirquet test are our only means of differentiation; but they should be quite sufficient. Clinical examination and history may fail us altogether.

In acute articular arthritis we have acute onset, much pain and disability, limitation of motion in all directions, fever, etc. The roentgenogram would show no change.

Acute osteomyelitis should present no difficulty. In chronic or healed osteomyelitis, reliance should be placed on the history and Roentgen findings.

TREATMENT

Perthes, with the widest experience of any one, concludes that operation is not indicated, that correction of abduction under anesthesia may be a good procedure, and that plaster spicas do no harm beyond inducing some atrophy, but that extension with massage is probably better.

I cannot agree with Delitala, who thinks that weight bearing has nothing to do with the crushing of the epiphysis, and that intimate alteration in the process of ossification is the only factor. Until we know the pathology absolutely and definitely, the child should be protected from weight bearing in the acute stage, but in the later stages allowed to run about regardless of the apparently alarming changes the Roentgen ray might show, as all cases run a benign course and tend to spontaneous recovery.

Perthes reports five cases seen from five to thirteen years after onset. The history and course were typical, although thought at that time to be tuberculosis. The uniform result was a broad flat head on a short thick neck, resembling coxa vara. There was a constant slight limitation of abduction. Otherwise functions and motion were restored. There was no pain or limp.

---

[1] Delitala: Am. Jour. Orthop. Surg., 1915, xii, 555.

During the last two years Dr. Sherman and I have observed three examples of this disease, with histories as follows:

Case 1.—B. F., boy, aged 3½ years, seen first by us in *July, 1913*, came from a family in which the parents and older children had never limped; his infancy had been normal; he had had pertussis at the age of 1½ years. He complained of *pain* in the left knee at the time of a fall six weeks before first seen; he limped a little and got better. Again five days before the first visit he twisted the left foot and leg; he heard a snap, and then had pain and difficulty in walking. At the first visit he walked with a decided limp, but on the table had free joint motion, except that the heel would not go so high into the opposite scarpa as normal. Two days later, when reexamined, the limp had disappeared. The von Pirquet was negative. The boy was not seen for ten months, during which time he had intermittent soreness and would limp for a few days. He then showed no limitation of motion or limp, but the roentgenographic changes were marked. Wassermann negative, normal thymus, genitalia, hemoglobin 75 per cent. In April of this year he was seen again. In the eleven months' interval he has had five or six limping spells, each lasting a day or two, *accompanied* by slight hip pain; the attacks lessened *in* severity, the last one occurring in September, 1914.

The parents say he has a tendency to stumble because he will not lift the foot so high as the right one, and is a little clumsy in running. Examination shows 40 degrees' abduction, as against 45 in right. Five cm. atrophy midthigh; hyperextension normal; no shortening.

No treatment was given.

Case 2.—L. W., boy, aged 6½, was first seen in December, 1913. The parents had never limped; the child was healthy as a baby; he had had pertussis and roseola, both lightly; he commenced to limp six months before the first visit, and complained of pain in the left knee, not enough to stop play. When seen in the office, he had no limp and no limitation of motion. Tonsils were removed, although no Rosenow bacilli found. A month later he had *no limp*, but *only* 14 degrees abduction were permitted, and slight limitation of hyperextension.

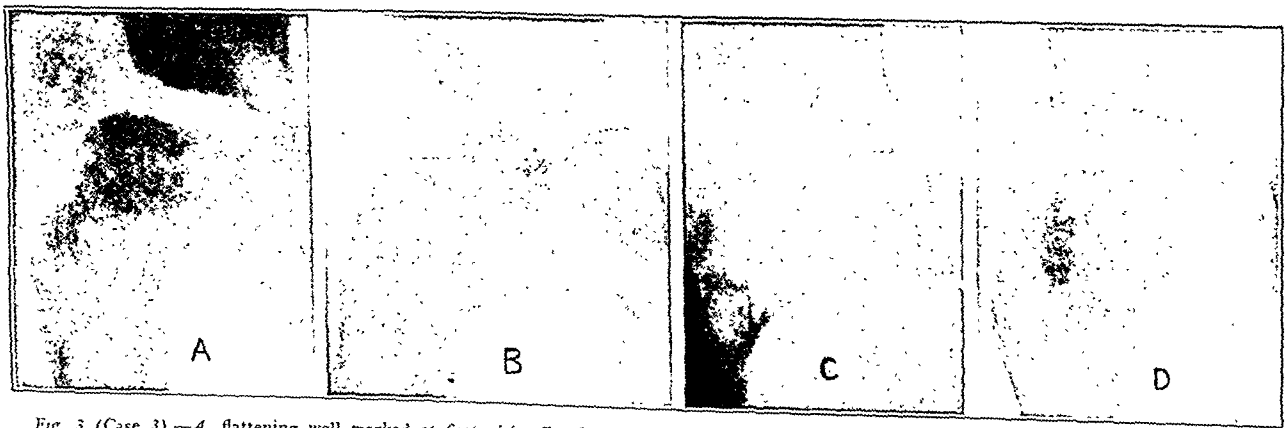

Fig. 3 (Case 3).—*A*, flattening well marked at first visit; *B*, after five months; continuation of process; *C*, five months later; fragmentation appearing; *D*, three months later; continuation of process.

Von Pirquet and 2 *mg.* Koch's Old Tuberculin were both negative. Wassermann was also negative.

The child was put in spica and on crutches to protect the joint. This was continued four months, when the abstract of Söderlund's article[2] induced us to remove the spica and consider the condition as therein described.

The course of the disease since has been quite typical. The parents have endeavored to make him use crutches, but he is as apt as not to discard *them when* at play, the joint being absolutely without pain.

Case 3.—B. C., boy, aged 7, seen first in May, 1914, with no history of limping, had whooping cough and measles lightly in infancy, but no other illnesses. Limping commenced after a fall from a tree, and the boy complained of pain in the groin. He limped a little, steadily, for three months, and then was placed under our care. We found only 15 degrees' abduction permitted, with limited rotation and hyperextension. Roentgenoscopy revealed marked flattening of the epiphysis. The von Pirquet and Wassermann tests were negative. In three weeks, the adduction and other joint restrictions being on the increase, an anesthetic was given, the adduction overcome, and a plaster-of-Paris splint applied.

At the end of seven months, or last March, there being abduction of 35 degrees, with free joint motion, splint treatment was discontinued, in spite of the increased flattening of the epiphysis, as shown in roentgenograms. Since March he has been kept on lift and crutches, although without them he has a slight limp, because of restricted motion; he has a little fulness over the neck of the femur; 25 degrees' abduction are permitted, and two-thirds normal rotation.

He has had no pain since the fall from a tree when the symptoms began.

These three histories and accompanying roentgenograms are quite typical of the syndrome brought into prominence by Perthes two years ago. Keeping it carefully in mind will save a small percentage (Delitala saw six in 1,500 cases of coxitis) from the dreaded diagnosis of tuberculosis. To us also will be given the satisfaction of making a definite advance in the scientific accuracy of our diagnoses.

One should also consider that other joints may be similarly affected. Ridlon,[3] two years ago, before this section reported two cases of osteochondritis dissecans, *producing* defects *in the* cartilage of the knee, resulting in small free bodies in the joint. Other rare and little understood joint affections may in time be grouped under a common pathology, having as the salient feature an inflammatory defect, a breaking down or delayed ossification (as in Perthes' disease) of the cartilage.

350 Post Street.

ABSTRACT OF DISCUSSION

Dr. H. M. Sherman, San Francisco: The cases were of interest to us because we had read of the condition before we found it in one of the *children*. The diagnosis must be made primarily, because an inaccurate diagnosis might cause one to put the child into a splint for a long while when it might not be really necessary. The local diagnosis, apart from the general one, can be made on two bases: first, on the clinical examination, in which one does *not* find the typical symptom of a hip joint tuberculosis, and second, by means of a roentgenogram. These two things, with a negative von Pirquet and a negative Wassermann, should serve to establish the character of the condition. We intended to treat all of these children without any splints at all after we had made our first diagnosis, but one of them evidently was suffering a certain amount of irritation in the neighborhood of the joint, which caused a reaction that impeded motion. We thought that needed protection, so that it was put into a spica which held the hip still for a certain length of time until we could safely take it off. Since then the patient has been without splints. We have not had opportunity to watch the patients far enough into life to know what the ultimate result will be.

[3] Ridlon, John: Osteochondritis Dissecans, The Journal A. M. A., Nov. 15, 1913, p. 1777.

Dr. Haas' paper, it seems to me, comes in here with great usefulness in the experiments which he made on the results of interfering with the circulation in a bone. I refer to the case in which he showed us two pictures in which there had been interference with the growth of a metatarsal bone following an interference with the circulation outside the bone. It would look as if that might be the case in these children with osteochondritis at the hip. If there has been an injury, that might be credited with having interfered with the circulation sufficiently to change development processes. If there has been no history of an injury—and of course one cannot always get a history of all the falls that a child has, because a child cannot tell—if there has been no history, it would not be unreasonable to suppose that every child falls more or less, and that an injury had occurred, in spite of there being no record of it. Experimental work would be difficult, except on animals in which the anatomy was so well worked out that you could tell just where each artery was going; but experimental work should promise an answer to questions of etiology.

A CASE OF STRAMONIUM POISONING

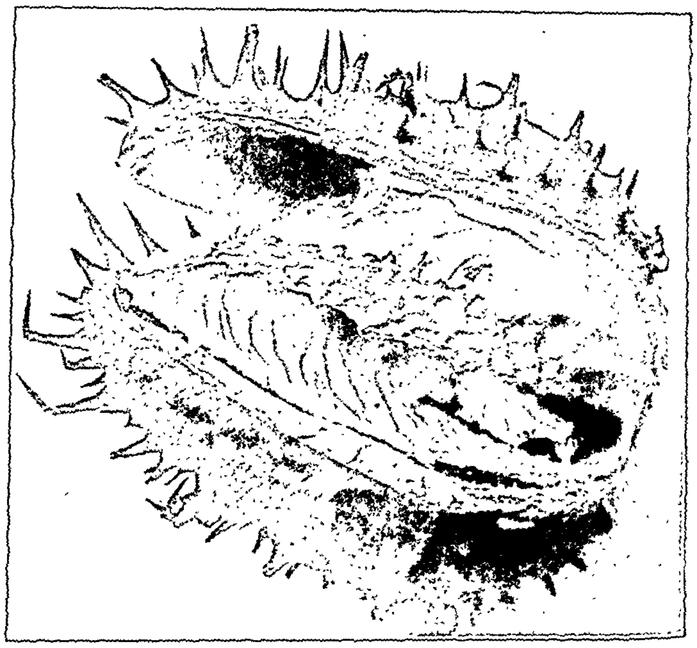
William D. McNally, A.B., Chicago
Chemist, Cook County Coroner's Laboratory

M. R., a strong healthy boy, aged 7 years, died suddenly Nov. 29, 1914. Part of the stomach contents, consisting of 130.5 gm. of poorly masticated food, mostly vegetables, was submitted to me for examination. About twenty small kidney-shaped seeds about 2 mm. long and 2.5 mm. wide, of a brown color, were found unbroken in the food. From the stomach contents which contained broken seeds, 2.2 mg. of an alkaloid were extracted which gave a purple violet with Vitali's test. A drop of a solution containing about $\frac{1}{240}$ grain in 1 c.c., was dropped into the right eye of a cat and compared in a half hour with the left eye, when a marked dilatation was noted. An amorphous precipitate was obtained with hydrobromic acid saturated with bromin. The precipitate became crystalline after standing, was insoluble in acetic acid and only sparingly soluble in hydrochloric acid. From the foregoing tests and the physical examination of the seeds, I concluded that the boy had eaten the seeds of the *Datura stramonium*, containing atropin and hyoscyamin.

At the home of the boy I obtained a "thorn apple," a four-valved, four-celled capsule thickly covered with sharp spines containing numerous seeds of the same appearance as those found in the stomach contents. A chemical and physical examination proved the seeds to be those of the *Datura stramonium* or Jamestown weed, sometimes called "jimson weed." The "thorn apples" were obtained in a neighboring yard, where the plant was cultivated for its white flowers. The "jimson weed" is an annual plant, of a very vigorous growth, found in vacant lots and in the country. Since it is so common and easy of access to children, it is singular that more cases of poisoning are not reported.

The seeds were eaten about 5 o'clock in the evening. The boy ate his supper at 6 o'clock, retiring at 8 o'clock feeling as well as usual. About 12:15 he called to his mother, complaining of being alternately cold and feverish. Half an hour later he was delirious, tossed about in his bed, wanted to go barefoot, and pulled at his nightgown. After about one hour of restlessness the boy went to sleep breathing very heavily. The family endeavored to obtain the services of a physician without avail. At 6 o'clock in the morning the mother found the boy resting easy. Fifteen minutes later she went in to awaken another child and found the boy dead, with his face sunk into the pillow, fourteen hours after eating the seeds. The boy did not have convulsions, vomiting or diarrhea.

At the necropsy made twenty-four hours after death, by Dr. H. W. Burmeister, there was no evidence of rash, and no skin petechiae were present. It was particularly noted that the pupils were not dilated to any marked degree. The lungs were slightly distended, and there were a few scattered subpleural petechiae over both lung surfaces. There was a hypostatic congestion in their posterior portions. Scattered over the epicardium of all portions of the heart were numerous (several hundred) small petechiae. These were for the most part discrete, and none measured over 0.1 cm. in their greatest dimension. The liver was negative except for an acute slight passive hyperemia and a parenchymatous degeneration. The jejunum and the ileum contained a thick semifluid yellowish material in considerable amount, and scattered throughout the course of the entire small intestine were about 100 seeds identified as above as coming from the *Datura stramonium*. Otherwise the organs were grossly negative.



Thorn apple of *Datura stramonium*.

The number of necropsies after death from atropic poisoning is small, and the lesions observed, as in this case, are not characteristic.

The literature does not give sufficient data to serve as a basis for even an approximate estimate of the lethal dose of stramonium. An Indian laborer[1] died in seven and one-half hours; the stomach contents contained eighty-nine seeds. A child of 2½ years died after having swallowed about 16 grains of seeds.[2] A girl,[3] aged 8 years, swallowed 237 seeds, and recovered with treatment. In the case reported above, the boy died from eating not more than 180 seeds. According to statistics of Falck, quoted by Kobert,[4] death occurred in 11.6 per cent. of the cases collected of atropin and hyoscyamin poisoning.

Special Article

THE AUTOLYSIN TREATMENT FOR CANCER

RICHARD WEIL, M.D.
NEW YORK

I have received so many requests for information concerning the new treatment for cancer described as "autolysin" that I have deemed it advisable to make a public statement on the subject. The fact that I had the opportunity of personally witnessing the application of this compound in a long series of cases has placed me in a position to express an independent opinion as to its merits. At the time when Dr. Beebe was still connected with the General Memorial Hospital,[1] New York City, a preparation was brought to the hospital authorities by Dr. A. Horowitz, with a request that its therapeutic effectiveness in cancer be made the subject of study. This mixture, which has since been described as autolysin, had been used in a number of cancer cases, and was stated to have proved of value. It had already achieved a local reputation and some degree of newspaper notoriety in the treatment of cancer.

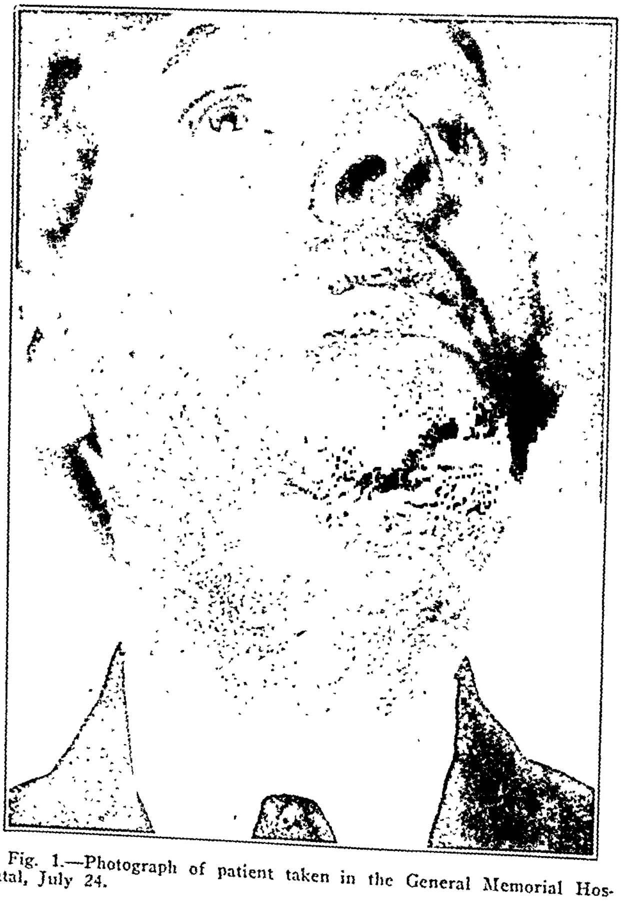

Fig. 1.—Photograph of patient taken in the General Memorial Hospital, July 24.

In accordance with a well-defined policy of the Memorial Hospital which approves of the further investigation of therapeutic measures of whatever description, provided they offer the hope of assistance in cancer, Dr. Horowitz' mixture was accepted for study. Dr. Beebe volunteered to carry on this study. The rules of the medical board of the hospital prescribe that in such cases the exact composition and formula of the preparation under investigation be disclosed to at least one member of the board, and Dr. Beebe informed the board that this regulation had been duly complied with, and that he was in possession of complete knowledge on that subject. Consequently, Dr. Beebe was given the privilege of applying the treatment in a considerable number of cases, and the fact that I had general supervision of the clinical activities of the institution imposed on me the duty of watching the progress of these cases.

The cases entrusted to Dr. Beebe comprised a wide and diverse group, including cancer and sarcoma of the various tissues and organs of the body. Dr. Beebe has stated, in his first paper, that the cases treated in the Memorial Hospital "represent the most hopelessly incurable and inoperable group of patients." That they were inoperable is indeed true. An ethical regard for the welfare of patients forbids the use of new and experimental remedies in cases which offer a hope of cure by the older and well-tried methods of medicine and surgery. Therefore, only such cases were submitted to his treatment as could not be helped materially by the other means at our disposal, such as surgery, radium or the Roentgen ray. In not a few instances, though not all, the patients were given the benefit of radium or Roentgen-ray treatment, while autolysin in addition was administered. That all of the patients were moribund, or even in very serious physical condition, is, however, not the case. There is a large group of cancer patients, as every physician knows, who are apparently in excellent, or even in perfect health, but in whom the condition of the disease entirely precludes the possibility of effective treatment. Some of the cases put in Dr. Beebe's hands at the Memorial Hospital were in good physical condition, and here the treatment, if of real value, should certainly have demonstrated its virtue.

Since Jan. 1, 1915, twenty-three cases have been treated in the wards of the hospital by Dr. Beebe with autolysin. Of these twenty-three cases, fourteen patients died in the hospital, and eight were discharged unimproved. Only one, to the best of our knowledge, is at the present time in a condition which could be described as an improvement on that presented at the time of admission to the hospital. To this case, which seems to be identical with Case 3 of Beebe's paper[2] of October 2, I shall come in a moment for more detailed discussion. Although the eventual outcome of the cases was not affected by Beebe's treatment, the clinical course was somewhat altered thereby. In those cases in which the mixture was injected directly into the tumors, there resulted necrosis, suppuration, and sloughing of portions of the tumor masses. This effect is quite characteristic of the action of a large number of irritant or destructive substances, whether of mineral or vegetable origin, on tumor tissue. It affects the size of the mass, and may impress the mind of the patient and his friends, but does not in the least degree impede the steady and relentless progress of the malignant growth. Indeed, there is a spontaneous tendency for malignant growths to break down and die at the center, while simultaneously the living cells at the periphery successfully ture for use in the treatment of cancer cases. An interesting document in this connection is furnished by a letter to a physician in Seattle, dated July 29, signed by S. P. Beebe,[5] and recently published by *Northwest Medicine*. In that letter Dr. Beebe declares to his correspondent that the ordinary physician is not competent to use the drug, and lays down the financial terms on which his firm is ready to examine the case — the sum of $250 for "examination, consultation, etc." Of course, writes Beebe, if the doctor will come to New York from Seattle they will be glad to show him how to administer autolysin. After this, the doctor will be able to administer it himself.

---

[1] To avoid further misunderstanding, it should be stated that Dr. Beebe's connection with the Cornell University Medical School and with the General Memorial Hospital terminated some time ago.

[2] Beebe, S. P.: New York Med. Jour., Oct. 2, 1915.

I wish to add a word in conclusion. The majority of those who will read this article have had practically no means of judging of this treatment through their own observation. Cancer patients are peculiarly gullible, and will snatch at any straw in the hopeless struggle against their disease. Such unfortunates gladly undertake long and painful journeys at the cost of great suffering, and surrender their last remaining dollar, in the hope of gaining relief. Surely they deserve to know all that we can tell them of the treatment which is so enticingly portrayed. My own personal belief, founded on long observation, is that autolysin is useless; that it adds nothing of value to the methods now generally accepted; and that it often aggravates the sufferings and accelerates the death of the patient.

970 Park Avenue.

Therapeutics

PNEUMONIA

(Concluded from page 1553)

SERUM AND VACCINE TREATMENT

The value, in all cases, of serum or vaccine treatment of pneumonia is still in doubt. Rosenow[6] found the opsonic content of the serum of the blood in lobar pneumonia to be below normal during the early part of the disease and to become, in favorable cases, above normal as the symptoms began to subside. When there is a severe infection and the patient is overwhelmed by the disease the antibodies in the serum were found to remain below normal. Rosenow developed an autolyzed pneumococcic vaccine which, when injected into a patient with pneumonia, he found, would hasten the production of the antibodies needed to fight the infection, and therefore would hasten recovery. Later Rosenow and Hektoen[7] reported that the mortality from pneumonia in their cases had been reduced by injecting this antigen or vaccine.

Vaccination as a prophylactic and to immunize against pneumonia is purely in the experimental stage.

MEDICINAL TREATMENT

We are past the stage when any dogmatic advice can be given in regard to the use of drugs in pneumonia. The physician who has charge of a pneumonia patient must decide whether a drug is needed to combat a condition or symptom and which drug is the best for the object aimed at. The following are suggestions of drugs that have positive value for certain conditions and brief descriptions of the pharmacolige action expected of them:

Morphin or Codein.—If the pain is acute in the beginning of pneumonia, one of these sedatives should be given. Acute pain is depressant and should not be allowed. Strapping of the chest is inadvisable in pneumonia. An ice bag over the painful region of the chest does not abort pneumonia and is generally not desirable, and on account of the generally high fever at this time, hot-water bags are not advisable.

A cough that is frequent and unproductive, as it may be in the first stage of pneumonia, will be quieted and the pain alleviated by codein sulphate in doses of 0.01 gm. every two, three or four hours as is necessary. If later there is great insomnia, with a very weak circulation, the safest hypnotic is morphin in a dose not sufficient to slow the respiration greatly or to prevent the needed and necessary expectoration. If there is meningeal irritation or an actual meningitis, morphin is generally contraindicated, as it will cause more delirium, unless the dose is undesirably large.

Acetanilid and Antipyrin.—Acetanilid, 0.10 gm. every three hours for four or five doses, or antipyrin, 0.50 gm. every four hours for two or three doses, may be of advantage in lowering the high temperature in the first stage of this disease. These drugs also will lower the blood-pressure and quiet the heart. Such an action may be needed in the very acute first stage of pneumonia, provided that the heart is normal. At this stage, the lowering of the blood-pressure produced by these drugs is often beneficial. Later in the disease, even if there is high temperature, such coal-tar products are not indicated and should not be given.

Ammonium Chlorid.—If the expectoration is very adhesive and cohesive, scanty in amount and hard to raise, ammonium chlorid acts satisfactorily and is indicated. The dose should be 0.25 gm. every two hours, given in a sour mixture, or in lemonade; and if there is much pain or if there is ineffective, frequent cough it may be combined with codein sulphate. Ammonium carbonate, with its irritant, nauseating action, has no tangible cardiac stimulant action; therefore it should not be used.

Sodium Iodid.—This drug in small doses, as 0.20 gm. three times a day, will promote an increased mucous secretion, render the cough easier, and may hasten a delayed resolution of the lungs. Also, the stimulant effect of the iodin may increase the inhibitory activity of the thyroid gland, and it is now known that the thyroid gland is always injured and soon becomes more or less insufficient in acute infections. A normal thyroid secretion is stimulating and more or less antitoxic.

Digitalis.—Digitalis is another drug that has sometimes been lauded, even in the first stages of pneumonia. If the blood-pressure is low and the heart is primarily weak, and there is a very bloody, prune-juice expectoration showing a poor activity of the right ventricle, digitalis may be of value and sometimes does a great deal of good. On the other hand, with the more sthenic type of pneumonia it seems to increase the lung congestion and may do harm. In the heart failure of pneumonia it does not seem to raise the blood-pressure. After the disease has been in progress a week or more there is more or less of a myocarditis, perhaps a very little, perhaps considerable; at all events, digitalis to increase muscular activity of the heart at this stage is generally inadvisable.

Strophanthin. — This drug procured in sterile ampules and injected directly into one of the veins in the elbow, provided digitalis has not been recently administered, is often efficient in tiding a patient over a shocked condition. It should rarely be repeated.

Strychnin.—This is a drug that has been very much overused. To begin strychnin immediately in acute disease is a serious mistake. To give it in large doses very frequently is an error. It excites the nervous system, renders the patient irritable, may cause muscle twitching, and may so irritate the heart as to prevent normal diastolic rest and normal diastolic relaxation. In acute disease, it has been shown not to raise the blood-pressure in serious conditions. In spite of these facts, clinically strychnin often does very good work and even seems to tide our patients over critical periods. In a sluggish, inefficiently contracting heart, when digitalis is contraindicated, strychnin is many times of benefit in making the heart more normal. If a patient is stupid, apathetic and indifferent to his condition, strychnin lights up the nervous system desirably. The rule for strychnin should be, when indicated as shown by this discussion, to give to an adult not more than $\frac{1}{30}$ of a grain, hypodermically, if deemed advisable, once in six hours, and such a dosage should not be long continued. As soon as there is improvement, it should be given by the mouth instead of hypodermically.

Camphor.—Laboratory findings and some hospital reports have not shown that camphor is of value in heart failure. On the other hand, clinical experience at the bedside not infrequently shows that hypodermic or intramuscular injections of a sterile preparation of camphor and oil improves the pulse as to its regularity and volume, causes the surface of the body to be warmer, and many times relieves a cardiac dyspnea by thus equalizing the circulation. At the same time it is a mild nervous and cerebral stimulant, which is often desirable, and it never irritates or causes any heart pangs as some of the so-called cardiac drugs can occasionally do. When there is cardiac dyspnea, when the pulse is small and especially when it is slow and weak and the surface of the body is cold, and when there is cold perspiration, that is, a partial collapse condition, camphor given hypodermically every three or four hours until there is improvement will many times be found of benefit.

Pituitary Fluid.—This represents one of the activities of the posterior lobe of the pituitary body. It has more or less superseded epinephrin in acute conditions, as pituitary raises the blood-pressure a little longer, is a little less sudden in its action, seems to stimulate the heart considerably, and stimulates and increases the activity of the kidneys. The contents of an aseptic ampule should be given hypodermically and perhaps repeated two or three times at three or four hour intervals.

Caffein.—The administration of this drug as coffee or tea has already been discussed under diet. Perhaps no drug, except epinephrin, the action of which is very fleeting, so frequently raises the blood-pressure in serious conditions as does caffein. In emergencies it may be administered hypodermically, or it may be given by the mouth several times in twenty-four hours. It should not be forgotten that it is a cerebral stimulant and not a sleep producer. Its action on the heart is almost always for good, except in some few patients who show an idiosyncrasy to it, the heart becoming irritable from any form of caffein.

Ergot.—This drug, when given in aseptic preparation intramuscularly, certainly raises the blood-pressure, quiets the central nervous system and gives a better vasomotor tone, and may relieve hypostatic congestion of the uninvolved lung, which is one of the dangers of a failing heart in pneumonia. If the blood-pressure is high, this drug should not be given.

Nitroglycerin.—When pneumonia occurs in a full-blooded, sturdy man, especially if he is of the age when his blood-pressure is a little high, small doses, as $\frac{1}{200}$ to $\frac{1}{100}$ grain, every four to six hours, tends to dilate the peripheral vessels and relieve the internal congestion. It also slows and quiets the circulation. By bringing more blood to the surface of the body, it also tends to promote loss of heat and a reduction of temperature. It will never weaken a heart as long as the blood-pressure is high; it should not be used if the blood-pressure is low.

Alcohol.—This drug has lately come into great disfavor. It was, of course, inexcusable to give it in large amounts in pneumonia. On the other hand, as a drug, it still has certain physiologic activities which may in certain cases be of value. In the first place, alcohol will inhibit more or less the acidemia which might otherwise result from a patient's inability to take enough nourishment or enough starch. It then becomes a food, given in such doses as not to cause flushing, throbbing of the head, or cerebral irritation. Also, every clinician has seen a rapid heart become slower, more regular, and the pulse become of more equalized volume under the proper use of alcohol in certain selected cases of pneumonia. In such patients small doses of alcohol may be of value. It will be seen from the discussion of nitroglycerin, however, that many times this drug will act as well, as far as the circulation is concerned, but of course nitroglycerin is not a food. The alcohol selected should generally be a good whisky or a gin. This is not to urge the administration of any form of alcohol, but is to show that alcohol is a drug with physiologic activities and may be used in certain conditions with as much discrimination as is used in giving any other drug.

Hypnotics.—It is hardly necessary to name the different hypnotics. As above stated, in very weak conditions the only safe hypnotic is morphin. In delirium and in insomnia it may be well to use some other hypnotic than morphin. Almost any one of them causes some subsequent cardiac depression. The best hypnotic is perhaps chloral, but there is a great prejudice against its use as it is supposed to be a very great cardiac depressant. There is some doubt about this. Probably an effective dose of chloral is no more depressant to the heart than is an effective dose of any other hypnotic. A few doses of sodium bromid may be advisable. If a synthetic drug is to be selected, sodium diethyl-barbiturate (veronal-sodium, medinal) is perhaps less depressant, in effective dose, than any other.

As stated at the outset, a restful, quiet room, a sensible, efficient nurse, a sufficient amount of fresh air, and a suitable diet and proper care of the bowels will prevent high temperature, heart failure, low blood-pressure, insomnia, tympanites and toxemia in very many cases, and prevention is far better than the treatment of these serious conditions.

STATISTICS OF INFANTS AT BIRTH

The variations in the weight of the human infant at birth have been the subject of considerable speculation and statistical study. It has been asserted that the weight at birth is greater the nearer the mother's age is to thirty-five years, the greater the weight of the mother, the greater the number of previous pregnancies, and the earlier the appearance of the first menstruation. Race and climate have also been assumed to be of influence.[1] Minot[2] believed that all of these influences work principally through prolonging or abbreviating the period of gestation, and that the variations at birth depend partly on the duration of gestation and partly on individual differences of the rate of growth in the uterus.

A recent careful statistical analysis of more than 500 confinements, yielding approximately equal numbers of male and female infants, showed that the length of the period of gestation is very much less variable in normal females than the weight of the infant which is delivered.[3] According to Robertson's calculations, the mean length of periods of gestation yielding males is 282.5 days, with a probable error of ± 0.55 days and a variability of 4.47 per cent. The mean length of periods of gestation yielding females is 284.5 days with a probable error of ± 0.57 days and a variability of 4.85 per cent. The deviation of normal periods of gestation from the mean are fortuitous in origin. The chances are a million to one against a male child being delivered at the termination of an otherwise normal pregnancy before 224 days or of a female child before 222 days after the onset of the last menstruation. Hence all seven-month children (210 days) may be regarded as the fruit of pathologic pregnancies. It is inferred that the length of the period of gestation in normal females is primarily determined, not by the fetal development, but by a maternal cycle of events which is to a considerable extent independent of the stage of development attained by the fetus.

Data now available for a number of different countries of the world bring out the striking similarities in the average weights at birth of infants from the same groups of people, and an unexpected difference between the averages for diverse peoples. For infants born in Great Britain the average weight measurements at birth have long been quoted as 113.6 ounces for males and 110.4 ounces for females. Newer figures by Karl Pearson[4] give the mean weight at birth of 1,000 male infants born in London (at the Lambeth Lying-in Hospital) as 116.8 ounces, while that of 1,000 female infants is 113.2 ounces. For Birmingham corresponding figures of 114.9 and 113.5 ounces respectively have been reported.[5]

T. B. Robertson calls attention to the excellent agreement with one another of the various estimates of the weight at birth of British infants born in the British Isles. Records which he has just published[5] in relation to the Queen's Home, a maternity hospital in Adelaide, South Australia, in which the admitted patients belong to the same laboring and unskilled artisan classes as do those furnishing the data for the British Isles, give unexpectedly different figures. Robertson found that the average weight at birth of 247 male infants born in South Australia, the fruit of normal confinements, is 127.3 ounces, while that of 264 female infants is 121.2 ounces. He thus emphasizes the striking fact that South Australian infants weigh from 8 to 10 ounces more at birth than infants born in Great Britain. They are also from 5 to 6 ounces heavier at birth than infants of English descent born in the Eastern United States.

Robertson points out that the results observed cannot be due to any racial selection among the immigrants from the British Isles who have given rise to the population of Australia: In the first place, there is no evidence that such selection has occurred to any greater extent than it has, for example, in London, of which city the very great increase in population during the past century has been contributed by all parts of the British Isles, and, in the second place, there is no evidence of the existence of a race in the British Isles which is in any noteworthy degree superior in physical dimensions to the average inhabitant of England. It has been said that the evolution of the Australian people may be regarded as that of the British people under changed climatic, social, and economic conditions. To these factors, therefore, Robertson is impelled to ascribe the superior weight of the Australian infant at birth. He specifically points out that the climate is much less rigorous than that of England, food is cheaper in proportion to income, or, when of a like price, better in quality, and the social and economic conditions are so far an improvement on those prevailing in England that whereas women of the laboring and unskilled artisan classes in England have frequently to supplement the family income by their own exertions, those of the corresponding classes in Australia as a rule confine their physical activities to the management of their households and families, a condition of affairs which, quite apart from the possible direct effects of physical labor on the mother, must have important indirect effects in ameliorating the nutritional and hygienic conditions within the household. Attention is called to the fact that these conditions may be conceived to have an appreciable prenatal effect on the growth of the child, since Pinard has shown that the rest and improved nutrition of hospital life cause a notable increase in the average weight of infants delivered by working mothers who spend a part or a whole of the period of pregnancy in lying-in hospital, and Prochownik has shown that e size of a child at birth may be reduced by restrict- g the diet of the mother.

[5] See Robertson, T. B.: A Comparison of the Weights at Birth of British Infants Born in the British Isles, the United States, and Australia, Univ. California Pub. Physiol., 1915, iv, 207.

As regards weight at birth, the Anglo-American fant is intermediate between the Australian infant nd the infant born in the British Isles. In a way this orresponds with the character of the social and eco- omic conditions prevailing in the three countries con- erned. The interesting suggestion is made that the ean weight of infants of the same race at birth is a ery sensitive criterion of the social and economic nvironment in which they are born. If this proves o be true, a new relation between the economic and ygienic problems of a nation will be brought into rominence.

THE "AUTOLYSIN" TREATMENT FOR CANCER

Modern science calls for proof — proof as indu- itable and unqualified as the case will permit. Scien- ific men accept new theories and new alleged facts only when they are supported by reliable evidence. Especially is this true in the realm of scientific medicine. Unlike the exact sciences, there are in medicine so many elements which may vitiate definite conclusions that the careful physician is slow to accept claims made for new therapeutic agents. And rightly so; for human health and life are too valuable to be made the sport of untried theories and unsupported claims. In a world largely dominated by commercial instincts, this unwillingness on the part of the physician to accept, at its face value, every claim made for a new therapeutic product has long been a source of irritation to the exploiter. It is not surprising, then, that the refinements of twentieth century advertising have been brought to bear in overcoming the physician's caution — a caution exercised wholly in the interests of his patients; hence the spectacle, during recent years, of the exploitation of additions to materia medica — some of which may have had an appearance of at least quasiscientific value — brought to the notice of the public, rather than to the medical profession, by every art known to the modern advertiser. At the same time a semblance of scientific standing has been given the products by publishing in such medical journals as would accept them articles describing these products. The theory, apparently, on which such methods are based is that by creating a sufficient demand on the part of the public for these products, the physician will be dragooned into using preparations which his sober judgment tells him have not passed through the refining fires of scientific investigation. It is only necessary to call to mind the Friedmann "consumption cure" campaign, and the resurrection of the discredited scopolamin-morphin anesthesia under the popular name of "Twilight Sleep," to realize the potentialities for harm that this method of exploitation carries.

The most recent example of this pernicious method of bringing into the public eye new therapeutic agents is exemplified in what has been called the "autolysin" treatment for cancer. Early in the publicity movement for this treatment THE JOURNAL[1] urged caution, calling attention to the secrecy and the unscientific character of the formula. "Autolysin" was brought into the limelight of publicity chiefly through the medium of sensational newspaper and magazine articles. This was accomplished before the preparation had been so tried out as to establish, without question, its value or lack of value. Its exploitation makes the thoughtful wonder whether it belongs in the realm of scientific discovery or in that of crude commercialism. As is always to be found in such cases, the failures are minimized and the successes are heralded. Its use for all practical purposes has been wholly in the hands of its friends and promoters. Naturally, reports emanating from such sources must be looked on as *ex parte* statements, rather than as scientific records. The time has evidently come, as it will come in all such cases, when we may expect to hear the other side. A little while ago[2] THE JOURNAL published a disclaimer from a Detroit physician whose name had been connected with one of the magazine articles boosting the treatment. Elsewhere in this issue is further evidence on the other side.[3] Also, THE JOURNAL submits some correspondence[4] relative to the exploitation of this new product, dealing with the commercial aspect of the case.

Some of the best brains in the world are working on the problem of the prevention and cure of cancer; so far the solution is not in sight. When it comes it will come as a gift of medical science to humanity. It will not come in the form of secret and mysterious combinations controlled by a few individuals to be doled out to those who are able, or willing, to pay the toll demanded. It will be determined after a series of experiments carefully conducted under scientific control in various institutions and under the observation of disinterested, scientific workers. Only under such conditions will it be possible to declare, with any degree of scientific accuracy, that a successful treatment has been established.

[4] Propaganda Department, p. 1662.

Whether the "autolysin" mixture may possess some elements of value in combating the scourge of cancer must be left to the future to decide. Even should it be found of use this would not alter the fact that the methods of exploitation have been unworthy of scientific men, and in their effects on the public, the very refinement of cruelty.

CRAIGIASIS

The classification of amebas was not an especially difficult task until after the pathogenic forms became known and artificial culture mediums were developed, when the difficulty of distinguishing between the pathogenic and the innocuous forms arose. At present, it is recognized that the nature of the pseudopodia and the ectoplasmic and endoplasmic differentiation are unsafe diagnostic characters by which to identify amebas; for these have been shown to vary widely in the same species under different conditions of environment. Gradually improvements in cultural methods, recognized nuclear differences and other dissimilarities in ameboid types of rhizopods have made generic separations among them imperative. Accordingly, the old genus *Ameba* has been distributed by a protozoologist into a series of allied genera: Ameba, Vahlkampfia, Nägleria, Craigia, Trismastigameba and Parameba.[1]

This growing complexity has been accompanied by changing views regarding the pathogenesis of some of the species. At one time some authors regarded all amebas as being without significance in relation to disease, because of the frequently reported presence of these forms in the stools of apparently healthy individuals. Thus, in 1905 Craig examined 200 persons not suffering with dysentery, and found amebas in sixty-five. Doubtless, periods occur in the course of amebic dysentery in which symptoms are entirely lacking. The recognized existence of unharmed or immune carriers of other types of organisms makes it seem less strange today than it might have seemed a few years ago to learn that there are some individuals apparently perfectly healthy who harbor amebas in large numbers for long periods without any unfavorable symptoms. Of course, lesions may exist without becoming evident during life. Strong[2] has expressed the questions at issue as follows: Are the instances cited cases of natural resistance or immunity against the parasite; or are they instances in which the parasites are unable to exert any harmful action until the proper symbiotic bacteria appear in the intestine, and are only awaiting this moment to become pathogenic; or are they cases in which the organisms are still incapable of producing any injury until through some mechanical disturbance a small erosion in the mucosa occurs; or are they instances of infection with an ameba harmless to man?

Between the extremes of opinion, that all amebas are harmful, and that none really have etiologic significance per se, it seems safe to say at present that the *Endameba histolytica* and its near relatives are pathogenic, whereas the *Endameba coli* may be a harmless inhabitant of the human intestine, where it lives on the available bacteria. In 1906, Captain Craig of the United States Army observed a small ameba in the human intestine in six cases of chronic diarrhea. He named it *Parameba hominis*, but it was later given the new generic designation *Craigia* in honor of its discoverer. Although its habitat in the human intestine was undisputed, the question as to its possible relation to chronic diarrhea has called for confirmation. Evidence of this sort has recently been furnished by Dr. Barlow,[3] of the Medical Department of the Cuyamel Fruit Company of Honduras.

In the course of Barlow's investigations concerning the prevalence of intestinal parasites on the coast of Honduras, a flagellated organism, differing from *Endameba histolytica,* was observed in numerous cases. All of these had presented symptoms of mild dysentery or chronic diarrhea. The additional fact that no cases of flagellates were found without the symptoms, along with other features which need not be detailed, have led to the identification of the parasite as *Craigia hominis* (Craig's *Parameba hominis*), and the indictment of it as the etiologic factor in the intestinal disease.

Craigiasis has accordingly been defined as a diseased condition of the body produced by infection with protozoa belonging to the genus *Craigia*. It is probable that the latter has a wide distribution. Craig's cases were all in residents of the Philippine Islands, or recent arrivals from there. Barlow's cases were found in Honduras. They have been grouped from among those furnished with drinking water from certain supplies. The grouping has been so marked that Barlow is strongly inclined to attribute the chief source of infection to polluted water, though the possibility of introduction of the parasites by direct or indirect contact is not excluded. It is reported that patients with craigiasis may remain as carriers for a long time.

In its morbid anatomy, this disease doubtless involves comparatively superficial ulcerations of any or all parts of the intestine, with a tendency to the formation of abscesses in the liver, and possibly in other organs. Secondary changes in other parts of the body, due either to intoxication from the derangement of function of the damaged organs, or to the entrance of bacteria in the lesions produced by the parasites, may occur. Among the many therapeutic measures tested, the only effective treatment was found to be either with emetin (alkaloid), hypodermically, or ipecac, internally.

THE IMPORTANCE OF AGGLUTINATION IN IMMUNITY

The well-known phenomenon of agglutination of bacteria by homologous immune serum has received little consideration as a factor in the defense of the organism against infection. Gruber and his associates, in their classical work on the nature of agglutinins, expressed the opinion that these substances were of primary importance in the protective mechanism of the body. They believed that the englobement of the bacteria by the leukocytes in vivo in the presence of immune serum was aided by the agglomeration of the bacteria and their accumulation in the different organs of the body. Subsequent investigators, although appreciating the great value of the reaction of agglutination in the diagnosis of certain infectious diseases and in the differentiation of varieties of bacteria, were unable to find experimental evidence in vitro in support of Gruber's hypothesis. Now, indeed, it is almost the general view of immunologists that the part played by the agglutinins in immunity is merely incidental and subordinate, the important factors being other antibodies such as the opsonins, bacteriolysins and antitoxins.

Some important observations pertaining to this phase of immunity have recently been made by Bull[1] which indicate a wide disparity between the results of agglutination experiments in vivo and in vitro. In an investigation of the manner of the rapid disappearance of pneumococci and other organisms from the blood stream of infected rabbits, following the injection of immune serum, it was found that the serum caused an almost instantaneous agglutination of the organisms. Smears taken from the heart's blood of the rabbit a few seconds after the injection of the serum often revealed a marked clumping of the invading bacteria. Furthermore, these clumps rapidly accumulated in the internal organs, especially the liver and spleen, where they were taken up by the assembled polymorphonuclear leukocytes and ultimately destroyed. These reactions were specific, as in the test-tube experiments, but agglutination seemed to take place in dilutions of serum which were entirely ineffective in experiments made in vitro. In all of Bull's researches, including instances of both natural and passive immunity, the agglutination of bacteria in the blood of the infected animal was followed by phagocytosis and destruction of the organisms in the viscera of the body, and a subsequent disappearance of the bacteria from the blood stream. It was observed, however, that when agglutination was not complete, a few organisms remained in the blood, later to multiply and cause a fatal bacteremia. In view of these facts, it seems probable that the agglutinins, like the opsonins, antitoxins and bacteriolysins, are important protective elements.

These observations are of great value in emphasizing the intricate nature of the protective mechanism in the animal body. The evidence at hand does not minimize the importance of other well-known phenomena occurring in the reaction to bacterial invasion, but emphasizes the cooperation of antibody actions and leukocytic activity as the forces on which depends the outcome of the struggle between many forms of infection and resistance.

ABOLISHING SECRECY AND MYSTERY IN "PATENT MEDICINES"

Nearly a year ago—Dec. 31, 1914—the New York Board of Health made a notable revision of the sanitary code. The revised code requires that on and after Dec. 31, 1915, no proprietary or "patent medicines" shall be sold in the city of New York until certain requirements have been met. The essential requirement is that the names of all ingredients for which therapeutic effects are claimed, and of all other ingredients, except such as are physiologically inactive, shall be furnished the department of health. A statement of the quantities of these ingredients is not required. This information will be given in confidence and will not be open to inspection by the public or any other than the official custodian of such records or those duly authorized to prosecute the laws, municipal, state and federal. An alternative is offered. Instead of depositing this information with the department of health, the exploiters of "patent medicines" may print on the label conspicuously, clearly and legibly the name—not quantity—of each ingredient in the product. If this is done, the preparation is removed from the class designated by the section of the code as constituting a "proprietary and patent medicine."

As was to be expected, this move on the part of the health authorities of the city of New York for the better protection of the public health met instant and active opposition on the part of "patent medicine" makers. Some of this opposition was described in the Propaganda Department of The Journal, Jan. 16, 1915. Many meetings have been held and much perfervid oratory dispensed by the "patent medicine" makers and their henchmen in the apparent attempt to bluff the health department. A good deal of the talk is, doubtless, of the same nature and for the same purpose as that indulged in by the small boy who passes the lonely churchyard after dark. Whether it has had the result of keeping up the flagging courage of those who might perforce be tempted otherwise to bey this new law in the interest of the public health remains to be seen.

---

[1] Bull, C. G.: The Agglutination of Bacteria in Vivo, Jour. Exper. Med., 1915, xxii, 484.

As the time for the enforcement of the ordinance comes nearer, that which originally seemed to be solid opposition begins to change. The *Weekly Bulletin* of the Department of Health of the City of New York for Oct. 23, 1915, reproduces a letter, signed by some leading wholesale druggists and dealers in proprietary medicines, in which the health department's registration ordinance is endorsed. These concerns go even farther. Not only do they signify their intention of selling only patent and proprietary articles that have registered under the new law, but they also "go on record as favoring a federal law regulating the sale of patent and proprietary articles, for the same reasons which brought about the passing of the above mentioned local ordinance." The names of the druggists and dealers who thus exhibit a wholesome respect for the public health and a due regard for the laws of their city are: Bakst Brothers, Britt, Loeffler & Weil, Bruen, Ritchey & Co., Eimer & Amend, Henry Klein & Co., Lehn & Fink, C. S. Littell & Co., Matz & Cohen, McKesson & Robbins, Schieffelin & Co., and Towns & James. These wholesale druggists and dealers have also sent a communication to the manufacturers of the patent and proprietary medicines informing them that they intend complying with the ordinance and would, therefore, request the manufacturers to make their articles legally salable, and in their letter they add, "As federal legislation of a similar nature seems to be impending, compliance with these new requirements seems to be more urgent in order to make your products salable in all parts of the country."

The New York ordinance is unquestionably a step in the right direction, a forward move in the interest of public health and safety. It would be more desirable if the ordinance required, without alternative, a definite quantitative declaration on the trade package of the active ingredients of each product. If the people desire to treat their own ailments — as they have a perfect right to do — they should know what they are getting in the preparations sold for the relief of such ailments. Nevertheless the New York law will, even in its present form, give a much larger degree of protection than has heretofore been possible. Dr. Goldwater, commissioner of health, is to be congratulated on the not inconsiderable service he has performed in bringing about the enactment of this ordinance. It is a service that is not confined to New York City alone, for every forward movement, no matter how local, is far reaching in its moral effect.

THE BOWEL MOVEMENT

"It may sound like a Hibernianism, but food does go down the [alimentary] tract more easily because it is put in at the upper end." This quotation, from a recent article[1] on the motor functions of the intestine, furnishes the text for what ought to be an important consideration in relation to the movement of the bowels. Nothing in the daily life of man is of greater import for his comfort and health than the proper evacuation of the alimentary canal. For some reason, the origin of which is not easily discovered, civilized man in the higher walks of life has attempted to establish an artificial habit with respect to this function. One copious movement of the bowel early every day — soon after rising — is regarded by thousands as conforming to a normal, healthful, physiologic routine. Precisely as the failure to perform this act once a day is popularly looked on as a menace to comfort and even good health, so its more frequent occurrence is not uncommonly the occasion for worry lest diarrhea or other forms of impaired alimentary behavior may be at hand.

What is the physiologic moment for the evacuation of the bowel? Is there any urgent theoretical reason why it should occur at any particular time, or rather, why habit should select for it the time immediately after rising? To the individual employed in business or other vocational pursuits, convenience may dictate the advantage of discharging a disagreeable duty at the most convenient moment, so as to be relieved from personal inconvenience during the remainder of the day. One may as reasonably, however, establish the habit of one meal a day or two meals at fixed hours, and disregard "the call of the stomach."

Even the most cursory observation of the higher animals shows that the emptying of the bowel does not conform to the fixed routine of infrequent defecation to which man has intentionally become resigned. The newer physiology of the alimentary tract clearly teaches that there are natural periods when peristaltic waves are initiated which would naturally induce an emptying of the lower bowel in due time. Every part of the intestine is in a state of activity which can be played on and modified by impulses reaching it from all portions, above and below. Hertz[2] has demonstrated in the case of man that, with the passage of food out of the stomach, the ileocecal valve relaxes, and material travels through the colon at the same time. These features have been emphasized by Alvarez,[1] who notes that the promptness with which a mouthful of food introduced in the stomach causes material to pass through the ileocecal valve or to rush through the colon shows that the human intestine exhibits the characteristic long-distance reflexes.

---

[1] Alvarez, W. C.: The Motor Function of the Intestine from a New Point of View, The Journal A. M. A., July 31, 1915, p. 388.

[2] Hertz, A. F.: Jour. Physiol., 1913, vii, 55.

Every one can recall the desire for evacuation which is frequently felt after a liberal meal. In children the movement of the bowel soon after feeding is familiar. Both adults and children have schooled themselves to repress the natural postprandial impulses to defecate; these impulses are not compatible with our social engagements. Custom in this respect is regulated by convenience rather than by physiologic considerations.

The question may well be raised whether this disregard of natural stimuli is not a potent factor in the widespread manifestation of constipation. Undoubtedly, habitual response to the normal incentives to defecation soon after the introduction of food into the stomach would be a wholesome reform. The facts of physiologic science speak for it. The roentgenologist knows that a contrast meal will go down the bowel faster if followed, a few hours later, by food. The effect of more than one stool per day, moreover, would bring timely relief from those all too familiar symptoms of malaise which have made us a nation of "pill-loving" sufferers. Of course, the "patent medicine" interests would suffer, but the bowel of man, which, according to Keith, contains enough muscular tissue in its colonic wall to form a mass as large as the biceps of a blacksmith's arm, ought to be expected to do its duty unaided.

Current Comment

BACTERIA IN THE AIR

To the air has long been attributed a subtle potency to incite disease when suitable conditions prevail. One need not go back far in history to reach the days when "night-air" and "sewer-air" were feared as the bearers of indefinable dangers to health. The discovery of the rôle of micro-organisms in the transmission of disease has largely changed this attitude. It is true that air from certain localities, such as soils or sewers, may contain an admixture of gaseous impurities—carbon monoxid and dioxid, marsh gas and hydrogen sulphid—which are not wholesome to the organism. But these admixtures are, in all except the most unusual circumstances, so small in amount as to have little if any harmful significance for health. The organic or solid impurities of the air give more cause for alarm, for they include the living bacteria. In sewer-air the proportion of micro-organisms is usually less than that of streets and houses, and they are usually harmless species. The movement of air in sewers is rather slow, so that abundant opportunity is afforded for the suspended particles, including the living agents, to become deposited on the moist surfaces. The gaseous components of the air are of secondary moment. There is a growing conviction, however, that in the majority of cases of so-called "air-borne" disease it is not the particulate constituents of the atmosphere that are directly responsible for the transmission of disease. Suspended particles, including bacteria, may, of course, be sprayed about by the acts of coughing and sneezing and thus aid in the dissemination of diseases, particularly those of the respiratory tract. But as a rule it appears that the diseases conveyed through the air are carried through the agency of insects acting as vectors or as hosts for the infective parasites. In many hospitals, therefore, the "air-borne" diseases are now treated side by side in the same ward without fear of greater transmission than if they were isolated in separate wards. Attention is centered on the possibility of the carrier agency, animate or inanimate, rather than on the atmosphere as such. As a recent speaker expressed a phase of it, the problem is one of wire screens more than of ventilation. It is, however, of interest to learn something regarding the prevalence of bacteria in the air of different regions. A recent systematic study by the New York State Commission on Ventilation[1] showed clearly that the air of occupied spaces such as factories, schools and offices contains more bacteria than that of open spaces in the city or country. It is significant that the increase in streptococci manifests itself promptly in the occupied spaces. Whereas in country or city air there are rarely more than ten of this group of micro-organisms per hundred cubic feet of air, the number may rise to more than forty in factories. There is a rapidly growing tendency, supported by much convincing evidence, to teach that ventilation has nothing whatever to do with either the transmission of the so-called "air-borne" diseases or the lessening of their transmission. Furthermore, the opinion is freely expressed that transmission by way of the air is of infinitely less importance than transmission by inanimate and animate carriers that have been in intimate contact with patients.[2] Nevertheless, the indisputable facts just cited regarding the comparative distribution of certain objectionable bacteria in occupied spaces still deserve respectful consideration in relation to the problems of public health.

MEDICAL MEN AS COLLEGE PRESIDENTS—WILBUR PRESIDENT OF LELAND STANFORD

In three instances during the last few years, medical men of national reputation have been selected as presidents of prominent universities. In 1913 Dr. Frank Fairchild Wesbrook was elected president of the newly established University of British Columbia at Vancouver. Dr. Wesbrook had for several years been dean of the University of Minnesota, College of Medicine and Surgery, where he had shown a remarkable administrative ability. He had been professor of pathology and bacteriology in that institution for eighteen years, and was also a prominent figure in various public health movements, having been elected president of the American Public Health Association in 1905. At the beginning of the present year Dr. Livingston Ferrand was elected president of the University of Colorado. Dr. Ferrand for several years had been the executive secretary of the National Association for the Study and Prevention of Tuberculosis, and the marked success of this body was largely due to his ability as an organizer and administrator. Word has now been received that Dr. Ray Lyman Wilbur of San Francisco has been elected president of Leland Stanford Junior University, a chair occupied until 1913 by David Starr Jordan and since that time by John Casper Branner. The latter accepted the chair with the understanding that a successor should be elected in 1915, when he would have reached the retiring age of 65. Dr. Wilbur has demonstrated a remarkable ability as an organizer and as an administrator, having occupied the deanship of Leland Stanford Junior University, School of Medicine, since 1910, and the chair of medicine since 1899. He has taken an active part in the discussion of educational problems during the last several years. The selection for the presidency of prominent universities of men who are familiar with the problems of medical education and public health gives promise of a deeper interest in those problems by the educators of the country and will lead to a wider dissemination among the people generally of information in regard to hygiene and the prevention of disease. The experience these men have had in medical affairs, furthermore, gives them a broad view which will aid them in their administrative duties, particularly in the last two universities, which have medical departments.

PUBLIC HEALTH PROPAGANDA IN CHINA

The spread of the educational propaganda in public health work is strikingly illustrated in articles in the July number of the *China Medical Journal,* the greater part of which is given up to a discussion of this subject. Dr. Arthur Stanley, health officer of China, discusses "How to Initiate Public Health Work in Chinese Cities"; Dr. Wu Lien Teh, medical officer to the Foreign Office of Harbin, "Awaking the Sanitary Conscience of China"; Dr. E. S. Tyau, "A Plea for a Campaign of Public Health Education in China," and Dr. W. W. Peter of the Council on Public Health, "Public Health Education in China." Evidently the problems, difficulties and remedies adopted differ surprisingly little from those in our own country. Dr. Teh, for instance, after enumerating the many insanitary customs of the Chinese, says that they have for centuries practiced a system of simple hygiene peculiarly adapted to their needs. They wear suitable clothes for summer and winter, drink tea, avoid alcohol, eat cooked food and are moderate in many things. The result is that many diseases frequently occurring in Europe and America are distinctively uncommon in China. Instruction through the public schools and the churches is recommended; and also the organization of the women of the community for public health work. Educational exhibits of photographs, charts and instructions in Chinese are also used. The Chinese prototype of the "Save the Babies" pamphlet, printed in large quantities and distributed by the American Medical Association, is an exhibit chart in Chinese characters entitled "Shelter the Babies." Wire screening, fly traps, "patent medicine" advertisements, lantern slides, illustrations and other educational methods are being used. Bulletins are being sent to the teachers and pupils in mission schools, and every effort is being made to develop public health sentiment among the people. Certainly the gospel of good health is being widely preached when China begins to educate her millions.

A NATIONAL ENTRANCE EXAMINATION BOARD

During the week beginning June 19, 1915, under the auspices of the College Entrance Examination Board, 4,941 high school students were examined for entrance to eighty-two colleges and universities, of which thirty-two had medical departments. The examination covered seventeen subjects, for each of which three examiners had been selected, two being teachers in colleges and one a teacher in a secondary school. Altogether, therefore, there were fifty-two examiners, experts in their various subjects, who prepared the questions. The examinations were held simultaneously in thirty-eight states of this country, altogether in 154 different localities. The examination in each city was given at some educational institution, under supervisors and proctors selected by the secretary of the board. After the examination papers were completed, they were placed in charge of readers who did the grading. This year 166 readers were appointed, and of these, seventy-nine were representatives of colleges and eighty-five were representatives of secondary schools. In fees from candidates examined, $26,090 was received. For the preparation of the questions and other services the fifty-two examiners were paid $1,719 for salaries and expenses; for grading the papers, the 166 readers were paid $15,254 for salaries and expenses; for supervision of the examinations and for proctors, $3,650 was expended for salaries and expenses.[1] Here we have an examining board which for fifteen years has been conducted on a nearly self-supporting basis; which gives a thorough, reliable examination recognized — so far as we have been able to learn — by all colleges and universities. The board will arrange to conduct its examinations in any locality where five or more applicants can meet, thereby making them convenient for the student, who is free to seek admission to any college of his choice. Since the opportunity to take a well-conducted and reliable examination has thus been made so convenient, one wonders why all examinations in high school branches could not be conducted by this board. It would do away at once with confusion of standards and ratings resulting from the multiplicity of agencies now conducting "examinations" and issuing "certificates," the value and reliability of which are so uncertain. Here is an examination of known quality to replace uncertainties. Here, indeed, seems to be the solution of what is still one of the gravest problems of medical education — the securing of a thorough and reliable "equivalent" credential by those who have not been fortunate enough to complete courses in standard high schools or colleges whereby they could be excused from examination. Meanwhile, the organization and methods of the College Entrance Examination Board also furnish many practical suggestions which would be of value if the organization of other examining boards, national in scope, should be deemed advisable.

---

[1] Those interested in preliminary examination should read the Fifteenth Annual Report, which may be obtained from the secretary of the board, Dr. Thomas S. Fiske, Substation 84, New York City.

RABIES

The modest report[1] of the results of antirabic inoculation at the Pasteur Institute in Paris for 1914 is another reminder that this classic therapeutic procedure of the great French scientist has brought down the mortality of a dreaded danger almost to the vanishing point. It is safe to say that the probable mortality of the usual run of cases untreated by the Pasteur method would be far more than 16 per cent. In 1912, 1913 and 1914, there were treated successively, *in the original institute*, 395, 330 and 373 persons, without a single death. Could anything speak more eloquently of this invaluable contribution to mankind which has made it possible to save, literally, thousands of persons in the few years that have intervened since those eventful days in the summer of 1885 when the first patient received antirabic treatment in Paris? The fact that among human beings rabies is no longer common in civilized countries, because early preventive antirabic treatment is successfully applied in almost all infected subjects, ought not to be allowed to obscure the danger of infection which is still possible. A remark attributed to Pasteur and reported by Sir Victor Horsley before the Royal Commission on Vivisection in 1907 deserves to be quoted because of the still timely advice contained in it. "The freedom of England from rabies," said Horsley, "I take to be one of the great achievements of modern science: and we owe it entirely to M. Pasteur. . . . I had the honor of acting as secretary of a committee that was appointed by the government to inquire into M. Pasteur's treatment; and, when the committee was in Paris, M. Pasteur said to us, 'Why do you come here to study my method? . . . You do not require it in England at all. I have proved that this is an infectious disease: all you have to do is to establish a brief quarantine covering the incubation period, muzzle all your dogs at the present moment, and in a few years you will be free.'" The passing of the muzzling act and rigid legislation regarding the importation of dogs have caused a practical eradication of rabies in England. This was largely due to Pasteur's influence. Shall other civilized countries continue to neglect the obvious duty of stamping out rabies, and to require the maintenance of special institutes to provide for emergencies largely within the control of suitable preventive measures?

Maternal Impressions.—Maternal impressions and prenatal culture are not facts, but superstitions. To realize their falsity, no deep researches are necessary; nothing more is needed than a knowledge of some elementary facts and scientific thought about those facts.—*Jour. Heredity.*

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST; SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

DELAWARE

Physician Receives Verdict.—Dr. Evan W. Roberts, Milford, received a verdict of $2,000 against the Queen Anne Railroad, October 23, on account of injuries received when the automobile in which he was riding was struck by a train.

New State Society Officers.—The one hundred and twenty-sixth annual meeting of the Delaware State Medical Society was held in Wilmington, October 12, and the following officers were elected: president, Dr. George I. McKelway, Dover; vice president, Dr. James T. Massey, Viola (reelected); secretary, Dr. George W. K. Forrest, Wilmington (reelected); and treasurer, Dr. Samuel C. Rumford, Wilmington (reelected). The society approved the establishment of a national board of medical examiners. The subject of the presidential address delivered by Dr. Henry W. Briggs, Wilmington, was "The Physician, Past, Present and Future."

DISTRICT OF COLUMBIA

Washington Health Rules.—A booklet entitled Washington Health Rules has been published by the Association for the Prevention of Tuberculosis of the District of Columbia. The book contains twelve chapters, each of which is based on one of the health rules first promulgated by the association in 1912. The booklet is to be placed in the hands of each teacher in the public schools.

The Evolution of Man.—Dr. Ales Hrdlicka, curator of anthropology in the National Museum, delivered an address before the Anthropological Society of Washington and the Medical Society of the District of Columbia, October 13, in the medical school building of George Washington University on "The Evolution of Man in the Light of Recent Discoveries and Its Relation to Medicine."

Personal.—Dr. Howard Fisher, Washington, has returned after several months of hospital work in Europe.——Dr. and Mrs. James McKee celebrated their golden wedding anniversary, October 12. Dr. McKee is a Civil War veteran and has been connected with the medical division of the Pension Bureau since 1902.——Dr. Lewis J. Battle, chairman of the medical committee which served during the Grand Army of the Republic encampment, was the guest of honor at a banquet given by the medical men on his committee, October 7. Nearly 100 local practitioners were present and Dr. A. Barnes Hooe presided as toastmaster.——Dr. Frank Fremont-Smith, while examining a revolver at his summer home at Bar Harbor, Me., was accidentally shot, but is making satisfactory progress toward recovery.——Dr. George von Pullinger Davis, Washington, has gone to Salt Lake City as professor of physiology in the University of Utah.——Under the auspices of the National Society of Keep Wells, Dr. William T. Davis, Washington, gave a talk in the parish hall of St. John's Church, October 29, on "The Eye—Its Uses and Abuses."

FLORIDA

Object to Occupation Tax.—Physicians of Tarpon Springs have asked the city council to exempt them from the medical license fee of $10 per annum, stating that they do sufficient charitable work to warrant this exemption.

Health Trains Soon in Operation.—The three Pullman cars which are being fitted up for the traveling exhibit of the State Board of Health are ready for the installation of the apparatus and should be ready to start on the first trip early this month. Every town in the state will be visited and demonstrations and lectures will be given.

Hospital Notes.—On September 27, application was made to the judge of the Circuit Court of Escambia County, for a charter incorporating the Pensacola Hospital.——The Pensacola Hospital was opened to receive patients, September 1, and is now in full operation.——The School for Nurses of the Pensacola Hospital was opened September 15. Twenty nurses have been enrolled for service, five of whom are pupil and nine probation nurses.——The Clearwater Hospital, built by the city of Clearwater at an expense of $25,000, and having an endowment of $100,000 given by Mr. M. F. Plant, will be opened this month.——Physicians and surgeons of Marianna and Jackson County are making plans to build a hospital in Marianna during the coming winter.——The City Owned Hospital Association was organized at Jacksonville, September 6, Dr. Mark B. Herlong being elected president, and Dr. Marvin H. Smith, secretary.——Plans for the Miami hospital have been approved by the directors and there is $50,000 available for construction, $30,000 of which is in the possession of the city, while bonds have been issued for the remaining $20,000.

ILLINOIS

Citizen Gives Medical Books.—A citizen of La Salle has made a gift to the Public Library of $10,000, the interest of which is to be used for buying medical books.

Superintendents Association Meets.—At the annual meeting of the Association of Superintendents of State Charitable Institutions held in Springfield, October 12, Dr. Henry J. Gahagan of the Elgin State Hospital was elected president, and Dr. William F. Schulz, superintendent of the Chicago Industrial Home for the Blind, secretary.

Foot and Mouth Disease.—The state supreme court has now issued an opinion, October 27, that the state board of live stock commissioners have the right to kill all cattle afflicted with foot and mouth disease. The state veterinarian, however, says that if the herd of Mrs. Scott Durand is found free of the disease, they will be spared.——Foot and mouth disease was discovered in five new localities in McDonough County, October 27, and on the following day, 108 head of cattle and 500 hogs belonging to Samuel Dougherty, and valued at $28,000, were slaughtered.

Scarlet Fever.—At Decatur an extensive epidemic of scarlet fever has existed for some time. On account, it is said, of the failure to cooperate on the part of the medical profession, the local health authorities have been unable successfully to cope with the epidemic. At the meeting of the city council, October 13, it was voted to employ an expert physician to assist in eradicating the disease. For this position, Dr. H. L. Wright, formerly of the health department of Chicago, was suggested and authority was given to employ Dr. Wright.——Dr. Charles E. Crawford of the State Board of Health has ordered school, churches and motion-picture shows in Pecatonia closed on account of the increasing number of cases of scarlet fever in the city.

Personal.—Dr. John R. von Achen, Peoria, has been appointed deputy coroner of Peoria County.——Dr. Joseph P. Comegys, Rock Island, fractured his arm while cranking his automobile, October 27.——Dr. Ben B. Griffith, secretary of the State Board of Health of Springfield, has resigned.——Dr. John D. Mandeville, Champaign, is reported to be seriously ill in the Julia F. Burnham Hospital in that city.——Dr. Wiliam S. Holliday, Monmouth, was operated on for appendicitis at the Monmouth Hospital, October 23, and is reported to be doing well.——Drs. William H. Maley and William O'R. Bradley have been appointed local surgeons of the Illinois Traction System in Galesburg.——Dr. Oliver O. Dyson, state veterinarian, who has been ill with typhoid fever at his home in Springfield, is convalescent and has returned to his duties, including the supervision of the state fight on foot and mouth disease.

Chicago

Personal.—Drs. Joseph M. Blake and George R. McAuliff were painfully injured in a collision between the automobile in which they were riding and an auto truck, October 25.

Psychopathic Clinic.—The first municipal psychopathic clinic was opened this week at the Iroquois Memorial Hospital under the direction of Dr. Harold N. Moyer, head of the psychopathic division of the new school of sanitary inspection of the department of health.

t) **Physicians' Club Meets.**—At the first meeting of the sea-
rec of the Physicians' Club of Chicago at the Hotel Sherman,
of th ber 19, Municipal Judge Jacob H. Hopkins, John L.
exhibi nan, superintendent of the Bridewell; Emory Sanford
Chinese he architect, and Miss Harriet Vittum of Northwestern
"Save the ty Settlement, were the speakers.
and distrib al **Safety.**—Physicians interested in the forming
is an exhibit of th and safety of industrial establishments in the
ter the Babies. he City Club, October 15, for the organization
al Association of Industrial Physicians and
committee having this matter in charge is
J. Chase Stubbs, Harry E. Mock, Andrew

M. Harvey, Wilber E. Post, F. M. McCurdy, William C. Lucas and C. G. Farnum.

INDIANA

Chiropractor Fined.—It is reported that William H. Monks, a chiropractor, was fined $25 by a jury in the Indiana Circuit Court, recently, for practicing medicine without a license. It is stated the case will be appealed to the supreme court.

Personal.—Dr. Herbert M. Senseny has been appointed local surgeon for the Nickel Plate System at Fort Wayne.——Dr. John Richards, for fifty-three years a practitioner of Laud, celebrated his eightieth birthday anniversary, October 21.——Dr. John Herman Wylie and wife, formerly of Bluffton, sailed from San Francisco for China, November 6. Dr. Wylie's new post of duty will be in a hospital established in North China by the Rockefeller Institute.——Dr. John P. Franz, Indianapolis, was painfully injured in a collision between his automobile and a street car, recently.——Dr. Henry P. Metcalf, New Salem, was thrown from his automobile and seriously injured, recently.——Dr. Guy A. Schultz, Lebanon, has declined appointment as assistant surgeon to the National Soldiers' Home, Johnson City, Tenn.

MARYLAND

Faculty Changes.—At the meeting of the faculty of the School of Medicine of the University of Maryland, Drs. Ridgley B. Warfield, Gordon Wilson, William S. Gardner, Harry Friedenwald and Arthur M. Shipley were elected members of the executive committee; Dr. Randolph Winslow was elected president of the faculty; Dr. John W. Chambers, vice president; Dr. James M. H. Rowland, secretary, and Dr. Samuel K. Merrick, treasurer.

Personal.—Dr. Lewis C. Spencer and Dr. Martillus H. Todd of the American staff of surgeons at Pau Hospital base in France have returned to Baltimore. Both physicians were on the staff of the Johns Hopkins Hospital until their departure for Pau.——Dr. Marshall B. West, health officer of the first district of Baltimore County, is confined to his home in Catonsville with a badly infected hand. He is reported as being slightly improved.——Dr. William F. Lockwood has been selected as dean of the School of Medicine of the University of Maryland, succeeding Dr. R. Dorsey Coale, deceased.

To Fight White Plague.—Following discussions of the question of tuberculosis in Baltimore and the means needed to hold it in check, steps were taken recently at a meeting in the Medical and Chirurgical Faculty Building to organize physicians, nurses and social workers engaged in fighting tuberculosis not only in the city, but in the state. The meeting and the action that grew out of it were the results of an effort of those engaged in preventive and curative work among tuberculosis patients to bring about a standardization of methods and to facilitate exchange of data and thus minimize duplication. Dr. Henry Barton Jacobs, president of the Maryland Association for the Prevention and Relief of Tuberculosis, acted as chairman of the meeting and at its conclusion appointed a committee to elect officers and organize the new body, the committee being formed of the heads of the various medical and social organizations for the relief of this disease.

MICHIGAN

Municipal Hospital Opened.—The new Municipal Receiving Hospital at Antoine and McComb streets, Detroit, which has been erected at a cost of $250,000, was formally opened October 12. The building will accommodate 135 patients and will be under the charge of Dr. Leo J. Dretzka. The main objects for this hospital are the provision of a clearing house for emergency cases and of a psychopathic ward for the mentally disturbed.

Personal.—Dr. George A. Trueman was elected mayor of Munising, October 17.——The resignation of Dr. Marinus L. Holm, Lansing, as bacteriologist for the branch laboratory of the State Board of Health at Houghton, has been accepted.——Dr. Samuel E. Barnhart, Battle Creek, who was seriously injured, September 26, at Pomona, Calif., in a collision between his automobile and a railway train, the injuries including the fracturing of both arms and seven ribs, is reported to be convalescent and has returned to Battle Creek.——Dr. Albert F. Stone, Bay City, caught his left hand in the gearing of the self-starter of his automobile, September 30, sustaining injuries, which necessitated the amputation of the terminal phalanges of the first and third fingers.

MISSOURI

Recognition Withdrawn.—It is reported that the Missouri State Board of Health, by unanimous vote at a meeting held October 18, declared the University of West Tennessee Medical Department of Memphis an unaccredited medical college in the state of Missouri.

New Public Clinics.—Public clinics for diseases of the eye, ear, nose and throat and for genito-urinary diseases, have been recommended by Dr. Paul Paquin, director of public health of Kansas City. Both of these clinics will be held at the Waterworks Building.——The dental clinic is to be transferred to the Karnes School.

Personal.—Dr. John A. Pringle, assistant superintendent of the Springfield City Hospital, has been appointed temporary superintendent, succeeding Dr. Frank E. Chapman, resigned.——Dr. Lincoln C. Chenoweth, Webb City, has been elected a member of the Board of Control of the Jasper County Tuberculosis Sanatorium.——Dr. George I. Mays, Joplin, who has been seriously ill in St. Vincent's Hospital, New York City, is reported to be improving.——Dr. Vincil B. Janes, Cameron, was seriously injured in a railway accident near Sheldon, recently.

St. Louis

Clinic Club Organized.—The St. Louis Clinic Club was organized, October 12, with about twenty charter members. Dr. George Richter was elected president, and Dr. Frederick A. Baldwin, secretary treasurer.

Personal.—Dr. Ellen M. Osborn was thrown from her buggy, October 20, by a collision with a coal wagon, and suffered a fracture of the nose and severe contusions of the face.——Dr. Leo Loeb has been appointed professor of comparative pathology in the medical school of Washington University.——B. Landis Elliott, instructor in physiology in Washington University, is reported to be ill with trichinosis in Barnes Medical Hospital.

NEW YORK

Vassar College in Welfare Work.—The students of Vassar College have raised a fund of $1,200 to support a district nurse for the town of Poughkeepsie.

Personal.—Dr. Henry L. Elsner is ill at his home in Syracuse.——Dr. Andrew R. Ellis, Roxbury, has been obliged to give up his medical practice on account of ill health and has moved to Livingstonville.

Lectures on Oral Hygiene Discontinued.—The State Department of Health announces that as the legislature made no appropriations for the services of the two lecturers on oral hygiene hitherto attached to the staff of the department it is necessary to discontinue this valuable work.

Boarding Houses for Tuberculosis Patients.—The state aid charities association and the committee on the prevention of Tuberculosis of the charity organization society of New York City have prepared a list of country boarding houses for tuberculosis patients to which any one interested can have access.

Popular Health Lectures.—The first of a series of public health lectures which the Albany Medical College has offered to the public was given October 13 in the auditorium of the State Education Building, Albany, by Dr. Herman M. Biggs, health commissioner of New York, on "The Public Health Law of New York State."

Municipal Piggery for Saranac Lake.—The Saranac Lake Board of Health proposes to establish a municipal piggery in which to dispose of properly sterilized garbage from the village. It is believed that the piggery will produce a revenue that will pay for the cost of garbage collection. This experiment is attracting wide attention throughout the state.

New York City

Harvey Society Lecture.—The second lecture of the Harvey Society series given at the New York Academy of Medicine, November 6, at 8:30 p. m., is by Prof. A. J. Carlson of the University of Chicago on "Recent Contributions to the Physiology of the Stomach."

Dr. Goldwater Quits Health Department.—Dr. Sigismund S. Goldwater, who has been commissioner of health for the past two years, relinquished the duties of his office, November 1. Dr. Goldwater handed his resignation to the mayor, July 1, stating that he had accomplished about all that he could under present conditions and was desirous to return to his work as head of Mount Sinai Hospital. Dr. Haven Emerson, deputy health commissioner, will succeed Dr. Goldwater.

Loving Cup Given.—Dr. George Chaffee, Bay Ridge, founder of the New York and New England Association of Railway Surgeons, was presented with a handsome silver loving cup by the association at its twenty-fifth annual session, October 21. The cup bears the following inscription: "Presented to Dr. George Chaffee, Founder, Ex-President and Corresponding Secretary of the New York and New England Association of Railway Surgeons, by the Ex-Presidents in Grateful Recognition of Twenty-Five Years of Devotion and Loyalty to the Association, 1890-1915."

Personal.—Dr. Abraham Sophian has returned from Europe.——Dr. William J. Maloney, who was seriously wounded while serving with the British troops at the Dardanelles, sailed for home, October 23.——Dr. Frank D. Jennings, Bushwick, was assaulted near his home, October 20, and rendered unconscious. The reason for the attack is unknown.——Dr. Harold Kniest Faber, formerly of the Rockefeller Institute, has been appoined assistant professor of pediatrics at the Leland Stanford University, San Francisco.

Health Department Strengthens Patent Medicine Ordinance.—At its last meeting the board of health strengthened the Goldwater Formula Disclosure ordinance which is to become effective Jan. 1, 1916. The vital paragraph of the section read: "The names of the ingredients of every such medicine shall be registered in the department of health in such a manner as the regulations of the board of health may prescribe." It was felt that this was not sufficiently clear and in addition certain patent medicine interests having declared their intention of disregarding the ordinance, the above paragraph has been amended to read: "The names of all ingredients to which the therapeutic effects claimed are attributed and the names of all other ingredients except such as are physiologically inactive shall be registered in the department of health in such a manner as the regulations of the board of health may prescribe."

NORTH CAROLINA

Leeward Islands Want Medical Men.—The government of the British West Indies has been advertising in North Carolina papers during the past few weeks, for capable young medical men to serve six months or longer in medical service in the Leeward Islands. These positions offer admirable opportunities for the study of tropical diseases.

Enforcement of Vital Statistic Laws.—The State Board of Health has placed a special agent in the field who will devote his attention to securing the enforcement of vital statistic laws. His work will be chiefly to impress on physicians, undertakers and others, the necessity of filing their reports of deaths and births promptly. In other words, this will be a campaign of education.

Hospital Notes.—The physicians and business men of Greensboro met October 5 to formulate plans for the establishment of a new general hospital in the city.——The Twin City Hospital Association, Winston-Salem, is endeavoring to raise an endowment fund of $100,000 for a city hospital, and the association will contribute $10,000 of this amount, provided the city secures the balance of $90,000.

Personal.—Mrs. R. S. Boyers has been elected municipal health officer of High Point and Mrs. J. E. Sells, health officer of Winston-Salem.——Dr. Albert Anderson, superintendent of the Raleigh State Hospital, has returned after an extended tour of inspection of psychopathic institutions in the East.—Dr. Edward C. Register, Charlotte, has been elected president of the American Medical Editors' Association.

PENNSYLVANIA

State Board Examination.—The State Bureau of Medical Education and Licensure announced, October 27, that medical examination for state licenses would be held at Philadelphia, January 18 to 20.

Laboratory for Allegheny General Hospital. — It is announced that the children of the late William H. Singer, Pittsburgh, will erect, equip and endow in his memory at a cost of $400,000, a research laboratory in connection with the Allegheny General Hospital.

Tuberculosis Home Opens.—The new buildings of the department for the treatment of tuberculosis of Allegheny County at Woodville, Pittsburgh, were dedicated September 2. The camp is situated on a hill about a mile from the main buildings of the county home.

Philadelphia

Medical Institutions.—The department for diseases of the chest of the Jefferson Hospital, 236 and 238 Pine Street, has opened a pay ward to a limited number of male patients suffering from pulmonary tuberculosis.

Personals.—Dr. Luther C. Peter has been elected associate professor of diseases of the eye in the Philadelphia Polyclinic and College for Graduates in Medicine.——Dr. Charles A. E. Codman, president-elect of the Medical Society of the State of Pennsylvania, was tendered a dinner and reception by the West Philadelphia Medical Association at Hotel Rittenhouse, October 26. Dr. John Welsh Croskey, president of the society, was toastmaster and spoke of the movement under way to make Philadelphia a world medical center and urged those present at the dinner to work toward this end.

WEST VIRGINIA

Trachoma Hospital Opened.—Surg. John McMullen, U. S. P. H. S., opened a trachoma hospital at Welch, October 4, with accommodation for twenty patients, and it was almost filled from the start.

Smallpox.—In a bulletin of the West Virginia Public Health Council, Dr. S. L. Jepson, State Health Commissioner, says, that in the past three years West Virginia has had 7,000 cases of smallpox and so far as has been ascertained, only 2 per cent. of these persons had ever been vaccinated. It is said that the most intense prejudice against vaccination exists in all parts of the state, based on false reports and erroneous beliefs as to the injurious results alleged to follow vaccination. Among the foolish and misleading reports was one that a number of patients had been taken to Wheeling to have their arms amputated as a result of vaccination. This report, Dr. Jepson says, was entirely baseless, and in more than forty years of experience in the practice of medicine, he had never seen as a result of vaccination anything worse than a sore arm. He calls attention to the vast financial loss to the state on account of this ignorance and prejudice which has resulted in the expense of quarantine and caring for the 7,000 cases during three years. Local health officials have been instructed by the State Health Council no longer to establish quarantine, but merely to placard the houses containing smallpox patients. It is said that if unvaccinated persons persist in refusing such a simple but positive preventive, there is no reason why the people in general should be taxed rigidly to quarantine and guard houses for their sole benefit.

WISCONSIN

Kenosha Sanatorium Nearly Ready.—The Kenosha County Sanatorium, which is being erected on an 87-acre site at a cost of $32,000, will be ready to receive patients December 1. The institution will accommodate twenty-four patients.

Sterilizing Law to Be in Effect.—The Wisconsin sterilization law, passed by the legislature of 1913, will, it is said, be put into actual operation by the State Board of Control in November when twenty-four inmates of the Home for the Feeble-Minded, Chippewa Falls, will be operated on. The work, which is being carried on in an effort to cope with the problem of stopping the propagation of children by feeble-minded and degenerate parents, will be continued as fast as circumstances will permit.

War on Quacks.—A war on "quack" doctors and "fake" medical institutes in Milwaukee has been begun. Arrangements have been made by the health department for free consultation and advice in connection with venereal diseases for all those who apply at the bacteriologic laboratory of the health department in the city hall. Dr. E. V. Brumbaugh of the health department will be in attendance. Following the plan adopted by New York City, no remedies will be prescribed, but those asking advice will, after the diagnosis is made, be urged to consult reputable physicians for treatment.

CANADA

Saskatchewan Hospital News.—A medical staff will be organized in connection with the Regina Grey Nuns' Hospital. A new nurses' home has recently been completed and will shortly be occupied. The necessary funds for the Saskatchewan Hospital Unit are now nearly in sight and only final instructions are awaited from the Imperial Government before proceeding with the work of organization.——The Isolation Building in connection with the Regina General Hospital is to be used for a nurses' home until a new building is completed.

Defectives in Toronto.—Dr. Charles K. Clarke, superintendent of the Toronto General Hospital, has dealt with 1,000 mental defectives, a great percentage of whom are juvenile criminals, at his clinic for feeble-minded children. It has been impossible to confine the clinic to children and he now treats adults. All efforts to obtain assistance from the provincial government and the Toronto civic authorities having proved fruitless, no very great results can be expected. Dr. Clarke states he has barely touched on the great number of criminally disposed feeble-minded adults and children. Of those treated during the past year only a few have reached institutions owing to the congested condition of all the provincial institutions for the insane and feeble-minded. He states that juvenile crime in Toronto has increased 100 per cent.

Personal.—Dr. Thomas C. Brandon, Watford, Ont., has been appointed surgeon in the British service and will leave in a few days for the front.——Dr. James Gow, Windsor, was painfully injured in a collision between automobiles, October 1.——Dr. Joseph A. Andrews, Indian Harbor, Labrador, reached New York, October 1, and reports that an epidemic of beriberi has existed among the natives of Indian Harbor.——Sir Wilfred Grenfell of Labrador was one of the speakers at the Interdenominational Medical Missionary Conference at Battle Creek, November 2 to 5.——Lieut.-Col. Henry R. Casgrain, Windsor, Ont., in charge of No. 3 Stationary Hospital at Alexandria, Egypt, reported seriously ill, is now on his way back to England. Just before sailing news of his condition was reassuring.——Drs. Vanwycke and Crompton of Toronto were added to the staff of the University of Toronto Base Hospital as captains before the unit sailed for the Mediterranean on October 16. Lieut.-Col. P. Walter H. McKeown of Toronto did not accompany the hospital but remained in England as president of a medical board to advise the pension board. Dr. Thomas G. Brodie returned to Toronto; Dr. Alfred H. W. Caulfield remains in London, and Dr. J. George A. Campbell who is ill will remain in England for a month or two.——Dr. Harry Morell, editor of the *Western Medical News*, Regina, Sask., is at present attached to the Canadian Red Cross, Duchess of Connaught Hospital, Taplow, Bucks, England. He is in charge of the pathologic department. The hospital has accommodation for 1,000 patients.

GENERAL

McCoy to Succeed Anderson.—Surgeon-General Rupert Blue, U. S. P. H. S., has announced the appointment of Surgeon George W. McCoy as director of the Hygienic Laboratory, Washington, succeeding Surgeon John F. Anderson who recently resigned to accept private employment. Dr. McCoy is at present in charge of leprosy work at Molokai, Hawaii.

Leprosy in the United States.—In an address made by Dr. William A. Pusey, Chicago, before the Chicago Medical Society, October 27, he stated that there are about 500 cases of leprosy in the United States, of which 275 were in Louisiana, 100 in New York City, 50 on the Mexican frontier and 5 in Chicago. He advocates the establishment of a general leprosarium.

Railway Surgeons Hold Meeting.—At the annual meeting of the Railway Surgeons' Association of Pennsylvania Lines East, in New York City, October 18 to 20, the following officers were elected: president, Dr. James B. Siggins, Oil City, Pa., vice president, Dr. Charles J. Roberts, Berwyn, Pa.; secretary, Dr. Amos W. Colcord, Clairton, Pa., and treasurer, Dr. Joseph C. Egbert, Wayne, Pa.

Accident Board Officers Elected.—At the meeting of the National Association of Industrial Accident Boards and Commissions, held in Seattle, October 2, Floyd L. Daggett, Olympia, was elected president; Wallace D. Yaple, Columbus, Ohio, vice president, and L. A. Tarrell, Madison, Wis., secretary treasurer. It was decided to hold the next annual meeting in Columbus, Ohio, April 25 to 28, 1916.

Pellagra Conference.—At the third triennial conference of the National Association for the Study of Pellagra held in Columbia, S. C., October 21 and 22, the following officers were elected: president, Capt. Joseph F. Siler, M.C., U. S. Army; vice presidents, P. A. Surg. R. M. Grimm, U. S. P. H. S., and Henry W. Rice, Columbia, S. C.; secretary, Dr. James W. Babcock, Columbia, S. C., and treasurer, Dr. James A. Hayne, Columbia, S. C.

Dakota and Montana Physicians Unite.—Physicians of western North Dakota and eastern Montana met in Williston, N. D., October 19, and organized the Kotana Medical Association, including Divide, Williams, McKenzie and the western half of Mountrail counties, as well as the Montana counties adjoining North Dakota. Dr. Melverton E. Trainor was elected president; Dr. Edward J. Hagen, vice president, and Dr. Frank W. McManus, secretary-treasurer, all of Williston. The next session of the association will be held in Williston.

Social Hygiene Problems Discussed.—At the annual meeting of the American Social Hygiene Association held in Boston, October 8, Pres. Abram W. Harris, Northwestern University, was elected president in the place of Dr. Charles W. Eliot, Cambridge, Mass.——The Central States Conference on Problems of Social Hygiene, under the auspices of the association, was held in Chicago, October 25 and 26, at which the subjects discussed were "The Social Hygiene Movement," "The Education and Moral Aspects of the Social Hygiene Movement," "Public Health," and "The Aspects of the Problem of Prostitution."

Prevention of Infant Mortality.—The preliminary program for the sixth annual meeting of the American Association for the Study and Prevention of Infant Mortality, to be held in Philadelphia, November 10 to 12, is most attractive. The general subjects discussed have been already noted in The Journal. The Bellevue-Stratford Hotel will be the general headquaters and here all the sessions, with the exception of the joint session with the Philadelphia County Medical Society on Economic Aspects of Infant Welfare, will be held. This latter session will convene at the College of Physicians, November 10 at 8:15 p. m.

Bequests and Donations.—The following bequests and donations have been announced:

Alice Home Hospital, Lake Forest (Ill.), and Lake Bluff (Ill.) Orphanage, each $5,500, the proceeds of the Lake Forest Country Fair.

Chicago Home for the Friendless, residuary beneficiary, and Eastern Maine General Hospital, Bangor, Maine, $5,000, by the will of Luther H. Pierce, Chicago.

Aid Association of the Philadelphia County Medical Society, $5,000, by the will of Dr. Eugene I. Santree.

Cancer Commission of Harvard University, the income from $25,000, by the will of William Endicott.

Cancer Commission in the City of Boston, $23,250, by the will of Julia M. Moselet.

Associated Jewish Charities and Jewish Consumptives Relief Society, Chicago, each $10,000, by the will of Bernard Baumgarden.

University of California, Berkeley, a donation of $10,000, as an endowment for a bed in the University Hospital of the University California Medical School, San Francisco, in memory of his wife, the late Belle Garber Pellache, and her brother, the late Joseph B. Garber, by Whitney Pellache, New Haven, Conn.

Tuberculosis Week.—As has been previously announced by the National Association for the Study and Prevention of Tuberculosis, Tuberculosis Day will this year be expanded into Tuberculosis Week, taking place December 6 to 12. For this week the National Association suggests three special days—National Medical Examination Day, December 8; Children's Health Crusade Day, December 10, and Tuberculosis Sunday, December 12. Circulars describing the general scope, plan and aim of the movement have been prepared and are sold by the National Association at 15 cents per 100. Sermon outlines have also been prepared and are sold at 25 cents per 100. It is suggested that these circulars be placed in the hands of teachers, ministers and others. A special circular on Medical Examination Day will be issued later and also some special literature on Children's Crusade Day. It is said that the object of the National Medical Examination Day is to secure the interest of physicians, employers of large groups of labor and lastly workingmen of all kinds. It is not hoped to have everyone examined on this day, but the object is to arouse interest so that people will be set to thinking about periodical medical examinations. It is suggested that the interest of physicians should be aroused by having the matter presented in the local medical society, where, if the general plan is approved, a wholesale rate of examination during a stipulated period might be fixed at $2.50 to $3, this examination to include a complete physical examination and such bacteriologic and chemical analysis as may be necessary. In Michigan, recently, it is said, at the request of the governor, nearly 500 physicians participated in Tuberculosis Day, making a large number of free examinations of tuberculous patients.

FOREIGN

Typhus in Australia.—According to a dispatch from Melbourne an epidemic of typhus fever has broken out in Victoria, Australia, where 447 cases have been reported with 144 deaths.

Nobel Prize to Vienna Physician.—It has been decided to award the Nobel prize for 1914 to Dr. Robert Bárány of the University of Vienna, on account of his work on the physiology and pathology of the ear.

Wood Alcohol Kills.—In a telegram from Berlin of October 18, it is stated that of 100 workmen, who while shipping wood alcohol from Nijni-Novgorod, Russia, opened a barrel and drank from it, twenty are dead and the remainder seriously ill.

Yellow Fever.—On October 5 it was reported that a young engineer had died from yellow fever in the Ancon (C. Z.) Hospital. The disease was contracted in Colombia.——Under date of October 27, it was reported that yellow fever is epidemic in Buena Ventura, Colombia.

WAR NOTES

Harvard Hospital to Be Continued.—Dr. E. H. Nichols, who organized the Harvard British Hospital at the front, announces that it will be maintained for another year and asks for applications from surgeons, physicians, dentists and nurses who are willing to serve with another Harvard Surgical unit in a British hospital. Transportation charges will be paid both ways and the pay will be the regular army rates with additional allowances. Preference will be given to Harvard medical men and young graduates at hospitals. The term of service will be at least six months. Application should be made to H. H. White, University Press, Cambridge, Mass.

Typhoid Mortality Reduced by Inoculation.—Dr. Leo Bernard reports that out of 800 cases of typhoid fever in French soldiers which he studied, the mortality of those who had been given the antityphoid inoculation was only 5½ per cent., while among the unvaccinated it was 17 per cent. He believes that if the triple inoculation had been made as in this country, the death rate would have been much lower.

American Physicians Decorated.—It is reported from Nish that Crown Prince Alexander of Serbia has decorated forty-three American physicians and sanitary engineers representing the Rockefeller Foundation and the American Red Cross, in recognition of their services in checking the typhus epidemic in Serbia.

Personal.—Dr. B. W. Caldwell and other physicians of the American Red Cross contingent from Serbia passed through Rome, October 29, on their way to Germany by way of Switzerland, to assist in the care of Russian prisoners on German soil.——Drs. Edward Stewart, Ralph W. Mendelson and Stanley Osborn, members of the staff of Lady Paget's Hospital at Uskub, Serbia, are believed to have been captured by the Bulgarians.——Drs. Taylor Jones, Thomas W. Jackson and George W. Mellon, who have been on duty in Serbia, and Dr. M. H. Todd, who has been on duty in a war hospital in France, reached Boston from Europe, October 21.——Drs. W. M. Lacy, W. A. Lane, W. J. Dodd, R. R. Sattler, Channing Simmons and Paul Withington, who went abroad with the Harvard unit, reached New York, October 19.

BERLIN LETTER

Berlin, Oct. 5, 1915.

Personal

Prof. Adolf von Baeyer, the father of German chemistry, will celebrate his eightieth birthday, October 31. With the beginning of the present semester he retired from his professional duties. He was appointed von Liebig's successor at the University of Munich in 1875, and for forty years he has been actively engaged in carrying on the work begun by von Liebig. Baeyer had much to do with the advancement of chemical knowledge in Germany; in fact, to him is due the credit of having placed it on the high plane it now occupies. Many of our best chemists have been trained under Baeyer. Among these one might mention Emil Fischer and Richard Willstätter; the latter probably will be Baeyer's successor. Baeyer discovered artificial indigo, a discovery on which rests the enormous development of the German dye industry. No other scientific discovery has ever led to such enormous financial and commercial advancement as the investigations made by Baeyer in 1865, which led to the discovery of indigo.

Reorganization of the Berlin Health Department

For many years the Berlin Medical Society has asked that the administration of the local health department be in keeping with the increase in population and the demands of present-day hygiene. The authorities have now met this demand by making provision for the creation of a city health bureau whose personnel is sufficient assurance for the proper administration of health laws. Nurslings, schoolchildren and recent graduates will receive such attention as should be given them by an adequate health department. Suitable provisions have also been made for the control of tuberculosis, alcoholism, venereal diseases and for the regulation of all hygienic matters pertaining to light, air, water, sewerage, food, housing, etc., the prevention of epidemics, disinfection, and the control of the sanitation of all municipal institutions. The municipal inspection bureau, administered until recently by the late Professor Proskauer, was placed under the jurisdiction of the health department. This department is not under the charge of a director, but of a committee or bureau, the president being the city physician, who is also the chairman of the health board. The health bureau is divided into a medicinal and a social hygiene division. The director of the latter is Professor Grotjahn, a man who has distinguished himself in this field. His writings on social pathology are well known. The director of the medicinal division has not been appointed. The health board has complete control of all health matters, and its decisions are final. All matters pertaining to health, hygiene and sanitation must be referred to this board or bureau. The city physician may attend the meetings of other bureaus in which health questions are under consideration, and participate in the work. He is also privileged to inspect all institutions concerned with hygienic work. He must be kept advised of any health activities participated in by other bureaus, and receive timely notice of all meetings at which such questions will come up for discussion, so that he may make arrangements to be present in person or by proxy.

Infant Mortality Among the German Nobility During the Nineteenth Century

Professor Schlossmann, director of the Children's Clinic in Düsseldorf, has made a study of infant mortality in the reigning families of Germany. His figures show that there has been a consistent and steady lowering of the infant mortality in each decennial period from 1800 to 1900. From 1800 to 1810 the death rate was 13.3 per cent.; in 1850 it was only 6.6 per cent., and in 1870 it was only 3 per cent. Among the older children, those under 14 years, the death rate during the first decade was 24.1 per cent., and in the last decade it was 8.6 per cent. In some families the mortality was extraordinarily high. The highest mortality was found in the house of Nassau. It was 35.1 per cent. In the house of Anhalt it was 30.7 per cent. among all the children, and 23 per cent. among the nurslings. Liechtenstein had only 2 per cent. mortality among its nurslings, and Bavaria 9 per cent. total children's mortality. The conclusion to be reached as the result of these observations is that the mortality among the children of the nobility today is much lower than it was a hundred years ago, and Professor Schlossmann is convinced that the progress made in hygiene is bound to lower these mortality figures considerably, not only among the nobility but among the populace in general. The regulation of infant feeding and the improvements made in housing are the two prime factors concerned in this reduction of the mortality. Schlossmann's findings are in accord with those published some time ago by Max Kemmerich, who showed that the duration of life is greater and the mortality lower among the royal families than it was a hundred years ago. This is also true of the people in general. Kemmerich concludes, therefore, that the oft-made statement that cultural and economic success lead to racial degeneration is wrong, and that the opposite is true.

PARIS LETTER

Paris, Oct. 7, 1915.

The War

TREATMENT OF ARTICULAR WOUNDS

This was the subject of an interesting discussion at the last session of the Réunion médicale de la IV-e armée. Dr. H. Fresson discussed particularly penetrating wounds of the knee. Care must be taken to avoid death, amputation and ankylosis. Early operation should be the rule in all penetrating wounds of the knee joint, without exception when there is a projectile or foreign body in the wound. Injections of iodoformized ether may be utilized in the exceptional cases of small penetrating wounds without any foreign body or in cases in which penetration is doubtful. This method, without other procedure, has given Fresson three recoveries. Simple arthrotomy is a classical bilateral arthrotomy with deep, long incisions to reach all the pockets; posterior drainage is thus avoided. Gauze drains dipped in iodoformized ether are placed transversely and renewed each day. A plaster and metal splint is placed in position immediately after the operation. During the following period, it is necessary to guard closely against the possibility of purulent fistulas, which must be eradicated, especially on the side of the popliteal fossa. Horseshoe arthrotomy with section of the patellar tendon is indicated (1) in cases of fracture of the patella necessitating an operation on that bone; (2) when bilateral arthrotomy will not give an opportunity to reach the foreign body; (3) when the classic arthrotomy will not be sufficient to arrest the evolution of the arthritis.

Attempts at flexing the knee should be begun as soon as possible. After the operation, the treatment demands great care. The results will be good in proportion as the operation has been performed early.

Dr. Anselme Schwartz, agrégé professor at the Faculté de médecine de Paris, and surgeon of the hospitals, divides articular wounds into three classes from the therapeutic point of view: (1) articular fractures; (2) articular wounds without osseous lesion; (3) articular wounds with slight osseous lesions.

In articular fractures, the treatment is, in the main, the same as in nonarticular fractures: opening up of the soft parts, removal of fragments and foreign bodies, careful cleansing and drainage of the focus. There is, however, one particular which distinguishes articular from nonarticular fractures; this is the necessity, in general, of completing the operation by a complete and regular resection.

Articular wounds without osseous lesions seldom occur except at the knee. Such a lesion is always caused by a very small projectile. There is a small orifice in the soft parts and an articular effusion. In two cases Schwartz has followed the following line of conduct: All is prepared for complete operation; then the course of the projectile is explored. If it leads into the synovial, arthrotomy is immediately performed. If it is doubtful, the course of the projectile is explored under anesthesia, and if it leads into the joint, operation is performed.

Articular wounds with slight osseous lesions are the most delicate cases. Here it is necessary to be guided by certain principles of general surgery: 1. It is permissible to sacrifice bone more freely in the arm, in which mobility is sought, than in the leg, in which the aim is solidity. Resections therefore may be made more liberally in the arm than in the leg. 2. There are certain differences among the various articulations; resections of the elbow and the shoulder and ablation of the astragalus give excellent results. 3. Certain articulations are more easily drained than others. In the knee, lateral patellar incisions, and if necessary, the transverse incision, give good drainage, while it is impossible to drain the elbow well without resection. As for immediate amputation, no matter what the gravity of the case, it ought to be a very rare exception.

Dr. Maurice Chevassu, agrégé professor at the Faculté de médecine de Paris and surgeon of the hospitals, is convinced that for articular wounds the question of time is perhaps most essential of all. Early operations give in general good or excellent results; late operations on the other hand give mediocre or bad results.

INTENSIVE TREATMENT OF SYPHILIS IN THE HOSPITALS

It may be readily understood that much interest is felt at present in reducing to a minimum the duration of the stay in hospital of syphilitic soldiers affected with contagious manifestations, in order that they may be sent back to the ranks as soon as possible. In a previous letter (The Journal, Aug. 28, 1915, p. 813), I mentioned a report from Drs. Dalimier and Debat on the treatment of syphilitic manifestations in soldiers by short and intensive courses of arsenic and mercury. Dr. André Bernheim has recently reported to the Société de médecine de Paris the technic which he employs in the service organized by Professor Gaucher and directed by Dr. Butte at the Chaptal Hospital. An injection of 0.03 gm. of mercury benzoate (1:100 solution) or red mercuric iodid is given daily. In order to reinforce the action of the mercury and at the same time to hasten its elimination, the patient each day takes a glass of water containing sulphids and every three days takes a sulphur bath. He is given a supplementary ration of a liter (about a quart) of milk. In the course of each meal, he takes a pill containing 1 mg. of arsenic trioxid and 1 mg. of strychnin sulphate. The patient uses a tooth brush and a tooth powder of mentholated chalk. Every day a nurse paints the gums with a 1:50 solution of chromic acid. During this intensive course, the patient is kept under very close observation, the urine being examined every six days. At the same time the local lesions are actively treated, the chancres being thermocauterized at a short distance and then dusted with calomel, the mucous plaques painted successively with 1:10 silver nitrate and 1:15 chromic acid and papulosquamous syphilids covered with Vigo's plaster [a 20 per cent. mercury plaster]. This intensive treatment may be carried out in any kind of a hospital organization. It permits the cicatrization of chancres in a period varying from five to sixteen days, and mucous plaques and secondary syphilids in fifteen days on an average.

LONDON LETTER

London, Oct. 15, 1915.

The War

THE SUPPLY OF ARMY SURGEONS

The consulting physicians and surgeons to the British expeditionary force in France have issued a statement that they have observed with some regret that many physicians have resigned their temporary commissions in the medical corps. No doubt a considerable proportion of these are recalled to Great Britain by personal and public claims on their services which they could not neglect. After a few months of comparative quiet, some of them have perhaps found the work monotonous. Those physicians who contemplate applying for commissions in the army are asked to consider the matter in another light. In order to insure a successful issue to the war our army and navy must show the greatest patience and tenacity of purpose. The same is true of the work of the medical profession. A similar tenacity of purpose and an equal patience are required in addition to the skill and energy which every battle calls forth. The excitement of great and moving events is necessarily transient, and men must be prepared to do their duty steadfastly during long periods of dulness. Yet it is during these dull periods that the services of the army surgeon are really of the greatest value, though they may be dull and uneventful to himself, and it is during these intervals that he gets into that close touch with officers and men which gains their confidence and gives him an influence without which mere professional knowledge is not of much avail. It is no doubt monotonous to be constantly watchful of the cleanliness of billets, to supervise food, to prevent parasitic infections, to treat sore feet, diarrhea or muscular rheumatism, and to do the thousand and one things which help to keep the soldier an efficient fighting man. But the medical officers who does these things is doing at least as much for his country as the man who performs operations or treats typhoid. The staffs of the field ambulances have also to deal with many minor ailments of little interest, but every division is dependent on them for the rapid return to the regiments of those whose illnesses are too slight to justify a return to England.

THE SIGNIFICANCE OF ABNORMAL SIGNS IN THE RECRUIT'S HEART

At the request of the War Office, Sir James Mackenzie has drawn up a memorandum to serve as a guide to medical examiners of recruits. He points out that the healthy heart in the young can exhibit murmurs, and variations in rate and rhythm, which are perfectly physiologic in origin and indicative neither of disease nor of impairment. Before examining the heart he recommends that the functional efficiency be found out by ascertaining how it responds to effort. This is shown by the amount of exertion the candidate has been accustomed to take in the past in his work or play, and if he can undergo severe bodily exertion without distress. The physiologic murmurs are always systolic in time, and the situation of the greatest intensity may be at the apex, midsternum, or base of the heart. If the candidate's response to effort be normal, and the heart normal in size, the murmur is negligible; for if the cause which produced the murmur hampers or embarrasses the heart in its work, the size of the embarrassed chamber will increase and its functional efficiency be impaired.

Only two forms of irregularity need be considered. Irregularities indicating serious mischief, such as the irregularity of auricular fibrillation or of heart block, will be associated with such diminution of the functional efficiency that the candidate would not seek to recruit. The most common irregularity is that which occurs in the healthy heart of the young. It is characterized by a lengthening and shortening of the pauses between the beats; it will often be found to vary with respiration, the beat increasing in rate during inspiration and decreasing during expiration. When it does not have the characteristic respiratory character it can be made to take on the character if the candidate is made to breathe slowly and deeply for a few minutes. It is frequent in perfectly healthy hearts, and is, therefore, of no importance. In rare cases the pulse may be found intermitting more or less frequently. If the heart be auscultated, two short sharp sounds rapidly following one on the other may be heard during the pause. If this is the only sign present, that is, if the functional efficiency of the heart be good and the size normal, then these extrasystoles are of no significance and the candidate should not be rejected. Many candidates whose hearts are perfectly healthy suffer from palpitation or excited action during examination. The beat becomes forcible and rapid, and a systolic murmur may be present. If such a candidate be told to lie down and breathe slowly and deeply for a few minutes, the heart's action becomes less violent and the rate slows during expiration. With a history of good functional efficiency, the candidate may be considered suitable for enlistment.

CASUALTIES FROM THE ZEPPELIN RAID

A fleet of airships has visited London and the eastern counties and dropped bombs with the following results: Twenty-seven men, 9 women and 5 children were killed, and 64 men, 30 women and 7 children were injured. Of these casualties, 32 killed and 95 injured occurred within the London area.

THE HEALTH OF THE ARMY

Prof. H. R. Kenwood, a well-known authority on hygiene, who has been appointed as an expert to the army in France, has made an interesting report on his branch of the medical work. Early in the war it was considered that the special circumstances demanded some strengthening of the sanitary personnel, and so additional sanitary sections were formed, each consisting of a commissioned officer, four noncommissioned officers and twenty-five men, one section being attached to each division. These sections were recruited from a good class of men, well trained, and including men who had had experience of sanitary work before enlistment; the staff sergeants, sergeants and corporals were generally inspectors in civil life, and the rank and file were mostly from the building and engineering trades; each section had its own motor lorry to carry its equipment. The duties of these special sections ranged from skilled sanitary work, such as disinfection, the purification of water, etc., to the construction of crude incinerators, simple arrangements for the bathing of the troops fresh from the trenches, and scavenging. Their skill has enabled many difficulties to be overcome. Many improvisations have had to be fashioned to suit novel conditions and difficulties, such as the destruction of vermin, the eradication of the fly population in a country which is highly manured under an intensive system of cultivation, the disposal of the carcasses of horses, etc. Steam is used to disinfect clothing and textile articles, and cresol solution is applied to infected surfaces. With regard to the drinking water, the circumstances of the campaign caused special precautions to be taken from the first. The army water carts were originally furnished with batteries of filters, capable of arresting the germs of water-borne disease, and mobile laboratories were equipped with the means of making a chemical and bacteriologic examination of any water supply which it was proposed to issue to the troops. But these precautions were soon supplemented by more effective measures, and since the early days of the war all the water issued has been previously treated as if it certainly contained the germs of typhoid, and in a manner that would effectually dispose of such organisms were they present. In short, the drinking water is chlorinated under skilled direction, and the result is an always safe water supply. The preventive measures against typhoid are as complete as science and ingenuity can devise, and the results have been exceptionally good. Although the figures of the units vary, the large majority of the forces have been inoculated against this disease, and this proved of the greatest value. The noninoculated British soldier is found to be between fourteen and fifteen times more liable to catch typhoid than the inoculated soldier. Precautions against "carriers" are also taken. Mobile laboratories with skilled bacteriologists go from place to place for the systematic examination of the feces of large numbers of men.

Marriages

Clarence Leon Fessenden, M.D., Fulton, N. Y., to Miss Louise W. Ryder of Roanoke, Va., at Towanda, Pa., October 20.

Archibald Wright Graham, M.D., to Miss Alecia Madden, both of Chisholm, Minn., at Rochester, Minn., September 29.

Fred William Robinson, M.D., Sturgis, Mich., to Miss Mildred Leonora Clarke of Milford, Conn., October 16.

William Duncan McKim, M.D., Washington, D. C., to Miss Leonora Jackson, in New York City, October 12.

James Stuart Pritchard, M.D., Ottawa, Ont., to Miss Myra Bradwell Helmer of Chicago, October 21.

Francis Leo Daly Scanlan, M.D., to Miss Margaret B. Williams, both of Syracuse, N. Y., October 20.

Walter Gerald Nuessle, M.D., Lansford, N. D., to Miss Helen Nippolt of Tacoma, Wash., September 8.

Furman Leaming Pyke, M.D., Lafayette, Ind., to Miss Inez Johnston of LaGrange, Ind., October 20.

William E. Kiser, M.D., Bellaire, Ohio, to Miss Gertrude Helen Coleman, at Dover, Ohio, October 19.

Allison Temple Wanamaker, M.D., to Miss Mary Helen Allmond Patten, both of Seattle, October 20.

Carl Shepard Oakman, M.D., Detroit, to Miss Harriet Brooks at San Antonio, Texas, October 20.

Edward J. H. Salmon, M.D., to Miss Theresa Kennedy, both of Jersey City, N. J., about August 7.

Arthur Knowlton Drake, M.D., Monmouth, Ill., to Miss Lois Potter of Galesburg, Ill., October 19.

Clarence H. Boswell, M.D., Rockford, Ill., to Miss Ruth F. Ward of Flushing, N. Y., October 20.

Charles L. Schang, M.D., Greenville, Pa., to Miss Susie Maxey of Vicksburg, Miss., October 18.

John S. B. Woolford, M.D., Chattanooga, Tenn., to Miss Eliza Winslow of Baltimore, October 23.

Harold M. Allen, M.D., Norway, Me., to Miss Emily Briggs of Lawrence, Mass., October 20.

James LeRoy Anderson, M.D., Winfield, Ill., to Miss Clare Leland Kinney, at Chicago, October 14.

George David Cutler, M.D., Boston, to Miss Jessie Barr Wright of St. Louis, October 19.

Conrad B. Vonnahme, M.D., to Miss Mary Rung, both of East St. Louis, Ill., October 31.

Patrick H. O'Malley, M.D., to Miss Elda Sharples, both of Chinook, Mont., October 8.

Roger Paul Dawson, M.D., to Miss Marguerite A. Long, both of Boston, October 20.

Deaths

John Henry Huddleston, M.D. Harvard Medical School, 1891; aged 51; a Fellow of the American Medical Association; a trustee of the New York Academy of Medicine; a member of the American Climatological Society, American Public Health Association, Association of Military Surgeons of the United States, and National Association for the Study and Prevention of Tuberculosis; a director of the Metropolitan Life Insurance Company; visiting physician to Gouverneur and Willard Parker hospitals, and the Riverside Sanatorium; consulting physician to the United Hospital, Port Chester, N. Y.; captain and assistant surgeon, Seventh Infantry, N. Y. N. G., from 1895 to 1907; Carpenter lecturer in 1902; secretary of the American Committee of the Fourteenth International Medical Congress; a trustee of the New York State Hospital for Incipient Tuberculosis; died at his home in New York City, October 30, from pneumonia.

Rear Admiral Joseph Benson Parker, M.D. Medical Director, U. S. Navy (retired). Bellevue Hospital Medical College, 1866; aged 74; who entered the volunteer service of the United States Navy, March, 1863; as an acting assistant surgeon; served in the Mississippi Squadron until his honorable discharge in 1865; and was appoined assistant surgeon, U. S. Navy in November, 1866; whose last services were the command of the Portsmouth (N. H.) Hospital and Navy Yard, the presidency of the Naval Medical Examining Board, Washington, and the command of the Naval Hospital, Washington, and who was retired June 20, 1903, with the next higher grade to that held on active list, on attaining the age of 63 years, after fifteen years and one month sea service and twenty years and six months shore or other duty; died at his home in Philadelphia, October 21.

Edmund C. Rivers, M.D. University of Maryland, Baltimore, 1879; aged 57; of Denver; a well-known specialist on diseases of the eye and ear; president of the board of trustees and professor of ophthalmology in the Denver and Gross College of Medicine, Denver; vice president of the board of directors and consulting oculist to the Denver Maternity and Woman's Hospital Association; while hunting in Barr Lake, near Denver, October 24, was drowned while attempting to save the life of a negro caretaker who was falling from his motor boat.

James A. McGuigan, M.D. Jefferson Medical College, 1862; aged 81; surgeon of volunteers during the Civil War; died at his home in Philadelphia, October 21, from heart disease. On March 8, 1912, Dr. McGuigan and Dr. William Williams Keen were the guests of honor at a dinner given by the medical profession of Philadelphia on the occasion of the fiftieth anniversary of their graduation in medicine.

Clayton L. Ransom, M.D. Willamette University, Salem, Ore., 1903; of Mill City, Ore.; a Fellow of the American Medical Association; who disappeared while hunting in the Jackson Hole country, Wyo., September 17, was found dead near his camping place, October 21, his death having been due to a gunshot wound supposed to have been accidentally self-inflicted while climbing over a log.

Eugene Shamon McCain, M.D. University of Texas, Galveston, 1903; aged 37; a Fellow of the American Medical Association and quarantine officer at Brownsville; formerly health officer at Tampico, Mexico; was shot and killed by Mexican bandits who held up and robbed a passenger train of the St. Louis, Brownsville and Mexico Railroad, about October 18.

Harvey R. McClellan, M.D. Starling Medical College, Columbus, Ohio, 1854; aged 88; a charter member of the Greene County Medical Association; for sixty years a practitioner of Xenia, Ohio; contract surgeon in the Army during the Civil War; founder of the McClellan Hospital, Xenia; died at his home in that city, October 17, from pneumonia.

Richard H. McBaine, M.D. College of Physicians and Surgeons in the City of New York, 1907; aged 32; a Fellow of the American Medical Association; a specialist on physical diagnosis; physician to outpatients in and a member of the faculty of Washington University, St. Louis; died in Barnes Hospital in that city, October 17, from septicemia.

Frederick Gillett Byles, M.D. Jefferson Medical College, 1882; aged 62; professor of hygiene and sanitation in the University of Colorado, School of Medicine, Denver; obstetrician to the Colorado Cottage Home and a member of the staff of the Denver City and County Hospital; died at his home in Denver, October 21, from arteriosclerosis.

William H. Pruner, M.D. College of Physicians and Surgeons, Baltimore, 1884; aged 60; a Fellow of the American Medical Association and for the last twenty-five years a practitioner of Washington County, Neb.; died at his home in Kennard, Neb., October 19, from prostatic abscess complicated with multiple abscesses of the kidney.

Joseph R. Huntt, M.D. College of Physicians and Surgeons, Baltimore, 1888; aged 50; mayor of Laurel, Md., for one term; formerly health officer; local surgeon of the Baltimore and Ohio Railroad and director of the Citizens' National Bank; died at his home in Laurel, October 18, from cerebral hemorrhage.

William George Kimball, M.D. Dartmouth Medical School, Hanover, N. H., 1876; aged 68; a member of the Massachusetts Medical Society; medical examiner for Hampshire County and representative in the Massachusetts Legislature in 1895 and 1896; died at his home in Huntington, October 20.

Mark H. O'Daniel, M.D. Atlanta (Ga.) Medical College, 1881; aged 53; formerly local surgeon at Jeffersonville, Ga., for the Southern Railway; for several years a member of the staff of the State Sanitarium, Milledgeville; died in Williams' Private Sanitarium, Macon, Ga., October 14.

Henry P. Mowry, M.D. Hahnemann Medical College, Chicago, 1877; aged 61; ex-president of the village of Bronson; formerly a member of the State Board of Charities and Correction; died at his home October 6, from angina pectoris.

Peter S. Leisenring, M.D. Pennsylvania Medical College, Philadelphia, 1852; aged 86; formerly professor of obstetrics in Omaha Medical College; secretary of the board of health and city physician of Omaha; formerly president of the San Diego (Calif.) Medical Society; died at his home in San Diego, October 15.

Mark Richards Crain, M.D. University of Vermont, Burlington, 1879; aged 59; a Fellow of the American Medical Association and a well-known surgeon of Rutland, Vt.; died in his office in Rutland, October 14, from the effects of morphin, self-administered, it is believed, with suicidal intent, while despondent.

Raymond Russ, M.D. University of California, San Francisco, 1900; aged 42; a Fellow of the American Medical Association; instructor in surgery in the University of California; formerly of San Francisco and San Mateo, Calif.; died at his home in Hillsborough, Calif., October 24, from tuberculosis.

Guerney Abner Gregory, M.D. Maryland Medical College, Baltimore, 1909; aged 35; of Stroudsburg, Pa.; formerly a member of the Medical Society of the State of Pennsylvania; died October 14, from acute gastritis, in the North Water Gap Sanitarium, Stroudsburg, where he was attending a patient.

William Patrick George, M.D. Washington University, St. Louis, 1875; aged 68; a member of the Arkansas Medical Society; a Confederate veteran; since 1869 a practitioner and druggist and president of the First National Bank of Berryville, Ark.; died at his home about October 13.

Alexander Perry, M.D. Vanderbilt University, Nashville, Tenn., 1905; aged 34; a Fellow of the American Medical Association; who began practice in Nashville and later was obliged to go to Denver and finally to Los Angeles in search of health; died in the latter city, October 20.

Joseph Jerome Noll, M.D. College of Physicians and Surgeons in the City of New York, 1885; aged 51; a member of the Medical Society of the State of New York; assistant physician to the New York Dispensary; died in his home in New York, October 17, from heart disease.

Samuel C. Rusmisell, M.D. Medical College of Ohio, Cincinnati, 1876; formerly a Fellow of the American Medical Association; of Buckhannon, W. Va.; president of the People's Bank of West Virginia, Buckhannon; died at his home about October 18.

Anthony J. Maslowsky, M.D. Kentucky School of Medicine, Louisville, 1907; of Mariah Hill, Ind.; formerly coroner of Spencer County, Ind.; died October 22, from injuries received in the overturning of his automobile near Rockport, Ind., the week before.

James Rankin Vincent, M.D. Medical College of Ohio, Cincinnati, 1884; aged 60; a Fellow of the American Medical Association; for many years a practitioner of Wilkinsburg and East Liberty, Pittsburgh; died at his home in East Liberty, October 23.

Frank Duane LeValley, M.D. University of Michigan, Ann Arbor, 1883; aged 58; a member of the Michigan State Medical Society and a practitioner of Vassar, Mich., since 1890; died at his home October 14, from heart disease.

John T. Hampton, M.D. Jefferson Medical College, 1879; aged about 70; a retired practitioner of Philadelphia; was found dead in his berth in a sleeping car on an Atlantic Coast Line train near Florence, S. C., October 9.

George M. Hite, M.D. Eclectic Medical Institute, Cincinnati, 1886; aged 56; of Nashville, Tenn.; also a clergyman of the Primitive Baptist Church; died in an infirmary in that city, October 21, after a surgical operation.

George W. Long, M.D. University of Pennsylvania, Philadelphia, 1874; aged 67; of Graham, N. C.; a member of the Medical Society of the State of North Carolina; died in a hospital in Statesville, N. C., October 16.

Thomas Henry Whalen, M.D. Illinois Medical College, Chicago, 1898; aged 57; who had charge of the smallpox epidemic in Tippecanoe County, Ind., in 1902; died at his home in Lafayette, Ind., October 19.

Patrick Wallace Cremin, M.D. College of Physicians and Surgeons in the City of New York, 1866; aged 74; a member of the Medical Society of the State of New York; died at his home in New York City, October 17.

Eugene Larrie Tupper, M.D. University of Minnesota, Minneapolis, 1897; aged 42; died at his home in Lima, Ohio, October 21, from organic heart disease.

Frank Butler Adams (license, Connecticut, 1893), aged 57; an eclectic practitioner of Hartford, Conn., for thirty-two years; died in St. Francis' Hospital in that city, September 23, from carcinoma of the throat.

John Clark Gauntlett, M.D. University of Michigan, Ann Arbor, 1887; aged 51; a resident of Elk Rapids, Mich., for more than twenty years; died at his home in that place, October 19, from heart disease.

George Corson Burnley, M.D. Hahnemann Medical College, Philadelphia, 1890; aged 49; a specialist on diseases of the eye; died at his home in Lock Haven, Pa., October 15, from angina pectoris.

Albert Schaffer Erney, M.D. Jefferson Medical College, 1877; aged 61; a practitioner and druggist of Philadelphia; died at the home of his son in that city, October 12, from cerebral thrombosis.

Michael J. Kenney, M.D. Marquette University, Milwaukee, Wis., 1911; aged 39; formerly a member of the State Medical Society of Wisconsin; died at his home in Manawa, Wis., October 22.

George A. Heintzelman (license, Philadelphia County, Pa., 1886), aged 81; for thirty years a practitioner and druggist of northwest Philadelphia; died at the home of his son in that city, October 19.

Adolphe Joseph Delcourt, M.D. University of Liege, Belgium, 1875; aged 68; formerly a Fellow of the American Medical Association; died at his home in Houma, La., October 16.

Charles Lee Caven, M.D. University of Southern California, Los Angeles, 1896; aged 43; a Fellow of the American Medical Association; died at his home in San Diego, Calif., October 18.

Matthew H. Sheldon, M.D. Eclectic Medical Institute, Cincinnati, 1876; aged 62; of Mt. Erie, Ill.; died in the Olney (Ill.) Sanitarium, September 17, from nephritis.

James K. Reader (license, Oregon, 1890), aged 69; a homeopathic practitioner of Ashland, Ore.; a veteran of the Civil War; died in Santa Rosa, Calif., October 11.

Amzi Jones, M.D. Vanderbilt University, Nashville, Tenn., 1900; aged 42; for fifteen years a practitioner of New York City; died at Saranac Lake, N. Y., October 22.

Clarence Ormsbee, M.D. New York University, New York City, 1865; aged 76; of Newburgh, N. Y.; died in Sadlier's Hospital, Poughkeepsie, N. Y., October 13.

Brooks A. Colomb, M.D. Tulane University, New Orleans, 1885; aged 53; president of St. James Parish, La.; died at his home in Colomb, La., September 20.

Joel F. Scott, M.D. Jefferson Medical College, 1883; aged 62; a Fellow of the American Medical Association; died at his home in Wilson, Pa., October 19.

Emil Haass (years of practice, Illinois, 1878), aged 88; for sixty years a practitioner of Will County, Ill.; died at his home in Frankfort, Ill., October 13.

James Henry Woodul, M.D. Kansas City (Mo.) Medical College, 1881; aged 80; died at his home in Whiting, Kan., September 12, from senile debility.

William J. Hicks, M.D. Medical College of Georgia, Augusta, 1889; aged 63; died at his home in Moultrie, Ga., August 5, from amebic dysentery.

Noah Woodrow Patton, M.D. Jefferson Medical College, 1884; aged 59; died at his home in Charleroi, Pa., October 14, from cerebral hemorrhage.

Samuel Chase Thayer, M.D. Medical School of Maine at Bowdoin College, Brunswick, 1881; aged 54; died at his home in Boston, October 11.

Sidney H. Minor, M.D. University of Tennessee, Nashville, 1893; aged 46; died at his summer home near Hendersonville, Tenn., October 15.

John A. Long, M.D. Baltimore Medical College, 1893; aged 45; died at his home in Bowmansville, Pa., October 8, from heart disease.

Hardin Welch Bright, M.D. Bellevue Hospital Medical College, 1886; aged 53; died at his home in Richmond, Ky., about October 21.

Cyrus L. Harnden, M.D. University of Wooster, Cleveland, 1875; aged 65; died at his home in Clyde, Ohio, October 19.

Powhatan Bledsoe, M.D. University of Maryland, Baltimore, 1860; aged 87; died at his home in Wildwood, Va., June 24.

The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

ARTICLES REFUSED RECOGNITION

Report of the Council on Pharmacy and Chemistry

Below appear abstracts of the Council's actions on articles refused recognition which were not deemed of sufficient importance to require lengthy reports:

Swan's Rheumatic Bacterin (Mixed) No. 47

According to the statement of the manufacturers (Swan-Myers Company, Indianapolis, Ind.), Swan's Rheumatic Bacterin (Mixed) No. 47 contains in each c.c., pneumococci 25,000,000, Friedländer's bacilli 25,000,000 and streptococci polyvalent 450,000,000.

The Council's Committee on Serums and Vaccines held that there is no satisfactory evidence that either the pneumococcus or Friedländer's bacillus is concerned in the etiology of acute and chronic rheumatism or rheumatoid arthritis, and no conclusive evidence that the streptococcus is an etiologic factor. In view of this the committee held this mixed vaccine unscientific in composition, and hence barred from admission to New and Nonofficial Remedies by Rule 10.

The Council adopted the report of the committee and, the report having been sent to the manufacturer and the manufacturer's reply considered, authorized its publication.

Elixir Iodo-Bromide of Calcium Comp. "Without Mercury" and "With Mercury"

The Tilden Company, New Lebanon, N. Y., and St. Louis, Mo., sells "Elixir Iodo-Bromide of Calcium Comp. without Mercury" and "Elixir Iodo-Bromide of Calcium Comp. with Mercury." The latter is said to contain, in addition to the ingredients of the former, 1/100 grain mercuric chlorid in each fluidram. According to the label the formula of the elixir "without mercury" is :

> "*Formula*—Salts of Iodine, Bromine, Potassium, Sodium, Calcium, Magnesium with Stillingia, Sarsaparilla, Rumex, Dulcamara, Lappa, Taraxacum, Menispermum."

A recent circular declares that the elixir contains:

> ". . . a number of the most powerful alteratives of the pharmacopeia such as chemically pure iodin, magnesium, potassium with sarsaparilla, stillingia, prickly ash, burdock, taraxacum, etc. . . . Each fluidounce contains seventy-two grains of the combined salts."

The same circular also alleges that each dram of the preparation contains:

> ". . . the equivalent of one and one-half grains of the combined iodids, potassium and calcium . . ."

It will be observed that, (1) the two statements quoted from the circular make no reference to bromids; (2) the statement that each dram contains "the equivalent" of 1½ grains of the combined iodids, potassium and calcium, accounts for but 12 of the 72 grains of "the combined salts" per fluidounce declared in the preceding quotation; (3) the circular mentions the presence of a drug—prickly ash—not declared on the label and, finally (4) none of the "formulas" gives the quantities of all of the several constituents.

It is evident from these "formulas" that the Tilden Company continues its policy of concealment and mystification as exemplified in the cases of Hydrocyanate of Iron, Tilden (discussed in The Journal, June 19, 1909, p. 2008), Febrisol (The Journal, June 29, 1912, p. 2043) and Respirazone (The Journal, June 14, 1913, p. 1899).

In the circular just quoted ("The Conquest of Syphilis"), all hope for the syphilitic is declared to rest in mercury and iodin, and it is implied that only through Elixir Iodo-Bromide of Calcium Comp. is it possible to obtain the greatest good from these drugs.

> "Were the cleansing influences of these two drugs [mercury and iodin] unavailable to the luetic patient, he, *truly*, would be as pitiable an object as the leper . . .
>
> "Modern Pharmacy has devised no better means of utilizing these anti-syphilitics than Elixir Iodo-Bromide of Calcium Comp. (Tilden) with or without mercury. . . . the Elixir, in proper dosage, acts in specific fashion and is adapted for use in all stages of the disease.
>
> "In the early months . . . *Elixir* Iodo-Bromide of Calcium Comp. (*Tilden*) with mercury is a trustworthy weapon and the physician need have no fear but that it will subjugate the disease . . .
>
> "When . . . the virulent stage is passed . . . Elixir Iodo-Bromide of Calcium Comp. (*Tilden*) without mercury *may* be given the *patient* with every assurance that medicine's most aggressive measures are being resorted to . . . From time to time, up to the very end of the time honored three years' period of treatment, it is well to put the patient back on the bichloride, using for this purpose the form of the Elixir administered in the *first stages* of the disease . . .
>
> "*This* regime . . . will indubitably antidote the virus of syphilis and eradicate from the organism its every vestige."

While it seems incredible that any physician would jeopardize the health—even the life—of a patient by accepting this boastful magniloquence as *sound* therapeutic advice, still the fact that certain medical journals lend their advertising pages to advertisements for *Tilden's* Elixir with the caption "The Conquest of Syphilis" makes it incumbent on the Council to record its condemnation of the employment of this unscientific, semisecret mixture.

It is recommended that Elixir Iodo-Bromide of Calcium Comp. "without mercury" and "with mercury" be held in conflict with Rule 1 (secrecy of composition), Rule 6 (unwarranted therapeutic claims) and Rule 10 (unscientific composition).

THE HOROWITZ-BEEBE AUTOLYSIN TREATMENT

Some Bids and Estimates for the Treatment of Cancer

Immediately after the publication, in a popular magazine, of the *first* articles on the autolysin treatment of cancer, inquiries were received from various parts of the country in regard to this treatment and its value. Cancer sufferers were *invited* in the magazine article to write to the Autolysin Laboratory for advice regarding the treatment. Naturally *many* responded. There were strong evidences from the beginning of a commercial spirit in the exploitation of the treatment. We quote below some of the evidence. The first is a series of telegrams that passed between a Seattle physician and Dr. Beebe:

Seattle, Wash., July 7, 1915.

Dr. S. P. Beebe,
New York, N. Y.

Kindly wire me collect at once particulars of autolysin treatment for cancer. Would it be possible for you to send me some autolysin with directions for using same for the treatment of an inoperable cancer of the uterus which involves the rectum and bladder.

NEW YORK N Y JULY 8 1915

DR ——————
SEATTLE WASH

WIRE RECEIVED AUTOLYSIN NOT GIVEN OUT FOR GENERAL USE BY
PROFESSION REASON UNACQUAINTED WITH THERAPEUTIC EFFECT
AND PHYSIOLOGICAL ACTION EITHER NECESSARY TO BRING PATIENT
HERE FOR TREATMENT OR HAVE MEMBER OF STAFF IN CONSULTATION
CONSULTATION FEE HERE TWO HUNDRED FIFTY DOLLARS CONSULTATION
FEE IN SEATTLE TWO THOUSAND DOLLARS A MEMBER OF OUR STAFF
WILL BE IN CONSULTATION WITH DR W COLFAX MATTHEWS AT BUTTE
MONT JULY FOURTEENTH YOU CAN ARRANGE THROUGH HIM FOR A
CONSULTATION AT THAT TIME FOR FIVE HUNDRED DOLLARS

S P BEEBE MD

Seattle, Wash., July 8, 1915.

Dr. S. P. Beebe:

Will Doctor who is coming to Butte to give *autolysin* come on to Seattle and give treatment necessary for trial for five hundred dollars. Wire me collect.

NEW YORK N Y JULY 9 1915

DR ——————
SEATTLE WASH

WIRE REC'D OUR STAFF MEMBER DOCTOR WILLIAM E FITCH WILL
BE IN BUTTE ON THE DAY AND DATE AND AT ADDRESS GIVEN IN DAY
LETTER OF EIGHTH AND WILL COME ON TO SEATTLE FOR FIVE
HUNDRED DOLLARS AND TRAVELING EXPENSES FROM BUTTE TRUST
YOU CAN HAVE MORE THAN ONE CASE FOR TREATMENT

S P BEEBE MD

A physician in Detroit wrote to Dr. W. H. Axford of Bayonne, N. J., whose name was mentioned in one of the popular articles as having used the treatment, asking for information regarding it. The following was the reply:

NEW YORK CITY, June 30, 1915.

My dear Doctor:—Your letter addressed to Dr. Axford, c/o The Polyclinic Hospital has been referred here for attention, and we note therefrom that you have a patient suffering from cancer of the liver and you desire information pertaining to this treatment concerning which we beg to submit the following:

For more than two years "Autolysin" has been subjected to the severest possible test in that only inoperable and hopelessly incurable cases were accepted for treatment, many of whom came with the verdict of the family physician hanging over them of having only two or three months lease of life. These patients have taken the treatment and the results on the whole have been satisfactory, in many instances, the improvement was so gratifying to the patients that they left the institution claiming they were fully recovered. We, however, are not so optimistic, but we feel that we can conservatively say that in many instances there were evidences of complete clinical recoveries.

At the present time "Autolysin" is not available for general use by the profession for the reason that they are unacquainted with its therapeutic effect and physiological action which is necessary for its intelligent administration. Before we consider it a safe remedy, a physician must first be personally instructed in the technic of its administration as well as have pointed out to him just what reactions are liable to follow—which govern future dosage—and have explained to him just the way to handle and take care of these reactions when they occur.

If your patient is able to be brought to New York for treatment, the fee for examination, consultation, etc., will be $250, and the after-treatments at the rate of from $25 to $35 per week. If this patient is unable to stand the trip then it will be necessary for a member of our staff to see her in consultation with you. The fee for this trip and consultation will be $1000 and traveling expenses.

Trusting this information will serve your purpose, and that we may have an opportunity of giving your patient the benefits of this treatment, we beg to remain W. E. FITCH.

Shortly after the publication of our editorial on this treatment, the following letter, dated July 27, 1915, was received from a subscriber in St. Louis:

To the Editor:—Following the "Beebe-Horowitz" editorial in this week's number of your Journal, I am venturing to send you the enclosed copy of a communication to one of my patients.

Briefly the history of my patient is as follows: One year after an operation for gall stones, at which gall stones were found and the gall bladder left without drainage, a second operation was done for a mass that was in the scar line. This was diagnosed, clinically, as carcinoma of the gallbladder and liver. A large mass grew on the abdominal wall and the patient suffered many hemorrhages that had almost caused his death a number of times before controlled.

He was brought to my office on a stretcher and the massive dose X-ray, Coolidge tube, was administered through several ports of entry. The first treatment controlled the bleeding and the mass wholly disappeared from the wall. There was also a great diminution of the liver dulness. He gained much in weight and has returned to his work.

Following his reading of the article in *Hearst's Magazine,* he wrote to Dr. Horowitz and got the enclosed reply—not, however, until after he had departed for New York, so great was his hurry to avail himself of the treatment.

He did not get farther than the "Financial Secretary" and came home for further X-ray treatment.

The following is the letter referred to. The second and third paragraphs, which are omitted, are the same as those in the letter already quoted. The fees, however, differ.

Dear Sirs—Your letter of the 19th *instant,* addressed to Dr. Horowitz has been received and carefully noted. We observe therefrom that you are suffering from a carcinoma of the gall bladder, and we believe from the report which you have very kindly given us that you should lose no time in availing yourself of the advantages offered from the administration of "Autolysin" in malignant disease such as you have.

. . . .

We note from your letter that you can come on to New York now in the next few days, and we should be very glad to welcome you and offer you the advantages of this new method of treatment. The examination with reports of the various laboratories and consultation will be $500. The treatment at $50 per week thereafter.

Trusting this information will serve your purpose and that we may have an opportunity of giving you the advantage of this treatment, we beg to remain,

Yours very truly,
(Signed) ALEXANDER HOROWITZ, M.D.
Per: W. E. F. [W. E. FITCH (?)—ED.]

The following letter appeared in *Northwest Medicine* for September, and was said to have been written to a physician in Seattle. We again omit the second and third paragraphs, as they are the same as those already quoted. It seems that these two paragraphs are utilized in many of the letters, no matter who signs them:

NEW YORK CITY, July 29, 1915.

Dear Doctor:—Your letter of the 24th inst. duly received. We note from it that you have a patient under observation who is suffering from an inoperable malignant disease of the uterus. We believe we can conservatively say to you that "autolysin" at the present time offers the only hope for patients of this deplorable condition.

. . . .

If your patient is able to stand the trip to New York, we should be very glad to receive her for treatment and to have you accompany her, in order that we might have the patient under our personal observation and at the same time show you every courtesy in the case by personally instructing you into the technic of the administration of "autolysin." The fee for examination, consultation, etc., here would be $250. If the patient cannot stand the trip to New York and is able to pay for a consultation in Seattle, we could arrange to send a member of our staff there to see her in consultation with you, which consultation would be $250 and traveling expenses and the allowance of $200 per day for the time consumed in a trip from here to Seattle and return.

Trusting this information will serve your purpose, we beg to remain,

Yours very truly,
S. P. BEEBE, M.D.

The following correspondence indicates that a change in method of exploitation—this time through the physician—was adopted. The first letter was addressed to THE JOURNAL, and is from a physician. The Samuel M. Noyes who is mentioned is, according to a letter-head, an attorney-at-law of Wheeling, W. Va. Noyes is now, according to an autolysin circular, the "distributor."

ELLSWORTH, IOWA, Sept. 20, 1915.

To the Editor:—In the recent numbers of *Hearst's* there have appeared articles on Autolysin, used in the treatment of carcinoma. Afflicted persons are directed to write to S. M. Noyes, New York, who would put the sufferer in touch with the remedy. I wrote as a layman requesting information and received the enclosed booklet and letter.

September 17, 1915.

Dear Sir:—Replying to your letter with reference to the Autolysin treatment of cancer.

I enclose a leaflet intended for the medical profession only, that tells something of the methods and results of the new treatment. I suggest that you hand this to a local physician in whom you have confidence, and ask him to read it. If after doing so he feels that this remedy might be of value in the case to which you have reference, let him communicate with me directly and arrangements can be made to secure a supply of Autolysin. The remedy is distributed solely through legally qualified medical practitioners.

Awaiting your further communications, I am,

Yours very sincerely,
S. M. NOYES.

To a physician in Virginia Mr. Noyes wrote:

September 8, 1915.

My dear Doctor:—Replying to yours of August 29, beg to advise that in all cases it is better that the physician administering Autolysin should, if possible, attend Dr. Beebe's clinic at 25 East 70th St., New York City, but where this is impossible I will send same direct with full instructions as to its use.

The regular price being Twenty-four Dollars ($24.00) per dozen 2 c.c. Ampules and special rates made to patients who are unable to pay this price.

In the future please address me at 17 East 38th St., New York City.

Yours very truly,
S. M. NOYES.

On the other hand, patients seem to have been directly favored. Another physician writes to THE JOURNAL:

Sept. 22, 1915.

"One of my patients handed me a draft of $24.00 for 12 ampoules of the Horowitz-Beebe cancer cure. He had written to them personally and received a reply stating their price.

The foregoing are samples of the correspondence that has been forwarded to THE JOURNAL. It presumably represents the methods of promoting this unproved, secret and possibly dangerous, treatment.

VARLEX COMPOUND

An Alleged Cure for the Liquor and Tobacco Habits

"Varlex Compound," put on the market by the Varlex Manufacturing Company, Kansas City., Mo., is one of those heartless frauds sold under the claim that it can be given secretly to "cure" the liquor and tobacco habits. The term "heartless" is used advisedly. There is no preparation that can be given secretly to cure alcoholism; wives and children of inebriates reading lying advertisements of the Varlex type purchase the worthless nostrums, often with money that can be ill afforded, in the hope of releasing father or husband from the thraldom of alcoholism. The sordid wretches engaged in the business of selling these alleged cures know full well that there is not one chance in a thousand that the return of the money spent will be demanded; for, in the nature of the case, the victims are unwilling to risk the publicity that such a demand would bring.

Varlex Compound is advertised by the "prescription fakes" method. Under the heading "Home Recipe for the Liquor Habit" the claim is made that a "well-known physician located in the Middle West, who has treated thousands of cases of the liquor habit" gives the following "simple inexpensive prescription that can be given secretly in coffee, milk, water or in the food." The alleged prescription is:

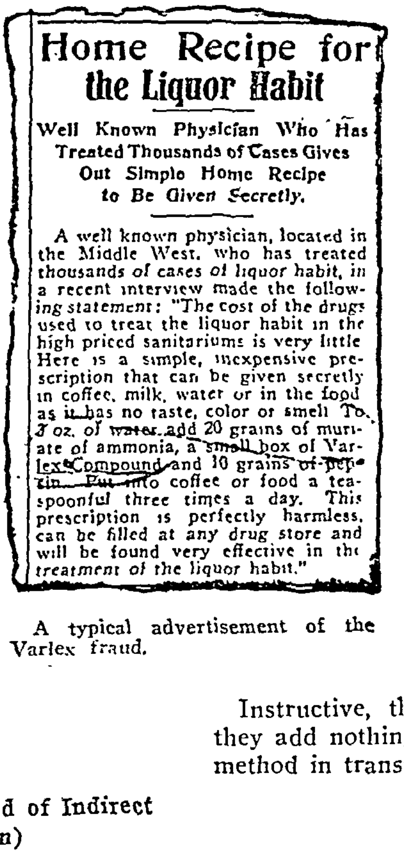
Water	3 oz.
Muriate of Ammonia	20 grains
Varlex Compound	1 pkg.
Pepsin	10 grains

A package of "Varlex Compound" was submitted to our Chemical Laboratory. Here is what the chemist reported:

CHEMIST'S REPORT

One package of "Varlex Compound for Making A Treatment For The Liquor And Tobacco Habit," prepared by Varlex Mfg. Co., Kansas City, Mo., was submitted to the Chemical Laboratory for examination. The package contained about 48 grains of a brownish-white powder, having a slightly sweet taste. Qualitative tests demonstrated the presence of milk sugar (lactose). Alkaloids and metallic substances were *not* found. Quantitative determinations indicated that the powder consisted of approximately 97 per cent. lactose and 3 per cent. moisture. In other words, it appears to be essentially milk-sugar.

The swindler who sells fake mining stock to widows and the hold-up man who makes women and girls his victims, rank higher, morally and ethically, than those who would sell worthless nostrums to unfortunate women who grasp, despairingly, at the promise that with the aid of these mixtures they can free their loved ones from the slavery of drink. Kansas City, Mo., is the home of more than one vicious and cruel medical fraud but *none is more conscienceless* than that exploited by the Varlex Manufacturing Company.



Home Recipe for the Liquor Habit

Well Known Physician Who Has Treated Thousands of Cases Gives Out Simple Home Recipe *to Be Given Secretly.*

A well known physician, located in the Middle West, who has treated *thousands of cases of liquor habit,* in a recent interview made the following statement: "The cost of the drugs used to treat the liquor habit in the high priced sanitariums is very little Here is a simple, inexpensive prescription that can be given secretly in coffee, milk, water or in the food as it has no taste, color or smell To 3 oz. of ~~water~~ add 20 grains of muriate of ammonia, a ~~small~~ box of Varlex Compound and 10 grains ~~of pepsin. Put into~~ coffee or food a teaspoonful three times a day. This prescription is perfectly harmless, can be filled at any drug store and will be found very effective in the *treatment of the liquor habit.*"

A typical advertisement of the Varlex fraud.

Correspondence

Experiences with the Sodium Citrate Method of Indirect Transfusion of Blood (Lewisohn)

To the Editor:—In a recent article on this subject by Dr. Irving Simons (The Journal, Oct. 16, 1915, p. 1339) occur some curious errors, which ought to be corrected lest they lead the profession not to estimate properly a method of transfusion which may turn out to be of great value. To those who have experience with transfusions it is evident that the accidents which occurred in two of Simons' series of three cases were not due to the use of citrate, as that author thinks, but to hemolysis or agglutination (or most probably both)—that is, to incompatibility between the blood of donor and that of patient. I know for a certainty, as a result of an experience now extending over more than 350 transfusions, that hemoglobinuria such as occurred in Simons' first case never occurs unless one of the bloods mixed is actively hemolytic toward the other. This is true irrespective of whether the transfusion is by anastomosis, syringe or citrate method. (Since publication of the recent article by Dr. Libman and myself [*Am. Jour. Med. Sc.,* 1915, cl, 36], I have performed the preliminary blood tests for twenty-five citrate transfusions in which no such accidents occurred.)

Simons states, indeed, that such a test was done before his first transfusion; but since he does not describe the technic of either test or transfusion (indeed, they were both performed by another man before Simons saw the case), and since a correct technic and interpretation of these tests require considerable laboratory experience, not too much reliance should be placed on this.

In fact, it is hard to see why Simons cites this case at all as against the citrate method since he says in his conclusion: "There is no reason to believe that hemoglobinuria may not occur with either type of transfusion [that is, direct or citrate] with equal frequency. . . . Infarction occasionally occurs (lung, kidney) and . . . hemoglobinuria is quite common and can occur even when the tests in vitro are negative." To this last statement I can only reply that hemoglobinuria and infarction are exceedingly rare and never occur when the tests in vitro (properly performed) are negative and the technic of the transfusion is correct.

In the description of Simons' other cases there is no mention of any tests at all. It is important to notice that *in the second of Simons' unhappy accidents the transfusion was the second one which the patient had undergone and was done eleven days after the first, and from the same donor*—the patient's son. Now it has been shown experimentally (Ottenberg, Kaliski and Friedman) *that it is possible to develop isohemolysins by direct transfusion from an animal of the same species.* And the time requisite for the development of these antibodies is probably the same as for the development of other antibodies, namely, from four to ten days. Corresponding with this is the striking fact that if one goes through the literature of fatal accidents after transfusion, one finds a disproportionately large number of these patients to have had second transfusions five days or more after the first and with no preliminary blood tests. I have seen one such case myself (described in the recent article with Dr. Libman). Simons' article adds another to the literature. In fact, it may be set down as an axiom that to subject a patient to a second transfusion without painstaking preliminary blood tests is to court danger. It need hardly be explained again, after all that has been written on the subject, that the mere fact that the donor is a near blood relative does not obviate the necessity for the preliminary blood test.

Instructive, therefore, as Simons' cases turn out to be, they add nothing to the question of the value of the citrate method in transfusion.

Reuben Ottenberg, M.D., New York.

To the Editor:—The results obtained by Dr. Simons with the citrate method of blood transfusion differ not only from my own but from the general experience of others. The citrate method, one of the latest of the innumerable transfusion methods, would not have acquired such great popularity in so short a time if the method had not given good results. My material comprises nearly fifty cases, and I have never had any untoward results with this method. Lately I have used the citrate method quite extensively in children (the youngest child being 20 days old), and though I have in some cases injected large quantities (for instance 350 c.c. to a child 3 years of age), I have never observed any toxic symptoms.

The records of Simons, as published in The Journal (Oct. 16, 1915, p. 1339), *seem incomplete.* It is obvious that his tests for hemolysis and agglutination are partly responsible for his results. We all know that the success of a blood transfusion depends largely on a careful execution of these tests. He does not tell us how he used the method, whether he used the proper proportion of citrate and blood, whether he had a free flow of blood from the donor's vein into the glass jar, etc.

I fail to understand why Simons was not satisfied with the result of the citrate method in his second case. He gave 500 c.c. of citrated blood, and the hemoglobin rose from 38 to 58 per cent., and had reached 75 per cent. on the following day. A reaction occurred, there being a temperature of 102, but a rise of temperature is apt to occur in a certain percentage of cases no matter what method is used (vessel anastomosis, syringe method, etc.).

The records of the first case are so incomplete that it is hardly possible to form any definite conclusion as to its clinical aspect. The patient was suffering from intestinal hemorrhages. An exploratory laparotomy was performed, but the cause of the hemorrhages was not ascertained. The patient had received a citrate transfusion and a Crile transfusion before the operation. He died a few hours after the operation; no postmortem examination was made.

Simons advocates the Crile method for blood transfusion. However, it is not clear how he would apply the vessel anastomosis in a case of acute hemorrhage. He states that he spent four hours on a Crile transfusion, and the patient would have been dead long before he succeeded in uniting the vessels. It is just in the cases of profuse hemorrhages, where the patient is pulseless from acute loss of blood and where minutes count, that the citrate method is the method of choice, as it can be performed in ten minutes.

We are indebted to Crile for having revived blood transfusion. His method, however, is practically never used now, because it has been proved that the same results can be obtained in a much more simple way by the syringe or citrate method. Any method which does not accurately indicate the amount of blood transfused cannot be considered a safe method.

I think we can definitely say that the vessel anastomosis will become more and more of historical interest.

In an editorial article on blood transfusion which appeared in the same issue (October 16, p. 1368), you state that "it would seem probable that eventually through the discovery of harmless anticoagulating methods, transfusion will become a simple procedure." The citrate method represents this desideratum. Richard Lewisohn, M.D., New York.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the *writer's name and address*, but these will be omitted, on request.

TOXIC EFFECTS OF BARIUM

To the Editor:—1. I have been approached by a friend for information about the toxic effects of barium compounds on the human system. 2. He is to have charge of a large barium plant and wishes to be posted on any possible trouble that the workmen may experience in handling this material. I have been unable to find any reliable data on this subject. H. R. Mutchler, M.D., Greystone Park, N. J.

Answer.—1. Barium acts as a powerful direct stimulant to all forms of muscle. It produces a slowing of the heart, a strong vasoconstrictor action with a consequent rise of blood pressure, and, when taken in large doses, paralysis of the cardiac muscle. It stimulates and later paralyzes the central nervous system. It is a peristaltic stimulant and a local irritant. The symptoms following the ingestion of large doses include vomiting, diarrhea, abdominal pain and dilatation of the pupils. Death is preceded by tonic and clonic convulsions. Fatal doses may be as low as 3 to 15 grains.

2. According to Oliver, the compounds of barium have never been studied in their relation to health. It is probably sufficient to say that special precautions should be taken to prevent the workmen being exposed to fumes arising from vats and tanks, to insist on the greatest cleanliness, to allow sufficient respirators during certain operations, and to take every precaution for insuring the removal of dust and thorough and efficient ventilation. Most of the instances of barium poisoning which are recorded have arisen through error, a large dose of barium having been taken when some other preparation similar in appearance was desired. Rambousek calls attention to cases of poisoning from sulphuretted hydrogen gas in plants devoted to the manufacture of sulphuric acid, in which process barium plays a large part. There are no instances, however, of barium poisoning in this industry.

THE COMPOSITION OF ALKALOL

To the Editor:—Please publish the formula of the nose and throat wash "*Alkalol.*" *W. B. C., M.D., Philadelphia.*

To the Editor:—I should like to know the approximate composition of a remedy known as Alkalol, which is sold by an Eastern concern without the formula being given on the wrapper or the advertisement that goes with the stuff. It is advertised as useful in inflammations of the mucosa of the nose and throat. A. J. Provost, M.D., Oshkosh, Wis.

Answer.—The Chemical Laboratory of the Association, having been requested to analyze a bottle of Alkalol purchased on the open market, reports as follows:

"Alkalol was found to be a clear, light brown liquid having an aromatic odor, a saline taste and an alkaline reaction toward litmus. It yielded about 2 per cent. of solids, mainly alkali, chlorid, chlorate and bicarbonate; of this 2 per cent., about one half was bicarbonate. During evaporation of the liquid, odors resembling eucalyptus, spearmint, cinnamon and vanilla were noted, the last, in view of the manufacturers' statement as to balsamic constituents, probably indicating the presence of some substance like Siam benzoin. Small quantities of salicylic and benzoic acids were found present. Alkalol thus appears to be essentially an aromatized, weakly alkaline, saline solution, containing a small amount of chlorate, probably potassium chlorate."

From this report physicians may judge for themselves how well justified are the claims that:

> "Alkalol is more, infinitely more than a simple alkaline solution."
>
> "Alkalol is an ideal agent for gargling, spraying or irrigating the postnasal, postpharyngeal spaces and tonsils."
>
> "For enteric diseases particularly of children, Alkalol is invaluable."
>
> "Appreciation of its peculiar physiological *action* will explain why and how it is of surpassing effectiveness in all conditions where there is ulceration or perforations of the drum membrane."

TINNITUS AURIUM, *CHRONIC RHINITIS* AND ALTITUDE

To the Editor:—1. *Please inform me if there* is any distinction between head noises and tinnitus aurium.

2. What effect would a high altitude have on tinnitus aurium, or head noises, or on chronic rhinitis? H. J. F., M.D., Wisconsin.

Answer.—1. Tinnitus aurium and head noises are different terms to define the same condition. Occasionally a patient will state that he does not hear the tinnitus in the ear but in the head.

2. A high altitude usually has no permanent effect on tinnitus aurium. Sometimes the conditions increase and sometimes diminish on moving to high altitudes. Chronic rhinitis of an intumescent character is likely to be benefited by a high altitude, unless dust in the atmosphere causes irritation. In such cases the affection would be aggravated. Chronic rhinitis with scabbing of the nares is usually aggravated by a high altitude.

DEATH PROBABLY FROM PULMONARY EMBOLISM

To the Editor:—At her second confinement, March 1, Mrs. B, aged 30, always healthy, was delivered of twins — girls. It was a forceps delivery, but there was no apparent trouble. She made a splendid recovery, and had no elevation of temperature after the fourth day. On the night of April 15, about 11:30, after retiring and having probably been asleep for some time, she called her husband and exclaimed that she was dying. He found her gasping for breath, blue in the face, trying to vomit a quantity of blood, froth and mucus which was pouring from her mouth. She died almost immediately. I have asked a number of physicians concerning this case, but none of them seem to know anything about it. H. D. S., Oklahoma.

Answer.—It is somewhat difficult, even when a case is actually before one, without a postmortem examination, to suggest the cause of death in such instances. Sudden death with similar symptoms may be due to a number of different causes. In the instance here described it seems most likely that death was due to pulmonary embolism.

COMING EXAMINATIONS

Arkansas: Regular, Little Rock, November 9-10. Sec., Dr. T. J. Stout, Brinkley. Homeopathic, Little Rock, November 11. Sec., Dr. Scott C. Runnels, 900 Scott St., Little Rock.

California: Los Angeles, December 14. Sec., Dr. Charles B. Pinkham, Room 527 Foram Bldg., Sacramento.

Connecticut: Regular, New Haven, November 9-10. Sec., Dr. Charles A. Tuttle, 196 York St., New Haven. Homeopathic, New Haven, November 9. Sec., Dr. Edwin C. M. Hall, 82 Grand Ave., New Haven. Eclectic, November 9. Sec., Dr. T. S. Hodge, 19 Main St., Torrington.

Delaware: Dover and Wilmington, December 14. Sec., Dr. H. W. Briggs, 1026 Jackson St., Wilmington.

Florida: Jacksonville, December 7-8. Sec., Dr. E. W. Warren, 102 Front St., Palatka.

Kentucky: Louisville, December 7-9. Sec., Dr. A. T. McCormack, Bowling Green.

Louisiana: New Orleans, December 2-4. Sec., Dr. E. L. Leckert, 716 Macheca Bldg., New Orleans.

Maine: Portland, November 9-10. Sec., Dr. Frank W. Searle, 776 Congress St., Portland.

Maryland: Regular, Baltimore, December 14. Sec., Dr. J. McP. Scott, Hagerstown. Homeopathic, Baltimore, December 15-16. Sec., Dr. O. N. Duvall, 1817 N. Fulton Ave., Baltimore.

Massachusetts: Boston, November 9-11. Sec., Dr. Walter P. Bowers, Room 159 State House, Boston.

Missouri: St. Louis, December 13-15. Sec., Dr. J. A. B. Adcock, State House, Jefferson City.

Nebraska: Lincoln, November 10-11. Sec., Dr. H. B. Cummins, Seward.

Ohio: Columbus, December 7-9. Sec., Dr. George H. Matson, Columbus.

South Carolina: Columbia, November 9. Sec., Dr. A. Earle Boozer, 1806 Hampton St., Columbia.

Texas: Dallas, November 9-11. Sec., Dr. M. P. McElhannon, Belton.

Virginia: Richmond, December 14-17. Sec., Dr. J. N. Barney, Fredericksburg.

West Virginia: Elkins, November 9. Sec., Dr. S. L. Jepson, Charleston.

Medical Council of Canada

The third annual announcement of the Medical Council of Canada has been received. This council is at present made up of thirty-two members, three being appointed by the government, two by each province of Canada, one from each medical school of Canada, and three representing the homeopathic school of medicine. From this membership six standing committees have been appointed, these being, besides the executive committee, committees on education, finance, discipline, rules and regulations, and educational standards.

The members of the board do not act as examiners. Prior to each examination, certain examiners are appointed from the faculties of the various medical schools. For example, for the examination held at Montreal and Halifax, Oct. 12, 1915, thirty examiners were appointed, four each in surgery, medicine (including therapeutics), anatomy, physiology, obstetrics and gynecology, hygiene and state medicine, pathology and bacteriology, and two homeopaths. Thus the board has been empowered to secure as examiners those who are best qualified because of their teaching positions to conduct examinations in the various subjects.

At the examination held in October, 1914, eighty-six candidates presented themselves for examination and of these candidates, forty-nine (57 per cent.) passed, twenty-two (25.6 per cent.) were rejected, and fifteen (17.4 per cent.) required to take subsequent examinations in one or two subjects.

The total expenses of the board for the year ending March 31, 1915, were $13,576.45; whereas the income, which included $15,000 from a government grant, amounted to $36,871.62.

The fee for the examination, including subsequent registration, is $100. In case of failure requiring reexamination, the candidate is required to pay one half of the original fee, that is, $50.

Candidates for the examination of the council are required to present either (*a*) a license of a provincial medical council or board of examiners, or (*b*) a certificate from the registrar of a provincial medical council, or board, that the requirements of that council or board in regard to preliminary education, matriculation, medical curriculum and graduation have been complied with.

Candidates who hold diplomas outside of Canada are required to present certificates from the registrar of a provincial medical council, the same as is required of graduates of the Canadian universities.

Applications for examinations, together with the necessary certificates and fee, must be deposited with the registrar at least four weeks before the date set for the commencement of the examinations.

The qualification granted by the Medical Council of Canada is known as the "License of the Medical Council of Canada" (L. M. C. C.).

The subjects of the examination are physiology, anatomy, hygiene and public health, pathology and bacteriology, midwifery and gynecology, surgery and medicine (including therapeutics), six questions being assigned in each subject. The examination consists of a written examination in each subject in the English or French language, and also (*a*) a clinical and oral examination in medicine and surgery, and (*b*) an oral examination in physiology, anatomy, hygiene and public health, pathology and bacteriology, and midwifery and gynecology. Sixty per cent. is required to pass. A candidate who fails in not more than two subjects may present himself at a subsequent examination for the subjects in which he failed. Failure in more than two subjects necessitates reexamination in all subjects. Grades are not subject to revision. The next examination will be held simultaneously at Toronto and Winnipeg, June 13, 1916.

New York January Report

Mr. H. H. Horner, chief of the examination division of the New York State Board of Medical Examiners, reports the written examination held at Albany, Buffalo, New York and Syracuse, Jan. 26-28, 1915. The total number of subjects examined in was 8; total number of questions asked, 80; percentage required to pass, 75. The total number of candidates examined was 156, of whom 118 passed, including 2 osteopaths, and 38 failed, including 1 osteopath. Fifteen candidates were licensed through reciprocity. Thirteen candidates were granted reregistration licenses. The following colleges were represented:

Book Notices

PRACTICAL MATERIA MEDICA AND PRESCRIPTION WRITING WITH ILLUSTRATIONS. By Oscar W. Bethea, M.D., Ph.G., F.C.S., Assistant Professor of Materia Medica, Tulane University. Cloth. Price, $4 net. Pp. 549. Philadelphia: F. A. Davis Company, 1915.

The subjects are handled chiefly from the standpoint of the practicing physician. The uses of remedies are mentioned briefly, most of the discussions being devoted to the forms in which medicines may be administered, that is, their pharmacy. According to the preface, the object of the book is to give instruction to the student concerning what preparations of a remedy, for example, iron, "will best meet the demands of particular conditions, the precautions to be observed in employing them, how to correctly prescribe them, alone or in combination, and, if in combination, with what forms or preparations of the other agents; how to order for the safest, most convenient and agreeable administration; how to use the correct names, conveniently estimate the proper quantities, the best hours for administration, and the many other matters an ignorance of which may render the physician unable to properly put to practical use his knowledge of the other departments of medical science." Medical students, physicians and pharmacists should find the book useful.

PATHOLOGICAL LYING, ACCUSATION AND SWINDLING. A Study in Forensic Psychology. By William Healy, A.B., M.D., Director, Psychopathic Institute, Juvenile Court, Chicago, and Mary Tenney Healy, B. L. Criminal Science Monograph No. 1. Cloth. Price, $2.50 net. Pp. 286. Boston: Little, Brown & Co., 1915.

The authors define pathologic lying as falsification entirely disproportionate to any discernable end in view. A liar of this type is not falsifying because he is insane, feebleminded or epileptic. His lying, too, represents a trait rather than an episode. It is an easy and a short step from this form of lying to swindling, and closely akin to these traits is that of accusation of self or of others without reasonable motive. Dr. Healy has had exceptional opportunity to become acquainted with this form of abnormal mentality. He is able to give detailed histories of nineteen cases. These cases have been carefully studied, and their peculiar features clearly set forth. Particular attention is given to the consideration of the influence of heredity, environment in early life, sex, physical condition of the patient, habits, psychic contagion, etc. A few borderline cases in which the lying is due to insanity, or is at least one manifestation of it, are considered. The prognosis in the patients under Dr. Healy's observation has been better than is generally believed to be possible. A brief outline of the treatment is given, with emphasis laid on the importance of removing harmful causes and of diverting the activities into channels in which lying will be readily detected and there will be opportunity to let off mental steam in some way easily consistent with truth-telling.

Books and articles on this subject in English are rare. This is shown by the review of the literature in the second chapter. A work on this topic in the English language, therefore, was really desirable. The book is well written and scholarly. It is broad minded, showing a knowledge not only of psychology and insanity but of general medicine as well. It shows, further, that the exceptional opportunities afforded for research in the psychopathic institute connected with the juvenile court of Chicago have been well utilized. Dr. Healy's reputation as the author of the excellent work, "The Individual Delinquent," will be further enhanced by this volume, though in it he shares the honors with his wife. The book is fittingly dedicated to Judge Merritt W. Pinckney of the juvenile court, Chicago, whose character, ability and self-sacrificing public spirit render him deserving of this tribute.

THE STARVATION TREATMENT OF DIABETES, WITH A SERIES OF GRADUATED DIETS AS USED AT THE MASSACHUSETTS GENERAL HOSPITAL. By Lewis Webb Hill, M.D., and Rena S. Eckman, Dietitian. Introduction by Richard C. Cabot, M.D. Cloth. Price, $1. Pp. 72. Boston: W. M. Leonard, 1915.

Allen's method of treatment of diabetes attained popularity with a rapidity which seems to indicate its worth as an accepted method of procedure in such cases. This little monograph contains the details of the treatment. The actual technic is not difficult to master. A series of graduated diets are offered which have proved successful in the use of the treatment at the Massachusetts General Hospital. The booklet will be found of value to the physician who wishes to undertake the treatment of a case of diabetes by this method. It is to be regretted, however, that the price of the book is out of all proportion to its evident cost of production.

THE PRINCIPLES AND PRACTICE OF OBSTETRICS. By Joseph B. DeLee, A.M., M.D., Professor of Obstetrics at the Northwestern University Medical School. Second Edition. Cloth. Price, $8 net. Pp. 1087, with 938 illustrations. Philadelphia: W. B. Saunders Company, 1915.

In this edition of this excellent work, the author has thoroughly revised the text and elaborated some of the sections. Many new illustrations and plates have been added. An apology is made for those illustrations in which rubber gloves are not shown on operator's hands, because of the difficulty of neat reproduction of such pictures. The book is marked by an excellent conservatism; for instance, in his discussion of "twilight sleep" and of the value of the Abderhalden test, the author realizes that neither the radical enthusiast nor the bitter opponents of these procedures have reached the correct points of view.

SCIENTIFIC AND APPLIED PHARMACOGNOSY. Intended for the Use of Students in Pharmacy, as a Handbook for Pharmacists and as a Reference Book for Food and Drug Analysts and Pharmacologists. By Henry Kraemer, Ph.B., Ph.M., Ph.D., Professor of Botany and Pharmacognosy, Philadelphia College of Pharmacy. Cloth. Price, $5. Pp. 867, with illustrations. Philadelphia: Published by the Author, 1915.

This contains a discussion of vegetable drugs arranged according to botanic families. It also includes a consideration of a few of the more important drugs obtained from the animal kingdom, and a key for the identification of powdered drugs and foods. A large number of interesting and instructive illustrations add to the value of the work, which is well adapted for the purpose for which it is intended. The author's "Applied and Economic Botany" is intended to be used as preparatory and supplementary to the present volume.

A TEXT-BOOK OF PATHOLOGY. By Alfred Stengel, M.D., Sc.D., Professor of Medicine, University of Pennsylvania, and Herbert Fox, M.D., Director of the Pepper Laboratory of Clinical Medicine, University of Pennsylvania. Sixth Edition. Cloth. Price, $6 net. Pp. 1045, with 468 illustrations. Philadelphia: W. B. Saunders Company, 1915.

This edition represents an extensive revision of this well-known textbook on pathology and the complete rewriting of many sections. A new section on transmissible diseases has been added, as well as on the pathology of the eye, ear and skin. The chapter on technic, of previous editions, has been omitted. The chapter on diseases of the nervous system has been much shortened. Numerous new illustrations have been added.

Medicolegal

Statute Violated by Granting Degree of Doctor of Chiropractic

(Commonwealth vs. New England College of Chiropractic, Inc. (Mass.), 108 N. E. R. 895)

The Supreme Judicial Court of Massachusetts overrules the exceptions of the defendant corporation, which was convicted of granting the degree of Doctor of Chiropractic without authority and contrary to the statute. The statute referred to provides, among other things, that, whoever, without the authority of a special act of the legislature granting the power to give degrees, offers or grants degrees as a school, college or as a private individual, shall be punished. The court says that it is not to be assumed that the statute was intended to relate only to such degrees as were in use at the time it was enacted. It is comprehensive in its terms and may include whatever properly may be described as a degree at any time. "Doctor" is used commonly to indicate skill in the general subject of medicine. Doubtless one purpose of the legislature in enacting the statute was to protect the public from the imposition and suffering which might follow the indiscriminate use of a title conveying the implication of skill to treat disease by those who have pursued no adequate course of study to qualify them. "Chiropractic" is a new word. But it is held in Commonwealth vs. Zimmerman, 108 N. E. R. 893, that one practicing it may be found to be practicing medicine. "Degree," as used in this statute, is any academic rank recognized by colleges and universities having a reputable character as institutions of learning, or any form of expression composed in whole or in part of words recognized as indicative of academic rank, alone or in combination with other words, so that there is conveyed to the ordinary mind the idea of some collegiate, university or scholastic distinction. While this definition may not include all instances, it is sufficiently accurate for the present case. When a title like "Doctor," commonly associated with unusual skill acquired by academic or professional study in schools or colleges, is conferred either separately or associated with other words, the statute is violated. The conferring of a title made up of the word "Doctor" and a word relating to the healing art may be found to be the granting of a degree within the meaning of the statute. The word "Doctor" in connection with an unusual and high-sounding word would be quite as likely to impose on the ignorant and credulous as the false use of the conventional Doctor of Medicine.

Chiropractic and the Practice of Medicine

(Commonwealth vs. Zimmerman (Mass.), 108 N. E. R. 893)

The Supreme Judicial Court of Massachusetts overrules exceptions to a conviction of the defendant of practicing medicine without having been lawfully authorized. The evidence tended to show that he had kept an office, indicated by a sign on which his name was followed by the word "chiropractor," and that he practiced for pay. The court says that the treatment pursued by the defendant was to have those who resorted to him to go into an inner room and remove their outer garments until they were stripped to the waist. The patient then took a sitting position. The defendant examined down the spine, beginning at the top, by feeling with his fingers to see whether each vertebra was in its proper position. The method to discover whether a vertebra was out of position was by making a gliding move of the three middle fingers of the right hand, which constituted the process of "palpation" whereby one vertebra was compared with another. As a result of this "analysis" the defendant was able to tell whether vertebrae were out of alignment or out of their normal positions. In making "adjustments," the patient was placed on a low table with face downward and the vertebra which was out of condition was given a quick thrust or push by the hands of the defendant. Although the defendant did not prescribe medicine, and testified that he paid no attention to the patient's description of symptoms or disease, yet it was obvious that his purpose was to treat the human body in order to make natural that which he found abnormal in the narrow field of his examination. The removal of pressure on nerves is a means of relieving the ills flowing from that source.

The plaintiff's manipulation was of a most important part of the body and related to a nerve center. It might have been found that it could have no other aim than a prevention of disease or relief from existing disarrangement of body functions. That which the defendant did and its manifest purpose might have been found to be practicing medicine within the meaning of the statute. Medicine relates to the prevention, cure and alleviation of disease, the repair of injury, or treatment of abnormal or unusual states of the body and their restoration to a healthful condition. It includes a broad field. It is not confined to the administering of medicinal substances or the use of surgical or other instruments. It comprehends a knowledge not only of the functions of the various organs of the human body, but also the diseases to which these organs are subject, and the laws of health and the modes of living which tend to avert or overcome disease as well as the specific methods of treatment that are most effective in promoting cures. In order to practice medicine one need not cover the entire field of the science. If he devotes himself to a very restricted part of it, he still may be found to practice medicine. It is a matter of common knowledge that there has been great specialization in that profession in recent years.

It was of no consequence that the defendant abstained from the use of the words "diagnosis," "treatment," or "disease" in description of what he did, and employed the terms "analysis," "palpation," and "adjustment." The acts which he did and their manifest design were to be examined rather than the words used, in order to ascertain the true nature of the defendant's conduct. The circumstance that the statute exempts certain classes, such as osteopaths and pharmacists, and those practicing Christian Science, mind cure, massage and others, does not render the statute unreasonable as to the defendant nor deny to him the equal protection of the laws. One of the exemptions is of the "cosmopathic method of healing." "Cosmopathic" is defined in the Standard Dictionary as "open to the access of supernormal knowledge or emotion supposedly from a preternatural world." Without undertaking to decide what a "cosmopathic method of healing" may be, plainly it does not include the defendant's operations.

Fraud Order Upheld After the Employment of a Physician

(Hall vs. Wilcox (U. S.), 225 Fed. R. 333)

The United States Circuit Court for the Southern District of New York in denying a motion, in this old but recently reported case, for a preliminary injunction to restrain the postmaster at New York City from withholding mail from the complainant, who was selling "electric belts" which were advertised as curing or aiding many ailments and increasing and preserving the sexual powers of men, holds that the presumption was that the postmaster general was right in his conclusion on which he issued the fraud order under which the mail was withheld. Certainly the complainant, the court says, did not meet the burden of proof imposed on him by the presumption. He admitted one recent instance of business to be indefensible, and scarcely denied that such instances may have been the rule. If they were even rare, he admitted that some fraudulent quackery existed until recently. To assert that the course of business indicated by the past had been mended by the sudden employment of a licensed physician, concerning whose professional qualifications (including pecuniary independence of the complainant and the electric belt business) nothing was shown, was asking too much of credulity. The complainant's argument was based on the proposition that his misdoing must be proved to be in the present tense, to justify a fraud order. The court knows of no more persuasive evidence of present conduct than past performance.

AMERICAN ROENTGEN RAY SOCIETY

Sixteenth Annual Meeting, held in Atlantic City, N. J., Sept. 22-25, 1915

(Continued from page 1581)

Roentgen Deep Therapy

DR. ARTHUR F. HOLDING, New York: The physical methods used with the Roentgen ray, such as radium coagulation and the ultraviolet light, gave 100 per cent. of cures in the treatment of nonmalignant cases, that is, where the disease was superficial. Seventy per cent. of deep therapy cases were improved in conjunction with surgery, and 7 per cent. of the inoperable cases were improved in about 20 per cent. of the hopeless, inoperable cases.

Radium Plus Roentgen Ray in the Treatment of Superficial Lesions

DR. RUSSELL H. BOGGS, Pittsburgh: Radium applied locally supplemented by the Roentgen rays to the adjacent tissues is the ideal form of radiation, because all the malignant cells can be rayed stronger with less injury to the healthy tissues. Surgery and radium are local methods of treatment. Metastases in distant parts of the body are beyond the reach of these methods. Radium destroys the malignant cells without injuring the normal ones, but the radium rays do not reach beyond a certain depth; hence it is evident that radium should be used only in cavities, cross-firing as much as possible before inserting the tube into the growth, and raying the adjacent lymph supply as thoroughly as possible.

DISCUSSION OF THE PAPERS OF DRS. HOLDING AND BOGGS

DR. HENRY K. PANCOAST, Philadelphia: I have been interested in radium for over a year and a half, and have treated more patients with radium than with other methods. Nevertheless, I have as much confidence in Roentgen therapy as I ever had. Radium and Roentgen rays can be combined to good advantage. There are certain conditions in which radium is superior to the Roentgen ray, such as nevi. It is useless to attempt to treat with radium unless a sufficient quantity is used. This is especially true of deep lesions, and even in the case of superficial lesions it is dangerous to treat large areas with small quantities of radium. It has been said that radium reactions are not as severe as Roentgen-ray reactions. That is not true; but radium reactions disappear more rapidly and more uniformly than Roentgen-ray reactions. It has been said that radium radiation is not manifested in a desirable way beyond an average of 2.5 cm. from the source of radiation. I believe that there is such a condition as stimulation of the growths. We may give too little radium or too little Roentgen radiation, and stimulate a malignant growth to greater activity, thus also increasing the danger of the occurrence of metastases. In inoperable carcinoma of the uterus, when radium has been used, patients with few exceptions have been markedly improved. The local lesion in the cervix has in many instances disappeared. The patient has moments of comparative comfort, without discharge or bleeding, although after a year I have received reports of recurrences and metastases. Why? For the simple reason that the man who used the radium did not have in mind the fact that effects were not being obtained beyond 2 or 3 cm. distant from the Roentgen tube. That can be overcome by a combination of the Roentgen and radium therapy.

DR. H. W. DACHTLER, Toledo, Ohio: I do not know of any case of epithelioma that has been cured by radium. I know of two patients who were treated with radium because the Roentgen ray was not satisfactory. One of these patients is dead and the other would like to be. As to the difference in reaction between radium and Roentgen rays, that is easily explained. Radium is applied to the surface, and the intensity of the Roentgen ray is 1,000 times greater; hence radium reactions clear up more rapidly.

DR. GEORGE E. PFAHLER, Philadelphia: The keynote of success in this line of work is a combination of radium and the Roentgen ray, the former to be applied in cavities and the latter on the surface.

Oxygen in Cystoscopy and Pyelography

DR. AMEDEE GRANGER, New Orleans: For six years I have used oxygen. It is easily obtained, does not harm the tissues, and is a mild antiseptic and analgesic; it is well borne by the bladder, and permits of much greater distention in the case of painful and irritable bladder than is possible with either air or boric acid solution. It is easily retained and easily expressed. Calculi show with remarkable clearness. If the prostate is enlarged, the shadow is easily made out. The entire outline of the bladder is distinctly visualized, and if the walls are unyielding because of adhesions or infiltrations, these are easily seen. Growths, diverticuli and other deformities are easily recognized.

Pyelography

DR. W. F. MANGES, Philadelphia: Pyeloscopy is preliminary to pyelography. A big catheter and an opaque fluid should be used. No attempt is made to settle the actual condition of the injected pelvis, but only to determine the proper time to make the pyelogram. The procedure causes the patient no additional discomfort, and is a safeguard against overdistention. The operator need not have any fear of personal danger, because fluoroscopy today can be made perfectly safe.

DISCUSSION ON THE PAPERS OF DRS. GRANGER AND MANGES

DR. JOHN H. SELBY, Washington, D. C.: Oxygen is a very valuable aid in the study of the bladder. Using it in the kidney requires much distention of the pelvis and calices, as well as of the ureter, in order to get the proper differentiation. That is dangerous. Therefore, I prefer the fluid which is allowed to flow in by the gravity method. Fluids, especially thorium nitrate, are not as irritating as oxygen, and do not overdistend. If there is danger of overdistention, the patient should be put immediately into a hot sitz bath, the back scalded, if necessary, and then he should be given 1/75 grain of atropin. I have had to do that several times. This work is very dangerous unless it is done carefully. It is a feasible and workable method in experienced hands. I am glad that Dr. Manges has taken up fluoroscopy in kidney cases. Our English confrères are well satisfied with this method, and some of them believe they can locate a stone in 80 per cent. of the cases without making any roentgenograms at all. The question of ascending infection, however, must be considered in these cases. In a few cases in which a 10 to 12 per cent. thorium nitrate solution was used after the bladder was filled and the patient was then placed in the Trendelenburg position, we could see the solution travel up the ureters.

DR. A. W. CRANE, Kalamazoo, Mich.: I have distended the bladder with filtered air for the last ten or twelve years, and have never had any bad results or accidents. It is not necessary to use oxygen. The air is filtered by pushing cotton into a medicine dropper and pumping air through that into the catheter until the patient feels some distention in the bladder. It is not necessary to overdistend the bladder, because if it can be outlined, one can decide whether the stone, if present, is inside or outside of that viscus.

DR. WILLIAM H. STEWART, New York: I made some investigations of enlarged prostates by injecting air into the bladder. I was much impressed with the detail of the coccyx which this method gave. One cannot get it in any other way. Overdistention and direct trauma of the calices can be avoided by using Dr. Manges' method. These two points have caused most of our trouble, but this method is not dangerous, if used by the expert.

Treatment of Exophthalmic Goiter by Roentgen Therapy

Drs. J. D. Zulick and George E. Pfahler, Philadelphia: The trial of the treatment of goiter by Roentgen therapy with an interval of waiting of one month is justifiable in all cases, and if operation is decided on, nothing is lost, and many operations can be avoided. The treatment should be directed toward both the thyroid and the thymus. An increase in weight and a decrease in pulse rate are the first signs of improvement, and are practically always found. Treatment must not be prolonged over too long a period, or hypothyroidism may be produced. The goiter and the exophthalmos are the last to show improvement, and in many cases have shown no change at all.

Method of Preventing Unpleasant Symptoms Following Deep Roentgen Therapy

Dr. Sidney Lange, Cincinnati: Unpleasant constitutional symptoms following deep Roentgen therapy may be the result of an acidosis. As the administration of sodium bicarbonate by mouth prevents the occurrence of these symptoms, I now prescribe as a routine 30 grains of sodium bicarbonate every three hours for the first forty-eight hours after each treatment. When the condition of the patient warrants, the sodium is also given for twenty-four hours before treatment, to increase the alkalinity of the blood, and the patient is encouraged to drink freely of alkaline water. We also apply Dodd's alkaline lotion twice daily to the skin areas under treatment as a prophylactic measure against the development of a reaction. We have thus been able to increase the skin tolerance and deliver a greater dose to the underlying tissues than would otherwise be possible.

Cause and Prevention of Constitutional Symptoms Associated with Deep Roentgen Therapy

Dr. George E. Pfahler, Philadelphia: The gases produced by the action of the high tension current on the air are an important factor in the production of these symptoms. We may possibly add the ionization effects of the rays. The highly sensitive and neurotic type of patient is more liable to develop these symptoms than the more sluggish and phlegmatic patient. The rational line of treatment is to eliminate the gases and to provide fresh air. The former may be accomplished by preventing leakage of the current by careful insulation, and the latter by giving the treatment in a large, well-ventilated room, and by the instillation of a fan which will carry the gases away from the patient. To supply fresh air and oxygen directly to the patient, I use a breathing mask placed over the nose and mouth. It is made of celluloid with a rubber cap similar to the mask that is used in connection with a nitrous oxid-ether apparatus. We also divide each series of treatment, giving part of the treatment on two or three successive days.

Roentgen Therapy of Menorrhagia, Dysmenorrhea and Uterine Myomas

Dr. Sidney Lange, Cincinnati: In fifty consecutive cases a satisfactory result was obtained by Roentgen treatment, and artificial menopause, apparently permanent, was established in every case in which it was desired, regardless of the age of the patient. Malignancy has not developed in any case, either during or following treatment, nor has there been a recurrence of menstruation, although in several cases there has been an occasional faint show during the few months just following the treatment. After the lapse of a few months, however, abatement of the ovarian function has been complete and permanent. It is a most satisfactory form of treatment, as it does not harm, causes no discomfort or pain, and is good in its results.

DISCUSSION ON THE PAPERS OF DRS. LANGE, ZULICK AND PFAHLER

Dr. Frederick H. Baetjer, Baltimore: I have been very much interested in deep therapy of the thymus. In all our cases we have made examinations of the chest to see whether there was any compression of the trachea or a substernal thyroid. After operation on the thyroid a certain percentage of the patients did not get well. The question is, Does the thymus play any rôle in these cases? We cannot demonstrate the thymus roentgenographically in every case, because its edges may be as thin as tissue paper, and hence throw little or no shadow. We have often seen the edges of the gland extending out beyond the sternum. We have started to treat all thyroid cases first by raying the thymus, protecting the thyroid as much as we could. In many ways the results have been satisfactory, and in some cases they have been disappointing. We always give this treatment first, however, and if there is no improvement an operation is performed. The difficulty in treating the thyroid with the Roentgen ray is that we cannot tell how much of the gland is being destroyed, and we must remember that a certain amount of gland tissue must be preserved for function. The surgeon is better able to approximate that when the gland is exposed to view.

Dr. Rollo H. Stevens, Detroit: To prevent constitutional symptoms, I use an electric fan, blowing directly on the patient, and I give the treatment in two sittings. I treat the patient from the side, and that position, together with covering the patient's mouth with a towel, seems to help them very much.

Dr. George E. Pfahler, Philadelphia: A prominent physiologist told me that the enlargement of the thyroid stimulates the enlargement of the thymus, and vice versa, and he suggested that the exophthalmic patient may have an enlargement of the thymus as the result of shock, nervous strain, or some condition which favors enlargement of the gland, but that the enlargement of the thymus might be responsible wholly for the thyroid enlargement.

Dr. Sidney Lange, Cincinnati: I treated a woman who had a sarcoma of the upper jaw, exophthalmos and blindness in each eye, with, in addition, occlusion of the nares. Deep therapy gave splendid results, the exophthalmos disappeared, the nares opened up, and the foul odor of the discharge stopped. A patient with lymphosarcoma of the neck made a symptomatic recovery. The patient, a railroad engineer, is still at his work. There has been complete disappearance of the tumor. Another patient with mediastinal sarcoma presented marked circulatory pressure symptoms. He also has made a symptomatic recovery, being entirely free from all pressure symptoms. *(To be continued)*

DELAWARE STATE MEDICAL SOCIETY

Annual Meeting, held in Wilmington, Oct. 11-12, 1915

The President, Dr. Henry W. Briggs, Wilmington, in the Chair

Anthrax

Dr. John Palmer, Jr., Wilmington: I have in the last eight years attended over forty-two cases of anthrax affecting the cutaneous and cellular tissues. The part is thoroughly but gently washed with 1:2,000 mercuric chlorid solution, dried well, then swabbed with 10 per cent. tincture of iodin and some alkali applied. This is repeated daily for several days until the slough has come away. It takes about two or three weeks for an ulcer to heal, which it does with very little scar as compared with the tissues involved. No systemic treatment is necessary other than cleaning out the bowels, though some require strychnin and alcoholic stimulants. If the trachea becomes much involved, nothing will prevent death by suffocation. It has been my experience that if the vesicles are kept unruptured it is better for the patient. The fatal cases I have seen were those in which the vesicles had been ruptured.

DISCUSSION

Dr. Joseph P. Wales, Wilmington: It is important to let the vesicle alone. When the blood vessels and lymphatics are opened, a worse infection in the tissues around the vesicle will ensue.

Dr. Joseph W. Bastian, Wilmington: I had a slight experience with anthrax and realize that the diagnosis will mislead the majority of us if we are not on our guard. The pimple is innocent looking, and as it develops, the surrounding tissue is slightly lighter in color than the healthy tissue.

In Wilmington, where we have a great number of Morocco factories, there is much more anthrax than is found in many other parts of the country, and it is a condition which is fatal so often that it is exceedingly important in two particulars: if it is not meddled with too much, the patient is liable to recover, and, if it is meddled with, the infection is going to spread, and may possibly reach other persons.

Uterine Fibroids

DR. HENRY J. STUBBS, Wilmington: These growths are the most common of all uterine tumors, and usually develop during menstrual life. They are prone to secondary degenerations and to septic infection. The latter condition may be brought about by the improper use of the uterine sound, by an injury or by extension from neighboring structures. These tumors not infrequently undergo malignant change, and for this reason alone should be removed early. The usual symptoms are hemorrhage, pressure and traction, constipation, rectal and vesical tenesmus, and frequent urination or retention of urine. In thirty-three patients operated on I have had five deaths. One successful case had had an exploratory operation in a large hospital and had been pronounced inoperable.

DISCUSSION

DR. S. C. RUMFORD, Wilmington: In making examinations for other conditions we frequently find fibroids. The ones, aside from those that are large and produce pressure, that generally call the patient's attention to the condition and cause her to consult us are the submucous variety with hemorrhage. We should bear in mind the possibility of malignancy. All fibroids should be removed. Fibroids producing pressure of any sort should be removed because they are likely to be infected by a bruise or blow on the abdomen, or by a fall, which may interfere with the blood supply sufficiently to cause an infection. A very unfortunate condition following operation is embolism. This happened to me in two cases; the patient got up perfectly well and died suddenly.

DR. GEORGE I. MCKELWAY, Dover: Fibroids of any size should be removed. They are liable to degenerative changes. The mere fact that these changes may not be fatal does not influence the fact that they do impair the general health and sometimes the mental health.

Unusual Case of Renal Calculi

DR. JAMES A. DRAPER, Wilmington: The patient, a man of 38, stated that ever since he could remember he had been subject to attacks of severe pain in the left loin extending to the bladder, during which the left side of the abdomen would swell and only a small amount of urine would be passed. The attacks would last from a few hours to a day and terminate by the passing of a large quantity of very thick offensive urine. At 11 years of age litholapaxy was done for stone in the bladder. This gave only temporary relief. When seen a year ago he was weak, pale and emaciated with a senile appearance. A roentgenogram revealed stone of the kidney. Operation was done and several calculi found aggregating in weight 1 pound 2½ drams. The patient died of kidney failure three weeks later.

DISCUSSION

DR. WILLIAM WERTENBAKER, Wilmington: The differential diagnosis between renal calculi, cholelithiasis and appendicitis is frequently not made. At times it is impossible. I recall a case in which I made a diagnosis of either gallstones or kidney stone. During an attack the doctor called in diagnosed the condition as suppurative appendicitis, and a surgeon verified the diagnosis. The patient fell into my hands some years afterward. She continued to have pain on the right side, radiating up to the right shoulder blade, with nausea and vomiting. In the meantime she developed strangulated hernia at the seat of the old incision. She was again rushed off to a surgeon, who afterward told me that he had palpated the gallbladder and could not find stones. After her return from the hospital she developed cystitis, and by that time I could feel a distinct mass in her right loin. On operation there was found a large pus cavity in the central part of which there was a renal stone. It is my opinion that that stone had existed from the very beginning.

DR. H. A. CLEAVER, Wilmington: This collection of stones was one of the greatest known. At the time when I first saw the plate I could hardly believe my eyes. It seemed to me incredible. In kidney calculus, clinical diagnosis is not sufficient. The history and urinalysis are important; but in any case with suspicious symptoms around the kidney, diagnosis is likely to be in doubt until the roentgenologist has made a careful examination.

Some Points in the Treatment of Fractures

DR. HAROLD L. SPRINGER, Wilmington: A roentgenogram should be made by an experienced man in all cases, whether one is sure of the diagnosis or not. This will serve as a protection for the physician, as well as give the patient the benefit of any doubt that might exist as to the correct diagnosis. It will also be of value in case of any legal complications. An anesthetic should be used without hesitation in securing perfect reduction. Fractures do not require emergency treatment. The soft parts should be given the first attention and allowed to become normal even if it takes several weeks. This will avoid those disastrous complications which require open operation to correct. Open operations should be used only in those cases in which conservative treatment has been tried and failed, with the exception of fractures of the patella, olecranon and capitellum, which should always be treated by the open method. Too absolute fixation of fractures of the shaft of the long bones should be avoided, and rigid immobility in fractures about joints should be secured. All movement in the latter should be postponed until the end of the fourth or fifth week. Disastrous results can be avoided only by the careful treatment of all fractures, particularly in the use of common sense in their dressing; and too much emphasis cannot be laid on the necessity for frequent and repeated inspections of the part to ascertain if it has been perfectly reduced and is remaining in good position, as well as to see that there is no undue pressure on the soft parts causing interference with the circulation.

DISCUSSION

DR. H. A. CLEAVER, Wilmington: It is astonishing what mistakes can be made with a condition apparently so simple as a fracture. An injury to the hip joint or shoulder joint should absolutely not be diagnosed without a roentgenogram.

DR. WILLIAM L. RODMAN, Philadelphia: No one at this time is justified in treating a fracture, particularly about the joints, the elbow joint more than any other, without an accurate diagnosis having been made by means of the Roentgen ray. Lawsuits are very apt to follow fractures that are treated, and for moral reasons we want every support possible. In addition to the valuable aid given by the Roentgen ray, one is putting oneself in a position in which one cannot be criticized if one has called to one's aid so valuable an agent as the Roentgen ray. An anesthetic should be used in practically all cases, particularly in the case of a fracture in a child. It is almost impossible to make an accurate diagnosis without an anesthetic, and it is almost impossible to secure an accurate coaptation of the fragments. Here is where not only the practitioner but also the surgeon fails to do his full duty by the patient. In our efforts to secure absolute immobility of the fragments we sometimes are responsible for ununited fracture. Particularly is that the case in the humerus and femur and in bones in which we know that nonunion or delayed union so frequently occurs. In other words, a certain amount of motion at the seat of fracture is not undesirable in some instances.

Military Preparedness in Relation to the Medical Man

MAJOR LA GARDE, Washington, D. C.: There is a responsibility that the civilian practitioner does not always take to himself when it comes to the condition of war. In the Spanish-American War we were a drop in the bucket as it were in numbers compared to the practitioners of medicine who came into the military establishment. There were six civilian practitioners for every one of the army's four. In the Civil War it was far greater. When it comes to a question of medicomilitary preparedness, your responsibility is just that much greater than ours, and you must take it home and consider it for all sorts of patriotic reasons. In the countries of France and England and Germany and Russia today every doctor is in one way or another connected with the military establishment. We in the regular army attempt to hold the framework of what you have got to work with in time of war. We keep it going as well as we can. When war comes we have got to have assistance, and we must have assistance that has been prepared and that has been trained, because, if we get people who do not know anything about the subject of camp sanitation, hygiene, administration and all the work that is necessary on the line of communication with an army, the help that we get is worse than useless. So we want an auxiliary staff we can put our hands on and whom we have work for. We have a national guard organization, but they are not sufficient. The general staff desires that there shall be at least six doctors for every thousand strength. We have reason to believe that we shall get that without any trouble from Congress. Congress for various reasons that I will not go into now is very liberal toward the medical department. The achievements of the medical department are world wide. Now what we want from the medical profession outside is assistance so that what we call the Medical Reserve Corps of the Army will be composed of more than average men from civilian life. Now if you will give us licentiates from the National Board of Examiners, which has been proposed, I am sure that I can vouch that after we have trained these men in the summer camps and after we have trained them through the correspondence school, there shall be no breakdown in the medical department of the army.

COLORADO STATE MEDICAL SOCIETY

Forty-Fifth Annual Meeting, held at Denver, Oct. 5-7, 1915

(Concluded from page 1582)

Peripheral Facial Paralysis: Treatment of the Refrigeration Type

Dr. George A. Moleen, Denver: When cases are seen early, within from sixty to seventy-two hours, a cantharidal vesication over the mastoid seems to cause a prompt improvement in proportion to the earliness of application, and a calomel purge, preferably in divided doses. The use of salicylates is advisable and seems to do good, rather in view of the stimulating hepatic influence than of their antirheumatic effects. The eye should be guarded through the use of a shield, and bathed and bandaged to keep the lid closed, especially at night. After from two to four days, strychnin increased with moderate rapidity to $\frac{1}{24}$ or $\frac{1}{20}$ grain should be given, and at the same time gentle massage with the aim to exercise passively the muscles; it is well to advise that voluntary attempts should be made to move the face muscles at the same time. The electric stimulation should be instituted at frequent intervals and for brief periods when the massage is begun. If no faradic contractions can be obtained, the galvanic current should be used. Just sufficient current to accomplish distinct motion is advisable, and if the anode causes a contraction with a *less* current strength than the cathode, this should be employed. The faradic current should replace the galvanic as soon as contractions may be obtained, unless a current strength is required, which is painful. Electricity has not the slightest curative value, and is used simply to obtain the mechanical *stimulation* caused by the movement of the paralyzed muscles in order to maintain their nutrition and to avoid atrophy as far as possible. In the more advanced cases, painting the mastoid with caustic solution of iodin, or the internal administration of potassium iodid, or both may be tried. Massage and electrically induced exercise of the muscles, together with strychnin, may be used advantageously. Persistent and patient use of these measures will often be rewarded by marked improvement, for even when the muscles have long since lost their electric contractibility, one must not despair, for electric response has reappeared after having been lost for a year. Recoveries of considerable movement have been observed in cases of even longer standing.

DISCUSSION

Dr. Howell T. Pershing, Denver: My experience has been very much the same as Dr. Moleen's, and I take the same view of the etiology which he has emphasized, namely, persons who suffer from Bell's palsy generally do so because the facial or fallopian canal through which the nerve travels is long, crooked and narrow, and if it is constricted the least bit more than it is in normal individuals, then the nerve has no room for swelling. Then, if the patient is exposed to cold on one side, such as might ordinarily cause rheumatic symptoms of stiff neck and a little pain about the ear, this nerve may swell. As there is no room for it to swell, pressure is immediately exercised, and the nerve fibers will not withstand the pressure and paralysis ensues. Hereditary cases can be explained from the fact that there is the anomaly of undue narrowness of this canal in the family. For instance, I have had four cases of Bell's palsy in one family. The father had two attacks of facial paralysis on the same side; his son had an attack of facial paralysis, and his daughter had a similar attack. I had the opportunity of treating them in all four attacks. As to treatment, if I get the case early, I put a blister behind the mastoid and give the salicylates on the theory that if it is not rheumatism it is something like rheumatism, and the salicylates are good in almost anything that resembles rheumatism. I myself believe these cases are rheumatic and probably infectious, and exposure to cold lowers the resistance and allows the infection to get a start. At any rate, I approve of the treatment which was recommended by Dr. Moleen.

Dr. G. A. Stoddard, Pueblo: It would seem almost presumptuous on my part to take issue with Dr. Pershing in cases of this kind; but I do not think the cause of the trouble is swelling of the nerve itself, but the lining of the cavity through which the nerve passes. It surprises me to hear Dr. Pershing speak of rheumatism as being anything but an infection.

Dr. James A. Patterson, Colorado Springs: I should like to put on record a series of cases in one family. The mother had one or two attacks of Bell's palsy. Her daughter had one attack, and the son had three attacks. The last attack was very persistent, but there was complete recovery. These patients are prone to have more than one attack. I have seen more than one attack in the same patient.

Heat in the Control of Inoperable Cancer

Dr. C. E. Tennant, Denver: Modern investigation seems to prove conclusively that heat is one of the most effective therapeutic means we have in the control of cancer, provided it is properly applied. The subsequent use of the Roentgen ray with crossfire applications of the rays from a hard tube is no doubt good after-treatment. The source of the heat may be varied from that of hot water to the actual cautery, but it must be constant, long continued, and free from insulation in order to spread evenly a temperature of from 120 to 150 F. throughout the mass. In applying the treatment to carcinoma of the pelvis or other easily accessible structures, the Percy cautery irons are probably most satisfactory. The Percy method is proving very satisfactory in inoperable cancers of the lip, face, neck and breast, and I believe it worthy of use as a preliminary treatment in borderline cases of this class, as well as pelvic lesions. This should be followed later by radical excision, thereby doing away with the possible metastatic recurrence.

DISCUSSION

Dr. W. A. Kickland, Fort Collins: There is a difference in the vitality of the cells of a new growth from the cells of normal tissue. This makes it possible to use any one of a number of agents to destroy the cancer cells. Arsenic, zinc chlorid, the Roentgen ray, radium, *heat, etc.*, are not selective in their action in the strict sense of the term, but destroy every living cell which comes under their influence, the weaker ones first, and finally the normal cells. Just how many degrees of heat there are between that which will cause the death of the abnormal cell and that of a normal one is perhaps still a question. Dr. Percy says that a cancer cell dies at 113 F., while a normal cell lives at 131 F. We know that in the application of heat to the lower forms of life, protoplasmic activity is increased up to 116 F., that at 120 all activity stops, and that the protoplasm will not recover if heated to 125. As a preliminary treatment in some inoperable cases, the application of heat may make some cases operable; but as a means of obtaining a permanent cure, it has not more selection in its action than has a scalpel in the hands of a competent surgeon.

Dr. William M. Spitzer, Denver: I believe that in the course of time heat will prove very effective in the treatment of not only inoperable but of operable cancer. Cancer of the bladder grows without deep infiltration for a long time. Until this time arrives, when it infiltrates the muscular and the peritoneal coats, we can treat it very successfully with heat. In 25 per cent. of the cases of cancer of the bladder we have heretofore failed to reach any result except death. In the last five or six years we have been able to apply heat to these cancers intravesically with excellent results.

Dr. Casper F. Hegner, Denver: The resistance of the normal cell depends not entirely on its inherent vitality, but in a large measure on the arterial circulation. Malignant cells may be extremely vascular, but the vascularity depends almost entirely on the venous content. A low grade heat, if applied at a temperature not exceeding 140, will affect actively the circulating blood. If it goes beyond that it causes more or less destruction of the vessel wall and coagulation. If the temperature is kept below that, it will kill nearly all cells having the power of arterial circulation, and a large venous content, and the normal cells having healthy circulation will not be affected. That is a more rational explanation of the efficacy of low grade temperatures in the treatment of malignant growths.

Further Experience in the Use of the Wire Tourniquet in Thyroidectomy

Dr. Leonard Freeman, Denver: Several years ago I reported a new, simple and safe method for the performance of partial thyroidectomy by means of the wire tourniquet. Since then I have had occasion to employ the procedure fifty-four times in forty-one cases, and have modified and perfected the technic considerably, so that I now feel justified in declaring that the method is a useful addition to the operative procedures in connection with goiter. The advantages of the wire tourniquet are several: It is easily and rapidly applied, requiring no particular skill in its adjustment and saving considerable time. It effectually controls all hemorrhage, thus obviating the necessity for crowding the field with hemostatic forceps. It does away with danger to either the recurrent laryngeal nerves or the parathyroid bodies, because it is employed at a safe distance from them, and even if they should by any chance be caught, the pressure is not great enough to injure them permanently. It compresses the goiter without crushing it, which is of importance in exophthalmic goiter at least. Lastly, the loops pass through the tissues and prevent the wires from slipping during the course of the resection irrespective of the size of the remaining stump. Neither clamp forceps nor a ligature of any kind answers the same purpose, nor can they be used, except in special cases. Forceps crush the tissues objectionably if they are applied tightly enough to prevent slipping when the lobe is cut away. Sutures are usually placed with much difficulty, and if tight enough to be efficient are apt to cut through, especially if the tissues are soft and vascular. Both forceps and ligatures may crush the nerves or the parathyroids.

DISCUSSION

Dr. Charles B. Lyman, Denver: I have seen Dr. Freeman use this method in many cases, and it is extremely satisfactory. There are types of large goiters that are not easily delivered in which it might be objectionable, and when the technic is applied close to the base may produce a sufficient amount of tugging on the trachea to interfere with proper respiration. I prefer to control hemorrhage with hemostats, using small ones, which are not in the way.

Dr. Charles A. Powers, Denver: One might perhaps question whether in this day the ligation of important tissues *en masse* is a procedure based on entirely sound surgical principles. I have been thinking that as time goes by Dr. Freeman will resort to the painstaking ligation of the individual vessels.

Dr. William B. Craig, Denver: I dislike to disagree with Dr. Powers. This is a recognized operation, and outside of enucleation of the tumor we have the operation of resection, one that can be done the speediest, and with the least loss of blood. It is the operation of choice. I have done more resections than enucleations or extirpations.

Dr. A. S. Taussig, Denver: The average man in doing much goiter work can use this method quite safely. It seems to me, many practitioners could use it who would not undertake it in another way.

Dr. Frost C. Buchtel, Denver: In the ordinary case of goiter, hemorrhage is not serious. In a large intratracheal goiter, particularly if one has associated with the goiter a small subretrotracheal lobe, hemorrhage is very serious. In a small goiter that is easily dislocated, I think the wire tourniquet would be eminently satisfactory. In these cases almost every form of hemostasis is satisfactory.

Etiology, Pathology and Therapy of Hodgkin's Disease and Allied Affections

Dr. J. L. Yates, Milwaukee, Wis.: In Hodgkin's disease there are four quite distinct types of lesion or stages in the development, from the earliest to the latest, or possibly from the most acute to the most chronic. The first has been reproduced experimentally. The other three are well established. Atypical lesions are remarkably numerous, and since apparently they may develop as the result of favorable therapy, it is fair to assume that they may be the result in part of variations in virulence and resistance. Since Bunting obtained the *B. hodgkini* in February, 1912, he has been able to cultivate it from all fresh affected tissue wherein the histologic diagnosis was positive or when the blood picture of the patient was characteristic unless that tissue had been contaminated or had been recently actively treated by the Roentgen ray. He has recovered it in pure culture five times from one individual at various intervals extending over three and a half years, three times from another, and twice from two others. Recently one of our earliest patients from whom a mass of cervical glands had been removed eight years previously suffered a relapse, and the organism was obtained from a recent axillary enlargement. The inoculation of dogs with small doses over many months has produced the chronic changes in the germinal centers in lymph glands and in the spleen identical with those occurring in Hodgkin's disease and Banti's disease, respectively. Moreover, these experimental animals and one normal man who was given a polyvalent vaccine prepared from similar organisms all developed the characteristic blood changes, the man reverting to normal after the vaccination was discontinued.

A study of our experiences and a review of the literature have indicated that certain more or less generally accepted therapeutic measures are harmful or futile. Arsenic is of benefit solely as a tonic. The administration of salvarsan is of no lasting if any benefit. Roentgen therapy must be given as an adjunct, since no cure due to this agency alone is on record. Aside from burns, the progress of the disease may be affected unfavorably by ill-advised roentgenologic treatments. Partial excisions are as indefensible as in cancer therapy, and this applies equally to the removal of test glands. A probable diagnosis can be obtained from the clinical history, the blood picture, the reaction to tuberculin and physical examination. If radical treatment be indicated, a primary excision with frozen section diagnosis may immediately precede it. Otherwise there is nothing to be gained for the patient but a probably certain diagnosis at the risk of a grave dissemination of the process. The only justification for routine test gland excision, the preparation of an autogenous vaccine, has been eliminated from our work.

MINNESOTA STATE MEDICAL ASSOCIATION

Forty-Seventh Annual Meeting, held at Rochester, September 30 and October 1, 1915

The President, Dr. J. T. Rogers, St. Paul, in the Chair

Radium in Dermatology

Dr. S. E. Sweitzer, Minneapolis: Radium has a definite value in the treatment of certain skin conditions. It is easily controlled and of accurate dosage. Its application is unattended by pain and is very pleasing to the patients, especially the young and the very old. The cosmetic results are excellent.

DISCUSSION

Dr. G. P. Crume, Minneapolis: The rays from the salts of radium or radioactive substances are very like those from the Roentgen-ray tube. Whether or not the emanations are identical in substance is not known, but their effect on normal and diseased tissues appears to be the same. The reactions are certainly very similar. Each one possesses some advantages, due chiefly to the form in which used. For example, radium lends itself especially to use in the cavities of the body, as the mouth, rectum and vagina, or may be placed in a capillary tube and inserted into a tumor with the hypodermic needle. The chief objection is that there is only a very limited quantity available, and the applicators are small, making it very tedious to radiate a large area.

Dr. G. B. New, Rochester: In treating large cavernous angiomas frequently seen in children, a large tube inserted directly into the tumor through a small incision, and left in for a longer time than the ordinary exposure, will give much better results. In large cavernous angiomas, the result is better if we make a small slit in the tumor and insert a large radium tube in the mass instead of using superficial packs outside.

Dr. R. E. Farr, Minneapolis: Some years ago under the use of the Roentgen ray in this class of cases I succeeded in obtaining a clinical cure in a number of instances, but later become dissatisfied with that treatment on account of failures. In those cases in which surgery does not hold out very hopeful success, radium can be tried.

Dr. J. W. Little, Minneapolis: When a tracheotomy tube is worn for a long time, we find that the granulations are not only around the tube but also in the trachea itself; and when the tube is removed, these granulations will fill up the trachea and cause difficult breathing. The tube has to be reinserted. Radium can be used here to get rid of these granulations and also the superficial ones, by being applied externally.

Dr. E. H. Beckman, Rochester: There is no question that epithelioma in the early stages is an absolutely local disease, and as such can be cured in a great many cases with radium and with the Roentgen ray. Very often in growths about the eye or on the cheek, a great deal better cosmetic results can be obtained with radium than with excision. But it must be remembered that we know very little about the penetrating power of the Roentgen ray and radium, and that when a malignant growth is situated in such a position that the adjacent lymph glands are subject to early involvement, while the primary growth may have entirely healed and may stay healed permanently, metastases may occur in the adjacent lymphatics, and for that reason I believe that a great many cases that are being treated at the present time with radium are hardly cases to be treated in that way.

Dr. H. G. Irvine, Minneapolis: Working with radium in dermatology, it should be taken for granted that the cases treated are selected cases, and the experienced dermatologist will not attempt to treat such cases with radium except when patients refuse to undergo operation. After excision, either the Roentgen ray or radium should be used. It is not possible in some locations to be sure that the entire tumor is removed. It is possible after excision that the Roentgen ray or the rays of radium will have a selective action on cancer tissue; exposure of the part to the rays will make one more reasonably sure that any remnants of cancer cells are destroyed. I think it is recognized in such a case as cancer of the lower lip that the best treatment would be first excision, followed by the use of radium or the Roentgen ray.

Syphilis

Dr. N. L. Linneman and **Dr. E. L. Tuohy**, Duluth: Our study was an attempt at a classification of 387 cases of syphilis. In the primary group there are 18 cases. Four were on the lip (3 on the lower and 1 on the upper); 1 on the right leg, above the knee; 2 at the meatus; 10 at the glans penis, and 1 on the tonsil. In the secondary cases, primary lesion in 5 was extragenital (2 being on the finger, 2 on the lip, and 1 under the scrotum). A mixed infection complicated 3 of the primaries, causing ulceration. There were 61 cases of secondary syphilis; 25 were macular, 13 were maculopapular, 19 papulopustular, and 1 ulcerative or malignant. These came under observation from one to twelve weeks after the onset. Ages varied from 2 to 61. A boy of 2 acquired the disease by being kissed by an aunt who had mucous patches in the mouth. Fifty of these cases occurred under the age of 30. The character and extent of the eruption had little to do with the constitutional disturbance. In the group of cases known to have syphilis, or in which there was parental or conjugal syphilis, there were forty-nine cases. Forty-one consulted us to find out whether they were still in need of treatment, and eight came because husband or wife had been infected, and it was desirous to know whether they had also contracted the disease. All gave positive Wassermanns and were treated. As far as could be ascertained, the disease had been contracted from six months to fifteen years previously. Fourteen of this group came because they were contemplating marriage and wished to know their condition. In most of these cases, the patient felt quite well, but in several, despite the absence of active complaint, evidences of syphilis, such as ulceration of the nose or tender points on the tibia, could be elicited.

In the cutaneous group, there were 40 cases. Mucous patches in the mouth and throat occurred in 3 cases. A great variety of ulcers were encountered: 5 on the leg; 1 on the right arm; 1 on the back of the neck; 5 on the tonsils; 1 on the tongue; 1 on the gum (about the back teeth), and in 1, a very large ulcer on the abdomen, below the umbilicus. One had ulcers about the rectum; 2 had large serpiginous ulcers back of the shoulders and neck; 4 had eczemalike, scaly patches in the palms of the hands; 1 had a rash like psoriasis quite generally over the body; 2 had gumma of the nose; 1, gumma of the upper lip; 1, gumma of the roof of the mouth, and 1, gumma of the left cheek. One had a large broken-down ulcerating gumma of the scalp; 1 had condylomata lata around the vagina and rectum; 6 had a scaly condition, notably on the cheek, tending to cover considerable areas of the body, and 1 patient had pemphiguslike blebs. In this cutaneous group were 7 congenital cases, the ages being from 1 month to 6 years. Ten of this group of acquired syphilis gave no history of the disease, and had no treatment. The others had had short courses of treatment.

In the nervous group there were 31 cases, 4 cases of cerebrospinal syphilis and 27 cases of tabes. Three of the 4 cases of cerebrospinal syphilis were advanced cases, and all 3 had more or less hemiplegia. The other case was an early case. The early case responded to treatment very readily. In one of the advanced cases, which was of five years' standing, the patient gradually grew worse, and finally died. Of the other 2 patients, 1 of them showed some improvement, especially so far as pain was concerned, and also gained considerable in weight, the general condition being improved very much. The other patient was under observation for four months, and thought he was hopeless because he did not improve more rapidly; consequently he quit treatment. Of the 27 cases of tabes, 11 cases were in the stage of ataxia, and had considerable impairment of motion. These cases had nervous symptoms from four to twenty years. Seven of these patients admitted having had syphilis, and had more or less treatment. The other 4 patients gave no history of syphilis. Five of these patients gave positive Wassermanns, and 3 of the negative Wassermanns gave positive cerebrospinal fluid. Eight of these patients showed more or less improvement, especially so far as pain was concerned. One patient showed very marked improvement, especially so far as motion was concerned. Three patients did not improve any at all as far as I could see. In the other 16 cases, there was little or no impairment of motion, and most of the patients consulted us on account of the pain, usually in the region of the legs. Three of the last group had optic atrophy of the primary type, and the eye symptoms were the primary manifestations of the disease.

DISCUSSION

Dr. G. B. Eusterman, Rochester: We are inclined to believe that syphilis predominates in the populous centers. This is true in the main, and it is especially borne out by the fact that in one general hospital in New York over 60 per cent. of the patients registering there showed a positive Wassermann reaction. In our rural centers, also, we are surprised at the frequency of syphilis as the cause of the syndrome. While the Wassermann reaction has been one of the most valuable contributions to medicine, it has its limitations. Repeated positive Wassermann reactions, particularly when they become strong, are definite corroborative evidence of syphilis. This, in addition to other evidences of syphilis, makes it conclusive.

Dr. C. R. Ball, St. Paul: In reading up the treatment of syphilis, one of the things which struck me forcibly was this: After reading a long discussion of whether the patients thoroughly treated were any more liable to late nervous syphilis than those who had never received any treatment at all, I found that statistics are quoted on both sides and the conclusion of the men who took part in the discussion, men who had reviewed the literature, and were competent in every way, was that it was about even.

Dr. G. J. Thomas, Rochester: If we are able to cure syphilis, say in ten or fifteen years, we are going to have compiled a large number of treated cases and the results of treatment and the kind of treatment used; and when men treating syphilis will do as Drs. Linneman and Tuohy have done, compile statistics or keep good records, at the same time, we shall have arrived at a certain system of treating this disease. We all know, there are many different ways, different combinations of salvarsan, neosalvarsan, mercury and the iodids, and practitioners seem to obtain the same results; but we must and will go a long way toward getting satisfactory results if we will compile our statistics and keep good records. This paper also emphasizes the point that syphilis is not a venereal or skin disease, but a general disease, and the quicker we realize that, the quicker shall we be able to cure it.

Medical Treatment of Diabetics Preparatory to Surgical Treatment

Dr. David M. Berkman, Rochester: Twenty-six patients suffering from glucosuria have been operated on in the Mayo Clinic during the past year. Two of these patients died following operation (mortality 7.7 per cent.): one died in typical coma, the other apparently from the result of the surgical condition. The observation of the diacetic acid and total ammonia output in twenty-four hours is of more importance than the sugar itself. The ultimate aim of treatment is not merely to render the urine sugar free but to decrease the tendency to acidosis and increase carbohydrate tolerance. Large doses of alkalies are urged, preferably sodium bicarbonate, for several days previous to and also after operation, since in this way the neutralization and elimination of the acids formed in the blood are greatly facilitated. Local anesthesia should be used whenever possible. Ether is the safest of the general anesthetics. In the series of cases reported, novocain was used in five instances, combined novocain and ether in one, and ether the remaining twenty. The operative conditions were varied.

(To be continued)

Current Medical Literature

AMERICAN

Titles marked with an asterisk (*) are abstracted below.

American Journal of Tropical Diseases and Preventive Medicine, New Orleans

September, III, No. 3, pp. 119-182

1 Epidemiology of Plague in New Orleans. R. H. Creel, San Juan, P. R.
2 *Epizootic Lymphangitis and Sporotrichosis. K. F. Meyer, Berkeley, Calif.
3 *Epidemiologic Study of Poliomyelitis. W. A. Sawyer, San Francisco.

2. Lymphangitis and Sporotrichosis.—Epizootic lymphangitis of equines, Meyer says, is caused in South Africa, Algeria and Jamaica by a parasite which morphologically (gram-positive, irregular inside structure, budding forms) has all the characteristics of a yeast and which biologically behaves, in the complement fixation test, like blastomyces. The similarity with leishmania bodies, which is suggested by some staining reactions (with Giemsa, etc.) and the position of the parasites in the phagocytes, is explained, and it is demonstrated that the serologic tests and the more careful morphologic studies with hematoxylin stains do not justify the creation of a new species of lymphosporidium (Gasparini, 1908). The parasite is not a protozoon, but a blastomyces, namely, the *Cryptococcus farciminosus*. In the United States the disease which was diagnosed as epizootic lymphangitis in 1907, has been recognized as being sporotrichosis. Epizootic lymphangitis apparently does not exist here. Morphologically, by cultures and serum tests, the two diseases can easily be separated. In horses the parasite of sporotrichosis is rare in the pus and can rarely be demonstrated microscopically. The serums from sporotrichotic infections give complement fixation with the *Cryptococcus farciminosus*, indicating a relation of the *Sporothrix schencki-beurmanni* to the cryptococcus. This observation is further proof of the vegetable nature of the parasite of epizootic lymphangitis. Human infections from equine sources of epizootic lymphangitis and sporotrichosis are rare. Meyer calls attention to the fact that it is in the interest of comparative tropical medicine that suspected cases of infections of epizootic lymphangitis should, in future, be carefully investigated bacteriologically and serologically.

3. Study of Poliomyelitis.—In the summer and fall of 1913 several groups of cases of epidemic poliomyelitis appeared in Northern California. Most of the cases were in small towns in which conditions were more favorable for tracing the probable path of infection than they would have been in larger and less isolated communities. The field investigations were carried on by Sawyer in August and November, 1913. The usual observations regarding symptoms of the cases, sanitation of premises, domestic animals, insects, climate, etc., were made, but only the data which bear on possible methods of transfer of the infection are presented by him. Many of the cases showed interesting group relations, suggesting the possibility of transfer by contact. Observations were made regarding the stable fly (*Stomoxys calcitrans*), but no important new evidence was obtained. In none of the cases was there a history of a stable-fly bite.

In many of the cases reported, the infection can be explained on the theory that epidemic poliomyelitis is transmitted through contact from acute cases or carriers. The active virus of poliomyelitis was demonstrated by animal inoculation to be present in rectal washings obtained from a patient fourteen days after the beginning of the paralysis. The virus of poliomyelitis may survive in demonstrable quantities for at least thirty-six hours in specimens of rectal washings if they are kept packed in ice. Therefore, samples taken during a field investigation may be sent to a central laboratory for examination. Since the active virus may leave the body from the rectum, as well as from the nose and mouth, precautions should be taken in the care of the poliomyelitis patient to prevent infection, not only from the nasal and buccal discharges, but also from feces and soiled bedding.

4. **Syphilis and Raynaud's Disease.**—The case reported by Lisser presented symmetrical gangrene of the feet, and four unquestioned attacks of local asphyxia of the fingers, without exposure to unusual cold. The transient nature of the glucosuria ruled out diabetes as the etiologic factor. A gonorrheal vaginitis with probable arthritis occurred, and a gonorrheal septicemia with emboli might be held responsible for the gangrene of the lower extremities; but the question of such sepsis was never proved and does not seem probable clinically. The patient had congenital syphilis, and an obliterative endarteritis could cause the condition. But the vasomotor attacks of the fingers, combined with the symmetrical gangrene of the feet was so typical of Raynaud's disease that the latter diagnosis must be considered very seriously. In fact, Lisser says, it seems justifiable to conclude that the patient simultaneously suffered from three diseases—gonorrheal vaginitis with arthritis, congenital syphilis and Raynaud's disease.

5. **Atrioventricular Rhythm Following Auricular Flutter.**—A cardiac rhythm is described by White which arises in the atrioventricular junctional tissues of a patient who showed flutter and fibrillation of the auricles prior to the onset of the present rhythm. This atrioventricular rhythm responds in rate readily to exercise, forced respiration, vagal pressure and atropin, but not to digitalis. The sequence of contraction *vs-as* is lengthened by vagal pressure and by digitalis, the latter apparently acting more on the auriculonodal junction than on the pacemaker in the *a-v* tissues. Atropin may shorten the *vs-as* interval prolonged by digitalis, but with the uninfluenced *a-v* rhythm the effect of atropin on the *vs-as* interval is overborne by the increase in the rate of the heart beat resulting from the action of the drug on the *a-v* pacemaker; under such circumstances the *R-P* interval is increased slightly. Premature beats interrupt the rhythm rarely; on such occasions the returning cycles are not compensatory. Coupled beats of an unusual character appear when the *vs-as* interval is markedly prolonged by digitalis or by vagal pressure. The constancy of the atrioventricular rhythm and the failure of sino-auricular rhythm to be restored by atropin or by vagal pressure point to a loss of function of the sino-auricular node, its task as pacemaker being assumed by the atrioventricular junctional tissues.

6. **Creatinin of Blood in Nephritis.**—The estimation of the blood creatinin has been of considerable prognostic value in the work of Myers and Lough, cases showing over 5 mg. per 100 c.c. of blood having invariably terminated fatally. Of eleven cases showing over 5 mg. of creatinin per 100 c.c. of blood, all terminated fatally in from a few days to two months. In this group of cases the phthalein output was practically zero. It seems reasonable to conclude that when a noticeable retention of creatinin has occurred, the functional condition of the kidney has been gravely impaired. In the authors' experience creatinin values from 2.5 to 3.0 mg. per 100 c.c. of blood should be viewed with suspicion and figures of from 3.0 to 5.0 mg. regarded as decidedly unfavorable, while figures over 5 mg. probably indicate an early fatal termination.

7. **Method for Determination of Plasma and Blood Volume.**—The principle underlying the method used by Keith, Rowntree and Geraghty is the introduction directly into the circulation of a nontoxic, slowly absorbable dye, which remains in the plasma long enough for thorough mixing, and the determination of its concentration in the plasma colorimetrically by comparison with a suitable standard mixture of dye and serum. The blood normally constitutes 8.8 per cent., or 1/11.4 of the body weight. Normal individuals have approximately 85 c.c. of blood per kilogram, the extremes being 78 and 97 per kilogram. In pregnancy, before term, the blood and plasma volumes are increased. A condition of serous plethora exists. Within a week or two after delivery, the blood values return to normal. In obesity, the plasma and blood volumes are relatively small. Many cases of anemia exhibit a relatively large plasma volume. Polycythemia in the sense of a high blood count may be dependent on a low plasma volume. It may be associated with a large plasma volume, in which case true plethora is indicated. Hyperglycemia exists without increase in blood volume. In anasarca accompanying myocardial insufficiency the blood volume may be absolutely increased. A small volume is shown in many cases of marked hypertension. Therefore so far as these studies go it would appear that hypertension is not dependent on a large blood volume.

9. **Venous Pressure in Cardiac Disease.**—The venous pressure was followed by Clark at frequent intervals in fourteen cases of cardiac insufficiency at various stages of decompensation and compensation. Two hundred and seventy-six observations were made. Hooker's modified method was used. A diurnal variation in venous pressure of from 8 to 12 cm. of water was noted in four normal and four cardiac cases, all the patients being confined to bed. This variation was based on two-hourly observations over a period of twenty-four hours. It was found that the highest venous pressures occurred during the sleeping hours in the cardiac cases, while in the normal cases, as previously observed by Hooker, the lowest pressures of diurnal variation occurred at night. In the patients who died, either a rapid rise in venous pressure or a continuously high pressure above the 20 cm. level was observed before death. A venous pressure continuously above 20 cm., which was not lowered by the digitalis series, was an indication of grave cardiac involvement.

A venous pressure continuously below 20 cm. gave no definite indication as to the effect of digitalis or strophanthin therapy. A fall in systolic arterial pressure and a rise in venous pressure occurred in four cases before death. Otherwise no constant relation could be noted either between the systolic, the diastolic, the pulse pressure, or the amplitude-frequency product on the one hand, and the venous pressure on the other. Venous pressure and urine output generally showed an inverse variation. The variation was usually coincident, but, if coincidence did not occur, the changes in venous pressure tended to precede the changes in kidney function. The venous pressure was lowered in seven out of eight pleural tappings. Venesection lowered the venous pressure in three cases observed, but the subsequent rise in pressure was rapid.

12. **Anemia with Remarkable Red Blood Cells.**—Many of the red cells in the case cited by Cook and Meyer, about one in three, on rough count, were elongated, oat-shaped or crescent-shaped, with the same color and structure as the normal red blood cells. Some of the crescent-shaped cells in the fresh drop would curl and bend as if they were unusually pliable. There was considerable variation in the size of the red cells and also many structures which seemed to be fragments of cells, as if some of the cells had been crushed. The rather uniform character of these fragments, however, suggests that they were not artefacts. Nucleated reds were always present

and at times were quite numerous. With Romanowsky stains there was only slight polychromatophilia. The red cells varied in number between 1,800,000 and 3,100,000, usually about 2,500,000; there was at all times a leukocytosis of mild degree; the color index averaged slightly below 1, and there was a constant eosinophilia at the expense of the polymorphonuclear cells.

13. **Hemolytic Activity of Spleen in Pernicious Anemia.**—In a study of the hemolytic activity of the fresh spleen obtained by Robertson at operation, from six patients with pernicious anemia, it was found that extracts of the spleen pulp made with both normal salt solution and alcohol, possessed no hemolytic properties. An ethereal extract, on the other hand, showed a marked hemolytic action. However, the hemolytic substance contained in this extract belonged to the group of unsaturated fatty acids and has been obtained in equally strong concentration from the normal liver and intestine. The only change in the splenic vein blood obtained at operation, which could not be accounted for by manipulation, was a decreased resistance of the red cells. These cells were definitely less resistant than those of the peripheral circulation in the same individual and in normal controls. These findings seem to exclude any gross or easily demonstrable manifestation of hemolytic activity on the part of the spleen. However, the decreased resistance of the red cells in the splenic vein, would suggest that the spleen in pernicious anemia elaborated some toxic substance or enzyme which so injures the blood cells during their passage through that organ that they are more susceptible than normally to destruction elsewhere. It seems probable that in some other part of the body there is elaborated an abnormal hemolysin or an abnormally acting normal hemolysin.

14. **Nontuberculous Infections and Value of Sputum Cultures.**—According to Leutscher the pneumococcus is the cause of 62.44 per cent. of all the nontuberculous infections below the larynx, and the influenza bacillus in 28.5 per cent. These two organisms cause 90.94 per cent. of the infections of the bronchi and lungs; 74.96 per cent. of the infections of the larynx, and 31.29 per cent. of the infections of the nose, throat and sinuses. The streptococcus, contrary to common belief and textbook reports, is only rarely the cause of infections in the lungs, and when found, is usually associated with complications such as lung abscess, bronchiectasis, carcinoma, etc. In infections of the head, however, it assumes the predominant rôle, especially in the tonsils. The *Staphylococcus aureus* was never found to be the cause of the acute infections of the lungs or larynx and only once was it found in acute coryza and acute sinusitis. The *Micrococcus catarrhalis* may cause rhinitis, laryngitis, acute bronchitis and acute bronchopneumonia. It was found in pure culture in three out of thirty-seven cases of acute rhinitis, five out of thirty-eight cases of acute laryngitis, and in one each of acute bronchitis and primary bronchopneumonia. The colon and typhoid bacillus rarely if ever produce acute lesions in the lung. The typhoid bacillus, however, may produce lung abscess following an infarct.

15. **Relation of Suprarenals to Pancreas.**—Mann and Drips were unable to demonstrate any specific relationship between the suprarenals and the pancreas.

41. **Mechanism of Anaphylactic Shock.**—The mechanism of acute intoxication is stated by the authors to be as follows: An immediate mobilization of a nonspecific protease in large amounts; the formation of a state of antiferment deficiency through colloidal changes; a simultaneous cleavage of serum proteins (proteoses) through the peptone stage to amino-acids; an intoxication by these peptones with a resulting cellular injury, made evident by an increase in serum lipase, the fall in temperature and other manifestations of acute shock. The elements of specificity lie in the mobilization of the nonspecific cellular ferment and the colloidal changes in the serum, not in the production of specific ferments.

42. **Peripheral Nerves in Transplantation.**—Ingebrigtsen found that in autoplastic transplanted nerves a degenerative process occurs which resembles the ordinary Wallerian degeneration, but appears a little more slowly than the latter. The cells of Schwann are in a condition of survival and are capable of multiplication after the transplantation. In homoplastic transplanted nerves a degenerative process resembling a Wallerian degeneration, somewhat delayed, occurs. The cells of Schwann multiply, and for sometime at least are in a condition of survival. After twelve to fourteen days an abundant and increasing immigration of lymphocytes is observed, and from the eighteenth day the cells of Schwann develop a necrobiotic appearance. In heteroplastic transplanted nerves numerous myelin ovoids are formed during the first four to five days, but there is no proliferation of the cells of Schwann and no Wallerian degeneration is seen. The graft becomes necrotic within about two weeks.

The formation of ovoids that occurs during the first four to five days after the performance of the heteroplastic transplantation does not reveal the condition of the life of the graft. This formation of myelin ovoids is found in the nerve fibers when they have been kept in an incubator for twenty-four hours in Ringer solution or in homologous or heterologous serum, but it is not found in the fibers after their incubation in isotonic salt solution, the presence of calcium being necessary for the occurrence of ovoid formation. Heteroplastic transplanted nerves become necrotic. They are unsuitable for bridges in cases of nerve defects, and Ingebrigtsen's results explain the failure of the attempts at heteroplastic transplantation of nerves in human beings. To bridge a nerve defect by implantation one must use autoplastic or homoplastic grafts. The occurrence of a Wallerian degeneration in these grafts during the first two or three weeks after the transplantation should make bridging a promising operation; for in this period the grafts resemble the peripheral part of a divided nerve and must be assumed to be capable of regeneration, and thus are different from dead material.

43. **Value of Placental Blood Film in Malaria.**—Clark claims that the pregnant state encourages attacks of malaria by lowering bodily resistance and by furnishing an additional harbor for the development of parasites. A tenable theory in regard to most attacks of this nature, occurring in cases under professional care, would appear to be the development of latent malaria (malarial carriers) into acute attacks toward the close of the pregnant state. The women who expose themselves offer favorable conditions to the introduction of a primary infection. Malaria frequently interrupts the late stages of pregnancy and sometimes causes the death of the mother and the fetus, more often the latter. The commonest mishap is miscarriage late in pregnancy. Occasional stillbirths occur and sometimes there is a fatal issue to both the mother and child. Clark found that the placental blood film examination is worthy of routine application wherever estivo-autumnal malaria is endemic. This type of malaria when associated with labor and the early days of the puerperium can be more easily and certainly diagnosed by the use of this film and a polychrome stain than by employing the usual films made from the mother's peripheral blood at the time of labor. The placental film in such an infection offers an abundance of adult parasites and far more evidence of the presence of pigment, while the peripheral blood film frequently offers but a scant number of the small ring or discoid forms of a parasite. The examination of the present series revealed positive placental films in nineteen cases, while but eight of these same cases were positive in the peripheral blood film examination. On the other hand, no peripheral blood films were found positive in which the associated placental films did not reveal a far more abundant evidence of the infection.

44. **Immunologic Study of Bacillus Influenza.**—Briefly, the results of Wollstein's investigation are as follows: Influenza bacilli therefore vary in pathogenic effect both for man and animals, but they are not distinguishable by means of serologic reactions into different types. Apparently all influenza bacilli belong to one class or race, irrespective of origin or virulence.

45. **Curative Action of Antipneumococcus Serum.**—According to Bull an active antipneumococcus serum causes agglutination of pneumococci in vitro and in vivo. The antiserum acts in far greater dilution in causing agglutination as determined by the microscopic than by the macroscopic test. The antiserum when injected into the circulation of rabbits suffering from pneumococcus bacteremia causes a rapid disappearance of the diplococci from the blood. This disappearance is brought about by instantaneous clumping of the diplococci in vivo and the removal of the clumps by the liver, spleen, lungs and possibly other organs. The diplococci which fail of agglutination tend not to be phagocyted and persist longer in viable form than the ingested clumps. The protection afforded by the immune serum is specific for the type organism and is determined by the presence of agglutinins which prepare the pneumococci for removal from the blood and phagocytosis on a large scale. Normal rabbit blood is devoid of agglutinating and of protective effect against virulent pneumococci. Agglutination is not merely an incidental phenomenon, but constitutes an essential process in association with phagocytosis in the protection of the rabbit against pneumococcus infection.

46. **Treatment of Pneumococcic Septicemia in Rabbits.**—The treatment of pneumococcic septicemia in rabbits by small repeated doses of immune serum was successfully carried out by Bull. The number of pneumococci capable of being brought to destruction through phagocytosis in the organs in this way was great. Not all the rabbits treated with small repeated doses of the serum survive. Those that succumb do so, not to a general infection, but to a pneumococcus meningitis. The explanation of this phenomenon is simple. When the number of pneumococci originally inoculated is great a small number penetrate into the subdural space. Those in this space do not come under the influence of the serum, hence they are not agglutinated and prepared for phagocytosis, whence they multiply and set up a fatal meningitis. The activity of the immune serum administered in this way against virulent pneumococci is so great that a revision of ones notions as to the limit of powers of the antiinfectious serums seems necessary. It is patent that the problem is not simply a relation between quantity of immune bodies and number of bacteria. It is more complex than that conception indicates. The factor of the leukocytes and the degree of their possible activities under the conditions of the experiment come into play. Hereafter, in defining the mode and power of action of antiinfectious serums the condition of cooperation of the body forces will have to be more strictly considered.

47. **Fate of Typhoid Bacilli Injected Into Normal Rabbits.**—Bull found that typhoid bacilli are agglutinated promptly in the circulating blood of normal rabbits and quickly removed from the blood stream. The clumped bacilli accumulate in the organs and are taken up by assembled polymorphonuclear leukocytes in the liver, spleen and possibly other organs. The phagocyted clumps of bacilli are digested and destroyed by the phagocytes. Hence, destruction of typhoid bacilli *intra vitam* is brought about by an entirely different process than is the destruction by serum and whole blood in vitro. While the latter is caused by bacteriolysis, the former results from agglutination and intraphagocytic digestion.

49. **Fatty Degeneration of Cerebral Cortex.**—From the data provided by his investigations Cotton concludes that in all pathologic processes of the cortex which end in dementia and death, the fatty degeneration of the elements of the cortex plays a not unimportant part. The characteristic change for most of the psychoses is found in a great increase in amount of fatty deposits when compared to normal individuals of the same age. In some processes such as senile dementia and dementia praecox the fatty substance appears to fill completely the cell body, and these cells have apparently lost all their functioning power. It is not common to find the fatty deposits in the processes of the ganglion cells except in dementia praecox, and to a limited extent in senile dementia. In other cases the pathologic variety of the fatty deposits in the ganglion cells is seen to be diffused over the whole ganglion cell. Cotton was able especially to observe this in infectious psychoses, in general paralysis, and in epilepsy. The so-called central neuritis assumes a peculiar attitude in that it plainly leads swiftly to an acute fatty degeneration of the ganglion cells, in which there exists an inclination of the fatty granules to flow together into large masses. Frequently the fatty degeneration of the ganglion cells appears to be connected with the sclerosis of the cells, especially when it is a matter of slowly progressing alterations of degeneration. In the young, chronic cases of dementia praecox, far-reaching fatty degeneration of the ganglion cells, especially in the second and third cortical strata, likewise occurs. These findings should constitute an important contribution to the pathologic anatomy of dementia praecox.

50. **Seat of Emetic Action of Various Drugs.**—The results of approximately 500 experiments, made to determine the probable seat of the emetic action of some of the more important drugs, and of others of less importance are reported by Eggleston and Hatcher. They found that practically all alkaloids and alkaloidal drugs in common use, including morphin and preparations containing it, which produce nausea and vomiting, either as their chief or as their side actions, do so by direct action on the vomiting center. Sodium salicylate, picrotoxin and the digitalis bodies also produce nausea and emesis through direct central action. There may be, in the case of certain drugs with irritant properties, synergistic reflex and central actions, whereby a smaller dose by mouth may be more effective than would be the case for either action alone. An illustration of this seems to be afforded by emetin. The evidence in favor of the central action does not in every instance exclude the possibility of the drugs also having an irritant action on the alimentary mucosa when given orally. It is probable that the ipecac alkaloids, veratrin and sodium salicylate may have this reflex action in man, at least in susceptible individuals. Some of the advantages claimed for certain proprietary preparations of opium, such as narcophin and pantopium are refuted by the results of the authors' experiments, and they believe that this is also probably true, to a certain extent, of some of the proprietary preparations of salicylic acid.

51. **Influence of Salicylates.**—The increased output of uric acid following salicylate medication, in Denis' opinion, is due to a lowered threshold value of the kidney, not only for uric acid, but in all probability for other waste products as well. Such being the case, he says, it may well be that the beneficial effects resulting from the use of salicylates in acute rheumatic fever, may in part, at least, be due to a power possessed by this class of drugs of increasing kidney permeability, thereby facilitating the rapid and more or less complete excretion of the toxins which produce symptoms of these diseases.

52. **Influence of Digitalis in Cases of Auricular Fibrillation.**—In three cases with auricular fibrillation, the blood flow in the hands was promptly and decidedly increased after the administration of digitalis. In a fourth case, which had not been considered to respond well to digitalis, the hand flow was somewhat increased when the drug was stopped after a rather long course of it. Digitalis having been again begun, the hand flow at the end of a week was again found to be diminished.

54. **Effects of Veratrum Viride.**—According to Pilcher and Sollmann veratrum viride and the related alkaloid cevadin are without direct action on the vasomotor center. As a result of anemia from the fall in blood pressure, or from asphyxia from respiratory depression, the center may be stimulated in about half the experiments; such action may be prevented by artificial respiration. Convulsant doses of cevadin also increase the central vasomotor tone.

55. **Physiologic Test for Cholin.**—The method proposed by Hunt consists in converting the cholin into the acetyl derivative (by heating the cholin with acetyl-chlorid in a sealed tube in the water bath) and testing the physiologic action of the reaction product. Details as to the method as applied to various fluids and organs are given.

76. **Immunized Milk in Treatment of Typhoid.**—Rosenberg states that immunized milk is absolutely safe and harmless, while antityphoid vaccination often causes more or less severe systemic symptoms. Immunized milk is an excellent medium to provide general immunization for typhoid at trifling expense and without risk. It causes neither local nor systemic ill-effects. It is fatal to but one organism, namely, the typhoid bacillus. Drinking one quart of immunized milk per day for a period of about two weeks provides adequate protection for two months. Immunity, however, can be prolonged indefinitely by drinking one or two quarts of immunized milk every ten days to two weeks. Besides an efficient prophylactic, immunized milk will probably prove itself to be a valuable aid in the treatment of typhoid, especially in the early stage of the disease. Rosenberg urges that immunized milk should be used at the onset, even before a diagnosis is possible, and should be given in every suspicious case; it may succeed in aborting the disease, preventing the infection by augmenting the body's natural defenses. It will provide the needed antibodies to destroy the invading host, neutralize the bacterial toxins at a period when the body is not as yet prepared to cope with the infectious organism.

1 *Injuries of Superior Longitudinal Sinus. G. Holmes and P. Sargent.
2 Treatment of Gunshot Wounds of Head, with Special Reference to Apparently Minor Injuries. J. E. H. Roberts.
3 Treatment of Gunshot Wounds of Head. G. G. Tabuteau.
4 *Treatment of Septic Wounds by Continuous Oxygenation or Irrigation. W. A. Wood.
5 Sandfly Fever and Bacteriology; Vaccine Treatment. C. J. Stocker.
6 Adaptable Eye Shade for Microscopic Use. S. G. Shattock.

1. Injuries of Superior Longitudinal Sinus.—Up to the present Holmes and Sargent have seen over seventy cases in which the longitudinal sinus was injured or the circulation in its venous tributaries disturbed in its immediate neighborhood, that is, in the lateral lacunae, or in cases in which the veins enter it. In many of these cases there was no direct damage to the brain, either by the projectile or by depressed fragments of bone, but in others the disturbance of the venous circulation was associated with gross cerebral lesions. The symptoms in these cases have varied much according to the severity of the injury and the region in which the sinus was damaged. In many cases in which the chief symptoms were due to injury of the longitudinal sinus or its tributary veins, associated lesions of the brain existed. The most common type of injury is a gutter or tangential wound at the middle line of the head, which may be either sagittal, coronal or oblique. Frequently, however, the injury was a perforating wound or an in-and-out-wound of the skull, the entrance and exit being on opposite sides of the middle line and close to it, with considerable comminution of the bone between them; here the sinus was generally lacerated, and in certain instances it was completely cut through by the missile, but it was occasionally only compressed by indriven fragments of bone.

The distribution of motor symptoms is unusual and the type of motor paralysis likewise. The extent of the palsy varies according to the site, severity and extent of the lesion; in twenty cases all limbs were affected; in thirty-one both legs and one arm were weak; in sixteen only the lower limbs were affected; in six the symptoms were mainly hemiplegic and in five one leg alone presented any palsy. The distribution of the paralysis and its relative severity in different segments of the limbs is, however, peculiar, and differs from that of the cerebral palsies, most commonly seen in civil practice. The more proximal segments of the upper limbs are most seriously paralyzed, and the weakness diminishes distalward. In this respect the paralysis contrasts strongly with that seen in the ordinary hemiplegia due to vascular lesions, in which the distal segments of the upper limbs are almost invariably more severely affected than the proximal and recover less rapidly. Further, a definite paresis of the face or tongue is extremely uncommon, and is at the most transient, while speech is never affected in the pure sinus injuries. The trunk muscles may be, however, affected, especially those of the back; the patient is then unable to sit up and often cannot roll over in bed.

The distribution of the palsy in the legs is the converse of that of the arms; here it is always the distal movements that suffer more severely, and in slight cases and during the recovery of more severe ones the authors have repeatedly seen complete paralysis of the toes and ankle only, with the knee movements only relatively weak and those of the hips strong. Even more striking than the unusual distribution of the paralysis is the rigidity which is almost always associated with it. It is generally coextensive with the paralysis, and closely related to it in its degree. The early onset of this rigidity is another striking point; the authors have seen it well marked within twenty-four hours of the infliction of the wound, and in some instances at least it has been noticed by the patient almost at once. It has shown no tendency to increase after the patients have reached the base hospitals; that is, usually within forty-eight hours, but, on the other hand, it gradually diminishes *pari passu* with any return of power that may occur.

The rigidity is often so great that the resistance to passive movement is extreme; it may, for instance, be quite impossible for a man of moderate strength to separate the knees. Peripheral stimulation, as pricking the sole or palm, increases the rigidity and the legs may become more rigid when the patient coughs or attempts any strong voluntary movement with his arms. Despite the great rigidity, there seems to be little tendency for contractures, that is, organic shortening of the muscles, to develop. The sensory disturbances in these cases are almost always those of a pure cortical lesion unaccompanied by any shock effect. In a certain number of cases the functions of the bladder were affected. As a rule, the functions of the cranial nerves were unaffected, but in several patients the ocular movements were disturbed. The general symptoms of intracranial pressure have been as a rule pronounced.

4. **Septic Wounds Treated by Continuous Oxygenation or Irrigation.**—A severely lacerated and septic wound about the knee in a child was treated by Wood by continuous oxygenation under pressure. A rubber bag constructed open at both ends and provided with sleeves at the ends and with a valve through which the oxygen can be introduced, was slipped over the leg like a stocking and the two ends were rendered gas-tight by firm bandaging. Oxygen was introduced from a cylinder up to the pressure of 3 to 4 pounds. With ordinary bandages the bag remained inflated with oxygen for about twelve hours, with rubber bandages, for longer. The wound rapidly cleaned and the granulation tissue assumed a most healthy appearance in a shorter time than one would have expected. The discharge collects at the bottom of the bag and can be either drawn off by a drain tube, or the bag can easily be removed, boiled, replaced and refilled within a short time and without pain.

27 Breathing and Physical Exercises for Use in Cases of Wounds in Pleura, Lung and Diaphragm. C. MacMahon.

21. **Plumbism from Unusual Sources.**—In the first case cited by Hall the patient drank for some years "horehound beer." While formerly they had sold it in stone jars, recently they had kept it in large barrels in the cellar and "drawn" it up into the shop by an ordinary "beer-tap." This meant several feet of lead piping for the acid solution to pass through. A sample of the "horehound beer" as drawn from the tap for the consumer contained 1 grain of lead per gallon. The second patient was fond of his garden, and in order to protect his fruit and flowers from the birds carried with him an air-gun to shoot the birds whenever he went into the garden. In every suit of clothes he reserved the right-hand vest pocket for the little lead pellets used in his gun, so that at any time he could quickly have a shot at any bird he saw. He had also acquired a habit of constantly putting the finger and thumb of his right hand into this vest pocket and fingering these pellets.

22. **Tonsils and Chronic Cervical Adenitis.**—Gardiner claims that in the majority of cases (80 per cent.) of chronic cervical adenitis in cases in which no obvious source of infection is present, the tonsils are infected. The size of the tonsil makes no difference as to their infectivity, except that the small fibrotic variety is likely to be more dangerous than the large. The number of cases in which tubercle bacilli are present is relatively small, but is larger than in simple cases of enlarged tonsils. The frequent presence of other organisms than the tubercle bacillus in these cases suggests that a large proportion of the so-called chronic tuberculous glands are in reality chronic septic glands. The organisms are present in the deepest parts of the gland, and are, therefore, only removed by operations involving complete enucleation.

37 Vicious Circle of Habitual Constipation. J. B. Hurry.
38 Case of Traumatic Subdural Hemorrhage. H. V. O'Shea.

34. **Dangers of Tuberculin.**—The question defended by Wilkinson is that, in the hands of experts, tuberculin is not only free from the dangers which have been associated too lightly and erroneously with its administration, but is at once a valuable aid in diagnosis and an invaluable and indispensable remedy in treatment. He does not contend that it is the *ne plus ultra*, but the irresistible evidence of an experience extending over five years in hundreds of cases of tuberculosis of all forms and in all stages, leaves not the smallest doubt in his mind that an independent and impartial inquiry would disabuse the medical mind of the imaginary evils alleged to arise from its use. Such an inquiry would, in his opinion, dispel many of the errors still hindering a solution of a difficult problem, which has not yet been

approached and analyzed in accordance with the rules of logic and science, and would be the first step toward the general exploitation of tuberculin as a valuable diagnostic agent in doubtful cases of tuberculosis and as an invaluable remedy in a disease which is so widespread and so difficult to treat with success that no useful remedy should be left untried.

35. **Emetin Hydrochlorid.**—Robinson has used this drug with good results in mucous colitis, dysmenorrhea, phthisis and intestinal hemorrhage.

42 *The Gait with Artificial Legs. (Etude cinematographique de la marche chez les sujets amputés de la cuisse ou de la jambe.) Ducroquet.

39. **Early Disinfection of Wounds.**—Tuffier's remarks were summarized in the Paris Letter, p. 1473. He declares that it can never be reiterated too often that infection can be nipped in the bud, while allowed a few hours to develop and spread, it gets quite beyond our control. To nip infection in the bud, the more recent workers have found a hypertonic salt solution most effectual, thanks to its osmotic properties, but it does not check the development of the streptococcus. Tuffier himself prefers Carrel and Dakin's method applied at once and completed within twelve hours. It is proving astonishingly effectual in warding off suppuration, he says.

42. See Paris Letter, p. 1473.

September 30, No. 46, pp. 377-384

50 *Research on Antiseptics in Treatment of Infected Wounds. H. D. Dakin.
51 *Albuminuria not a Constant Sign of Meningeal Hemorrhage. E. Macris.

43. **Determination of the Reserve Force of the Heart.**—Martinet says that the ordinary methods of examination do not reveal whether the heart will be able to stand sudden stress. Some hearts, even with organic disease, are able to sustain extra strain while others apparently valid break down under it. Clinicians have grown gray, he remarks, studying this subject, but certainty has not yet been realized. The findings with various tests are subjective (dyspnea under exercise), or they are tardy (enlargement of the liver, edema, etc.), or they are not pathognomonic (oliguria, enlargement of the liver, etc.). The only exploratory means at our disposal which yield objective results are the pulse rate and the arterial tension, noting the curves for each, measured as the patient reclines, then again as he stands, and then again after a special exercise (bending the legs twenty times), and then again after reclining anew. In taking these measurements, he waits each time until two successive measures give the same figure, thus eliminating the emotional factor. The curves for the pulse and for the arterial pressure are given for a series of such tests applied to a healthy person and to one with a weak heart. With the former the pulse figures were respectively 76, 80, 96, 76 and 60, while the corresponding pulse with the weak heart was 104, 122, 148, 124 and 120. Between these extremes lies a broad field in which the figures reveal whether the heart is capable of extra effort or will break down under it, thus permitting the sifting out of the men still capable of military service although their cardiovascular system is not intact.

45. **Improved Technic for Serodiagnosis of Syphilis.**—Busila relates that syphilitic serum may contain a sensitizer that resists heating and also one that is destroyed by heat. The deviation of complement and Wassermann tests do not discriminate with sufficient precision between these two sensitizers, while the preponderance or absence of one or the other has a pronounced influence on the outcome of the tests. In order to eliminate error from this source, Busila has modified the technic and states that his method is applicable to all serums and requires only two hours or two and a half from the moment the blood is drawn. Instead of heating, to suppress the human complement, he titrates it simultaneously with the reaction. When the serum is heated this destroys the thermolabile sensitizer, and it is in the cases in which this sensitizer predominates, that the syphilis is most difficult to diagnose. Hence his modified technic is particularly useful, he declares, in cases of latent, imperfectly treated, or "nervous" syphilis.

47. **Cytophylaxis Under Magnesium Chlorid.**—Practically the same article was summarized in these columns October 23, p. 1492.

50. **Technic for Sodium Hypochlorite Disinfection of Wounds.**—The main points in this communication have already been summarized in The Journal, Oct. 2, 1915, p. 1221.

51. **Albuminuria with Meningeal Hemorrhage.**—Macris' article was summarized on p. 986, Sept. 11, 1915.

Revue Médicale de la Suisse Romande, Geneva

September, XXXV, No. 9, pp. 469-532

52 *Constitutional Iodism and Its Relation to Exophthalmic Goiter. A. Oswald.
53 The Pseudodiphtheria Bacillus. (De la résistance du bacille pseudo-diphtérique à la decoloration, moyen de diagnostic différentiel d'avec le bacille diphtérique.) Reh.
54 Bradycardia from Heart Block in Boy of 9. A. d'Espine and Cottin.
55 Trauma as a Factor in Tuberculosis. Meyer.

52. **Constitutional Iodism.**—Oswald discusses the phenomena liable to develop after administration of iodin internally, saying that the Zurich region seems to be the headquarters for this type of disturbances. They were first systematically described in Rilliet's classic work with the above title, published in 1860. The syndrome he described occurs mostly in persons over 40. Besides this, there is a syndrome which resembles exophthalmic goiter in every respect; it develops in the young, and in those who have never had any previous symptoms of exophthalmic goiter, and it usually subsides in time after suspension of the iodin treatment. The entire literature on the subject has been studied by Oswald and he relates considerable personal experiences. Everything seems to indicate that the iodin stimulates the thyroid, and possibly other glands with an internal secretion, to extra functioning. The result is thus the same as in primary exophthalmic goiter, which is now ascribed to extra functioning of the thyroid. Both syndromes are the result of an excess of thyroid secretion being poured into the circulation, and there is no reason for surprise that iodin thus can induce the true Basedow syndrome. A predisposition is necessary for both, but it is not necessary to assume for either that the thyroid is producing an abnormal secretion; an excessive amount of a normal secretion is enough to explain all the symptoms observed, given an abnormally sensitive nervous system. With iodin hyperthyroidism the nervous system is suffering from the iodin, and it recuperates when the iodin is withdrawn. With true exophthalmic goiter, the nervous system is suffering from the chronic oversupply of thyroid secretion and the nervous factor is thus both a predisposing and the provocative ele-

ment in the clinical syndrome. Recuperation is consequently more difficult.

55. **Traumatic Tuberculosis.**—Meyer relates the case of an apparently robust young man who seemed entirely healthy until a shell wound of the chest, which was followed by hemoptysis and tubercle bacilli in the sputum. There is every reason to assume that the tuberculosis might not have developed if it had not been for the chest wound, which evidently roused to virulence some latent tuberculous focus.

Berliner klinische Wochenschrift

September 20, LII, No. 38, pp. 989-1012

61 *Sham Cysts in Spinal Meninges. (Meningeale Scheincysten am Rückenmark.) K. Bonhoeffer.
62 Serum Diagnosis of Glanders. (Zur Rotzdiagnose.) W. Pfeiler.
63 Some Judicial Decisions Affecting Physicians in Germany. (Aerztliche Rechtsfragen.) H. Lieske.

56. **Gunshot and Shell Wounds of the Nervous System.**—Bruns is consultant neurologist in the tenth German army corps, and here reviews what he has learned from study of 900 cases traced over considerable periods. The outcome in a large proportion of the cases has been favorable beyond all anticipations, even after wounds of the brain itself. He takes up in turn the injuries of the peripheral nerves, brain and skull and spinal cord and vertebrae, the disturbances from ischemia and other injury of the muscles, the cases of neurasthenia, hysteria, etc., tetanus and other diseases of the nervous system, and cases of aggravation or simulation of such, and the indications for treatment based on these experiences.

57. **Influence of Intercurrent Febrile Diseases on Diabetes.**—The diabetic man of 26 had been able to stand the stress of the campaign for a time, but the lack of proper diet brought weakness and loss of thirty pounds in weight. Then came a mild typhoid and during convalescence febrile serous meningitis developed. Under the influence of the fever and loss of appetite he received only 30.2 calories per kilogram of weight while the output of sugar rose abruptly to such a height that only 19.2 calories remained to be utilized. There must have been destruction of 189 gm. of albumin.

58. **The Miostagmin Reaction in Malignant Disease.**—Wissing has applied the stalagmometer in 115 cases to ascertain the changes in the drop-forming property of the serum in various pathologic conditions. He has modified Ascoli's original technic for this miostagmin reaction by refraining from heating the serum. The reaction is more reliable at room temperature, and the findings during the first hour are the criterion. The reaction is not specific for cancer, but none of the other conditions in which it is likewise positive are liable to be confounded with cancer, except possibly when there is jaundice. The reaction is always positive with the latter, but it disappears with the cholemia, while in malignant disease it persists without change. The miostagmin reaction was found constantly negative in conditions difficult to differentiate from cancer, such as benign tumors, gastric ulcer, chronic inflammation of the stomach or bowel, leg ulcer, afebrile surgical tuberculosis, chronic inflammatory conditions in the female genital organs, and syphilis.

61. **False Cysts in Spinal Meninges.**—Bonhoeffer relates the details of two cases of spinal-cord trouble in which the discovery of cysts in the pia and arachnoid apparently explained the disturbances. But the lack of any benefit from their evacuation and other circumstances justify the assumption that the cyst-like protuberances had developed casually in the course of the laminectomy, in consequence of the abnormal pressure in the subdural space, and had not existed before. In any event they had nothing to do with the previous clinical picture. The actual disease of the spinal cord has progressed since, unmodified by the laminectomy and draining of these sham cysts. Necropsy in one case further confirmed these views.

70 Radiotherapy of Lupus and Other Tuberculous Disease of the Skin. (*Hohensonnenbehandlung tuberkulöser Erkrankungen der Haut.*) G. A. Rost.
71 *"Scrofula." (Wesen und Behandlung der Skrofulose.) H. Schelble.
72 Localization of Foreign Bodies. (Einfacher Apparat zur Ortsbestimmung von *Fremdkörpern.*) *H. Günther* and G. Vogel.
73 **Improved Technic for Hospital Construction and Ventilation.* (Einige Ratschläge für den Bau von *Krankenhäusern.*) W. Block.

65. **Action of Morphin on the Heart.**—Hering discusses the experimentally demonstrated fact that morphin in large doses, by increasing vagus tonicity, may indirectly induce a heterotopic impulse for the heart action, that is, induce ventricle automatism. The effect of the morphin varies as the heart is sound or diseased, the pathologic heart responding more readily. Hence extra caution is necessary when giving morphin in cases with a tendency to abnormally located impulse production. The sudden onset of fibrillation is a reasonable explanation in many cases of an immediately fatal attack of angina pectoris, and morphin, by promoting the tendency to fibrillation, that is, to heterotopic impulse production, may prove a factor in the fatal outcome. At the same time, he warns that the valuable aid from morphin in angina pectoris should not be discarded, but only that the dosage should be supervised with special care. He remarks parenthetically that the action of drugs on animals has been studied too exclusively on healthy animals. Diseased organs respond more readily to smaller doses.

71. **"Scrofula."**—Schelble discusses the old conception of scrofula, showing that when one has eliminated from it tuberculous affections of the skin, soft parts, bones and lymph glands, there is nothing left of the "scrofula" syndrome but the facies scrophulosa. This, he asserts, belongs to the exudative diathesis, and it is still a question whether tuberculosis is involved in this or not. Clinical experience seems against it. The cases should be designated as the exudative diathesis in connection with measles, with vaccination, with catarrhal infection, or the like. This affords insight into the individual cases and promotes causal treatment. The fine results obtained by treatment of the exudative diathesis and the provocative factors, ignoring the hypothetic tuberculosis, testify to the correctness of the above assumption, especially in cases of conjunctivitis with phlyctenas. All observers agree that signs of the exudative diathesis are manifest in all cases of phlyctenous conjunctivitis, and that the exudative diathesis is always in a severe form. It is hard to explain, however, why the phlyctenas develop so late, later than the other manifestations of the exudative diathesis, sometimes not until long after puberty. In these cases tuberculosis may be the provocative factor. It would be interesting to learn whether the phlyctenas are more rebellious to treatment in the cases with a positive response to tuberculin than without. The treatment is discussed in detail and the point emphasized that when the exudative diathesis

is known to exist, every aggravation of the condition should be early recognized and appropriate measures enforced. By the exudative diathesis he means Czerny's original clinical picture, confirmed in thousands of cases, the congenital anomaly consisting in a tendency to exudation in the skin and mucosa, plus hyperplasia of the lymphoid organs, without tuberculosis as a primary factor. He warns against attempts to remove the enlarged glands in the neck even when they are known to be tuberculous. They are frequently secondary to pathologic changes in the mouth or tonsils and retrogress under appropriate treatment of the latter. If the lymphoma has softened it will heal under a mere incision. Only when the suppuration involves adjacent tissues is more of an operation required. Many of the leading surgeons now denounce all attempts at operative removal of enlarged glands in the neck and commend conservative measures, including radiotherapy. Rollier's fine results with heliotherapy conservative treatment bring to mind the tragic histories of recurrence after extensive operative procedures.

73. **Construction of Hospitals.**—Block gives a number of practical suggestions which were carried out in the construction of a large hospital at Hannover and have proved their usefulness during the year since the hospital has been in service. The floors are made of asphalt and covered with cork linoleum. Various advantages are claimed for this combination, including superior elasticity, waterproof properties and that the linoleum can be laid twenty-four hours after the asphalt has been applied. Sheets of cork on both sides of the wall effectually deaden the sounds between adjoining rooms. The ventilation contrivance found practical and serviceable is to have double windows, each with a cover opening inward. The cold air entering low down in the outer window is warmed by a radiator below and rises to emerge through the broad opening high up in the inner window. The radiators should not be too far apart, and their surface should be smooth to facilitate keeping them clean. For the same reason they should stand a few inches from the wall. Soiled clothes shafts disseminate odors, and it is much better, he insists, to collect the linen in airtight metal cans.

78 *Serotherapy in Epidemic Cerebrospinal Meningitis. M. Kurak.

74. **Typhoid Among the Troops.**—In the typhoid service in charge of Hirsch and Hecker the mortality was only 5.4 per cent. excluding the cases suffering from long transportation, and 7.4 per cent. including all the cases. Saline infusion rendered valuable service; also systematic ingestion of salt. Some of the more seriously sick, with recurring collapse, were given 200 or 300 injections (camphor, caffein, digitalis) and finally recovered, without displaying any signs of drug intoxication. The main point is ample nourishment plus careful supervision of the heart and vasomotors. The severer cases were in men who had been inoculated against typhoid while they were in the incubation stage. The course of the disease was milder, the longer the interval since the last inoculation. Another rule which seemed to prevail also was that relapses were more numerous the milder the primary disease. The fever curve in the inoculated seems to lose its characteristic features.

78. **Serotherapy of Meningitis.**—Kurak reports from Vienna that in seventy-five cases of epidemic meningitis in the last thirteen years, forty-three were treated by serotherapy and the proportion recovering jumped from 31 to 56 per cent.; all but 39 per cent., however, were left with some permanent defect. The dosage of the antiserum had been small, the maximum 60 c.c. In the last series of twenty cases the doses were materially increased. These cases are described in detail to emphasize the far better results obtained when the serotherapy is begun early and when three or four injections of 80 c.c. each are made (40 c.c. intralumbar and 40 c.c. intramuscular) on successive days. All recovered of the six given from 160 to 300 c.c., although one was left with deafness. In the total twenty cases, there were six deaths (33.3 per cent.).

80. **Roentgen Estimation of Measurements of Pelvis.**—Runge and Gruenhagen think they have solved the problem of measuring the diameters of the pelvis by a stereoscopic Roentgen technic which they describe in detail. The patient lies comfortably flat on her back. The tube is slightly displaced for the second, the stereoscopic, picture, but the impression from both negatives is taken on a single sheet of paper, and the measurements are calculated by an algebraic or geometric formula. They give a table with the measurements computed for the different figures usually obtained, and state that the method ensures absolute accuracy, or at most an error of a small fraction of a millimeter. They have had no opportunity to test the method on women since they have completed their computations, but have found it absolutely correct on men; some of them were examined postmortem and the figures obtained were identical with the computed findings or varied only from four to six tenths of a millimeter.

81. **Abnormal Childbirth from Defective Development of the Uterus.**—Van de Velde discusses the various forms of double uterus in their bearing on delivery at term, and also dystocia from defective development of the uterus, or from congenital deformity of the cervix. The uterine musculature is liable to be weak, the cervix rigid and the axis of the fetus and uterus slant in respect to the pelvic inlet. This combination readily explains the rupture of the uterus in certain rare cases. The diagnosis in these abnormal conditions is misleading; in Tissier's case external version had been done and the placenta separated by hand without suspicion that the uterus was double, until this was revealed by the laparotomy. In a personal case described the fetus had developed to term in a double uterus which had no opening into the vagina in the gravid half. The finger could be introduced into the empty other half and the child was safely delivered by vaginal cesarean section. The woman passed through several pregnancies later, twice in the other half and once in this, but none developed to term. Tuberculous peritonitis followed in later life and compelled laparotomy before recovery, and the anatomic conditions were minutely inspected. The few somewhat similar cases on record are compared with this case, but no answer is suggested for the question why this half of the uterus with atresia permitted conception although it had never apparently participated in menstruation. After the artificial opening had been made, menstrual hemorrhages issued from it as regularly and normally as from the normal half.

82. **Rupture of the Symphysis.**—Kehrer has compiled quite an extensive literature on rupture of the symphysis during delivery, and gives the details of 100 cases. He adds to the series a case personally observed. The patient was a previously healthy tertipara with contracted pelvis. Her children had all been stillborn and the high forceps had been applied repeatedly at this time, with external impression of the head into the pelvis, the woman in Walcher's position. On failure of the high forceps again, perforation and cranioclast extraction at once had been planned, but the symphysis ruptured

during the high forceps. The urethra was torn loose and slit almost its entire length, and the neighboring ligaments were also torn. The sound of the tearing was audible and unmistakable, and a gap over an inch wide could be felt in the symphysis. The head came through at once, and the bleeding in the region of the rupture was arrested by tamponing. The patient died sixteen days later from embolism in the pulmonary artery. In conclusion Kehrer summarizes fourteen cases of traumatic rupture of the symphysis, all but one in men.

Three degrees of rupture of the symphysis have been observed; partial rupture of the ligaments, occurring during delivery and, exceptionally, during pregnancy; complete rupture occurring acutely during delivery or supplementing a previous partial rupture. The third type of rupture is that from overstretching and loosening up of the symphysis ligaments, with or without gaps in the cartilage. The result is a kind of flail joint, developing during a pregnancy or returning in successive pregnancies. A distinct noise is usually heard, and the woman feels as if something had torn. The sound is made mostly by air rushing in as the vagina is torn. When this does not occur and the symphysis ruptures while the woman is under the influence of an anesthetic, the cause for the pains and tenderness in the region may not be suspected for days. The sudden dropping down of the fetus' head is characteristic, and the skin over the symphysis can be pressed down in the form of a long groove. The gap is most evident, however, on palpation through the vagina. After rupture of the symphysis the legs turn outward, so that the knees and feet lie on their outer side. Tearing of the urethra and bladder complicate the rupture at times beyond repair. Gangrene of the foot was observed in one case; fatal embolism in two, and in a few cases bone or cartilage sequesters were expelled months afterward. The ultimate outcome is about the same as after subcutaneous symphysiotomy.

The obstetrician cannot be held responsible for the rupture unless possibly in most exceptional cases of application of extreme force, and then only presumptively, as the records show that such ruptures have occurred with spontaneous births, also spontaneously during pregnancy and delivery, and during delivery under the hands of the most experienced obstetricians. Even when the physician fails to recognize the rupture, and fever and other symptoms develop, these may be masked by puerperal fever or parametritic exudates. A partial rupture during delivery may become complete days or weeks later. It is not always easy to determine whether suppuration at the symphysis is the result of rupture during labor or a puerperal metastatic process. The patient must be kept absolutely still on her back; if the gap is not large it may grow up in two weeks. At future deliveries, conditions favoring rupture must be avoided. The pelvis must be held up with a supporting band and spreading of the knees avoided.

89. **Disinfection of Field of Operation.**—Zur Verth declares that before disinfection can be done there must be infection and it is by no means certain that the skin of the field of operation is already infected. As a rule this is not the case, and hence measures to disinfect are superfluous and do merely harm. It is better, he insists, to omit this alleged disinfection of sound skin until we have some method for disinfection which is actually harmless. Wounds with much destruction of tissue require mechanical disinfection. The iodin technic represents progress as it simplified and crowded out more harmful measures. But the experience in this war has shown that the iodin is far from harmless. He adds that, while denouncing our present methods of chemical disinfection, he still emphasizes the dire importance of contact infection.

90. **Open Treatment of Wounds.**—Härtel is enthusiastic over the advantages of leaving wounds open to the air, merely covering them with a single layer of gauze to keep flies away and veil the lesion. The gauze is held up by a light wire support, the "wire butterfly," and the patients are grateful that they are spared the painful changes of dressings, while the physician appreciates it as he can thus keep the lesion under his eye all the time. There is no odor from the lesion. It is indispensable, however, that the limb should be immobilized. This leaves the organism free to devote all its energies to repair, and it does this without requiring the aid of chemicals.

103 *Differential Diagnosis of Leukemic and Leukemoid Blood Pictures; Four Cases. H. Buhl. Commenced in No. 38.

103. **Differential Diagnosis of Leukemic Blood Picture.**—Buhl gives the minute details of four acute cases suggesting a generalized disease of the blood-producing apparatus. He compares them with the classic types, and discusses the views of various clinicians on the leukemic and leukemoid blood pictures. The article is illustrated. In each of his four cases the blood picture was that of one-sided neutrophil leukemia, but the numbers of leukocytes never reached the typical leukemic figure. The cases, thus, were of the transitional type between simple neutrophil leukocytosis and true leukemia. The patients were young men of 19 and 21 and two women of 24 and 25. The necropsy findings in two of the cases are also given. Death occurred after the first symptoms in nineteen days in one case, but the intervals were longer in the others. Radiotherapy seems to be contraindicated in primary "neutroleukemia," as a change in the blood picture to this type in true leukemia under benzol, radium or Roentgen treatment is generally regarded as a signal warning to suspend these vigorous measures. Benzol was tried in two of the cases here reported, but the results discourage further attempts in this line. In any event, one is on the safe side in taking the behavior of the eosinophils as a guide in treatment, in connection with large numbers of leukocytes. Subleukemic leukocyte figures may occur likewise with complications (sepsis), during remissions of leukemia, and under the influence of treatment.

107. **Research on Heredity.**—Bonnevie devotes nearly fifty pages to a study of various families in Norway showing inheritance of anomalies such as polydactylism, harelip, hemophilia, twin births or dwarf growth. His work to date is fragmentary, he admits, and is mainly to stimulate interest in the subject. He says that conditions in the families of Norway permit such research through several generations better than is possible elsewhere. The large families and the stable residence in remote hamlets facilitate the tracing of Mendel's laws of heredity. He urges that research of this kind should be planned to be carried on through future generations. Material should be accumulated now to serve as the bases for research workers ten or twenty years from now, and still later. The family trees he here presents will be far more significant when carried on further after an interval of twenty years. Cooperation between physicians and biologists is necessary for this, and the work must be organized and correlated. He suggests a central headquarters for the purpose, a heredity institute, to which single reports from different districts can be made, and where the data can be classified and correlated. He adds that Lundborg has already done considerable work in this line in Sweden; studying the hereditary development of myoclonus-epilepsy in certain rural families. His charts, published in 1913, embrace 2,232 persons in the Blekinge province; the myoclonus-epilepsy is shown to be recessive.

110 *Practical Suggestions for Sanatorium Treatment. N. J. Strandgaard.
111 *A Portable "Dark Room." (Et transportabelt Mørkekammer.) K. K. K. Lundsgaard.

110. **Practical Points in Sanatorium Treatment.**—Strandgaard draws some practical conclusions from his experience at the Boserup sanatorium in Denmark. He reiterates that a sanatorium is a combination of a hospital and a rural health resort, and would still maintain its usefulness even if a specific cure for tuberculosis should be discovered. Nowhere else could it be applied to such effect. He makes no attempt at overfeeding, merely striving to bring the patient's weight up to the standard of the life insurance tables. It generally soon reaches this spontaneously, and keeps there. He says that percussion and auscultation do not require complicated instruments or methods; the simplest are the most instructive. The main thing is to examine exactly symmetrical points, the patient sitting on a high stool without a back, and told to cough lightly as each point is auscultated. The stethoscope should be applied systematically at successive points; he enumerates a series of six regions in front, nine at the back and three at the side to be auscultated in turn. For recording the findings he lauds Bang's system of signs; the principles can be learned in five minutes, and several years' experience has confirmed the practicability and great value of the method. It saves fully an hour's work each day in the sanatorium. In comparison with Sahli's and other systems of signs, he has found the Bang method much more of a time-saver.

The prognosis of tuberculosis depends, he declares, on the benign or virulent character of the infection even more than on the stage it has reached. The patient's carelessness, abuse of alcohol, or similar accidental factors explain the recurrence in many cases. One young man, dismissed as clinically cured, had recurrence of trouble after a serious bicycle accident. In several other cases the family did not appreciate the necessity for sparing the recently "cured" patients and set them to hard physical labor which soon brought recurrence, as also return to unhygienic occupations or home privations. These points are familiar to all but can never be reiterated too often, as also the pernicious influence of worry and care. A fracture heals whether one is happy or sad, but psychic factors may turn the scale with a tuberculous process in the lung. In some cases related the patients' homesickness counteracted the benefits of sanatorium treatment; in others, under grief at the death of some member of the family, or fear of scandal, the lung process flared up anew. In another case a young man worried over his wife's approaching confinement and long failed to benefit from the sanatorium treatment. His condition began to improve as if by magic after the baby came. Emotional factors are particularly potent for good or ill in women, both young and old.

111. **Portable Dark Chamber.**—Lundsgaard has found very useful for ophthalmoscopy in the sickroom and elsewhere a dark chamber contrived from an umbrella made with a deep curtain all around. An illustration is given of the one he uses.

115. **The Sugar Content of the Blood after Oral and after Rectal Intake of Dextrose.**—Blohm's tests were made on three healthy men of 24 and two diabetic men of 44 and 73. They took 10 gm. of dextrose by the mouth, or were given 30 gm. by rectal injection, all in an isotonic solution. These amounts were given at a single dose or fractioned. The sugar content of the blood rose at once after ingestion of the dextrose by the mouth, both in the diabetics and in the healthy, but no increase was perceptible in either after the rectal injection of the sugar. There seems to be thus some marked difference in the behavior of sugar in the body according as it is absorbed by the upper or lower bowel. The fact of the absorption by the rectum was established beyond question, but the cause of its different behavior after absorption at this point is still a mystery.

116. **Exposure to Tuberculosis as a Factor in Tuberculosis Later.**—Wallgren found a history of tuberculosis in the family before the age of 15 in 51 per cent. of 100 tuberculous persons, and in 13 per cent. of 100 healthy, all under the age of 40. A history of exposure to tuberculosis before the child was 5 years old was ascertained in 15 per cent. of the tuberculous and in only 1 per cent. of the healthy. Among the 100 tuberculous one or both parents had been tuberculous in 27 per cent.; a brother or sister in 6 per cent., and other relatives in 11 per cent. Among the 100 healthy persons only 2 per cent. had a history of a tuberculous parent; 2 per cent. had a tuberculous brother or sister, and 3 per cent. other relatives. The sexes were represented about equally in both series.

ELECTIVE LOCALIZATION OF STREPTOCOCCI [*]

EDWARD C. ROSENOW, M.D.
ROCHESTER, MINN.

The general systemic distribution of micro-organisms in certain diseases with a localized focus is well established, but the factors which determine the localization of bacteria after they gain entrance into the circulation are obscure.

In this paper I wish to record a summary of the results obtained from the intravenous injection, under a standard technic, of streptococci isolated from appendicitis, ulcer of the stomach and duodenum, cholecystitis, rheumatic fever, erythema nodosum, herpes zoster, epidemic parotitis, myositis and endocarditis, and to discuss the bearing of these results on localization of streptococci.

TECHNIC

The streptococci were usually grown from sixteen to twenty-four hours at 37 C. in tall columns of ascites (10 per cent.) dextrose (0.2 per cent.) broth (0.6+ to 0.8+) to which sterile tissue (guinea-pig kidney or heart muscle) was often added; the sterility of the ascites fluid and broth containing the tissue was always proved beforehand. After incubation smears were made, the cultures were centrifuged in the containers in which they were cultivated,[1] the supernatant fluid was decanted and the sediment suspended in sodium chlorid solution so that 1 c.c. of the suspension contained the growth from 15 c.c. of broth. The doses for rabbits (ear vein) were usually from 0.5 to 3 c.c., and for dogs (leg vein) from 1 to 5 c.c. of this suspension. The injections were made quite rapidly through a rather fine needle (22 gage), usually within an hour after the suspension was made. Blood agar plate cultures were made at the time the suspensions were injected to study the character of the organisms, to test their viability and to save them from further study. This is an important precaution because negative results have at times proved to be due to early death of the recently isolated organisms in the broth cultures. In the accompanying table, "when isolated" indicates the first or second and, occasionally, the third or fourth cultures, or the first culture after one animal passage. "Later" indicates that the strains were cultivated for a week or longer. "After animal passage" indicates usually from the second to the sixth animal passage.

The strains tested from appendicitis, ulcer of the stomach, cholecystitis, rheumatic fever, erythema nodosum, myositis and endocarditis include strains isolated from the characteristic lesions as well as from the apparent atrium of infection. Those from herpes zoster were from the tonsils and spinal fluid, and those from epidemic parotitis were obtained by catheterizing Steno's duct and from the tonsils. The strains from miscellaneous sources were usually from tonsils approaching the normal condition; and the laboratory strains were streptococci or pneumococci cultivated on artificial mediums for a long time and had lost all apparent virulence. The figures in the lowest line of the table represent the average percentage incidence of lesions in individual organs following injection of various strains of streptococci except those from the specific disease. Thus the first figure indicates that 5 per cent. of the animals, injected with the various strains except those from appendicitis, showed lesions in the appendix.

Care was exercised to obtain growths from the depths of the supposed primary focus with as little contamination from the surface as possible, the cultures being made from the material expressed from the tonsils or from emulsion of extirpated tonsils after thorough washing in sodium chlorid solution. The material from the depths of pyorrheal pockets was obtained by means of a pipet.

For the study of pathogenicity of the cultures, dogs and rabbits were chiefly used, being killed with chloroform at the desired time, usually in from twenty-four to forty-eight hours. Postmortem examinations were always made as soon after death as possible. A thorough inspection in a bright light with the unaided eye or with the aid of a hand lens was made for focal lesions. The exact character of the lesions and the presence of the streptococci in each of the various diseases have been determined by microscopic study of sections. Cloudy swelling is not included in the results given in the table. Hemorrhage, localized necrosis, exudation and infiltration were the usual lesions. Thus, in case of the joints, hemorrhage about the joint or turbidity of fluid, as determined with a pipet, or both, were considered as evidence of arthritis. Hemorrhages in the pericardium and turbidity of pericardial fluid, due to leukocytes, were considered as evidence of pericarditis. The postmortem study of animals often symptomless is essential to obtain accurate knowledge of the pathogenicity of a culture, and must supplant the older method of merely finding out whether a culture produces death or not, a method still too much in vogue. The table includes data only from those animals in which the postmortem was comprehensive, and does not include some of the earlier experiments, especially on endocarditis.

---

[*] From the Memorial Institute of Infectious Diseases, Chicago, and the Mayo Foundation, Rochester, Minn.

[1] The common 8-ounce nursing bottle is used both as a culture flask and centrifugal tube, and serves the purpose admirably.

Increase in mortality rate, earlier death and greater degree and distribution of lesions following standard dosage were considered as proof of high virulence. Changes in the spleen and liver were so rare following injection of the strains as isolated, except those from cholecystitis, that they are not included in the table. Acute splenitis and such changes in the liver as focal necrosis, parenchymatous and bile duct hemorrhages and acute degeneration with marked acidity occurred, however, after the strains had acquired greater virulence from animal passage. In the earlier experiments not sufficient attention was paid to the occurrence of lesions in the thyroid, thymus, suprarenals and lymphatic glands. Later a closer search for lesions in these structures was made, especially after it was found that lesions in the thyroid followed intravenous injection of bacteria isolated from goiter. It must be said, too, that strains of streptococci from rheumatic fever, myositis and cholecystitis produce hemorrhages in the thyroid quite commonly, while those from other sources rarely produce them.

RESULTS

A study of the table shows that streptococci from the various diseases often have a most striking affinity or tropism for the organs or tissues from which they are isolated. Thus, fourteen strains from appendicitis produced lesions in the appendix in 68 per cent. of the sixty-eight rabbits injected, which is in marked contrast to an average of only 5 per cent. (given in lowest line of table) of lesions in the appendix in the animals injected with the strains as isolated from sources other than appendicitis. Eighteen strains from ulcer of the stomach or duodenum produced hemorrhages in 60 per cent. and ulcer of the stomach or duodenum in 60 per cent., a combined total of 74 per cent. of the 103 animals injected, in contrast to an average of 20 per cent. hemorrhages and 9 per cent. ulcer following injection of other strains. Twelve strains from cholecystitis produced lesions in the gallbladder in 80 per cent. of the forty-one animals injected, in contrast to an average incidence of lesions here of only 11 per cent. with the other strains. Twenty-four strains from rheumatic fever produced arthritis in 66 per cent., endocarditis in 46 per cent., pericarditis in 27 per cent., and myocarditis in 44 per cent. of the seventy-one animals injected, in contrast to an average of arthritis in 27 per cent., endocardial lesions in 14 per cent., pericarditis in 2 per cent. and myocarditis in 10 per cent. of the animals injected with strains from sources other than rheumatic fever. Six strains from erythema nodosum produced lesions of the skin in 90 per cent. of twenty animals injected, in contrast to an average of 2 per cent. in the animals injected with the strains from sources other than erythema nodosum and herpes zoster. Eleven strains from herpes zoster produced herpetiform lesions of the skin, lips, tongue or conjunctivae in 77 per cent. of the sixty-one animals injected, in contrast to the average of only 1 per cent. of what seemed to be herpes of the skin with the other strains. Nine strains of streptococcal organism from epidemic parotitis produced lesions in one or both parotid glands in 73 per cent. of the nineteen animals injected intravenously, in contrast to no instance of lesions here with the other strains. Three strains from cases of true myositis produced myositis in 75 per cent. and myocarditis (chiefly of the right ventricle) in 35 per cent. of the forty animals injected, in contrast to an average of myositis of 12 per cent. and myocarditis of 10 per cent. following injection of strains from sources other than myositis or rheumatic fever; and eight strains of *Streptococcus viridans* from chronic septic endocarditis produced lesions in the endocardium in 84 per cent. of the forty-four animals injected, in contrast to an average of 15 per cent. with the strains other than those from endocarditis. The results following injection of the miscellaneous strains (usually the first culture from tonsils) and the laboratory strains serve as a basis of comparison with those following injection of the strains from the various diseases, and correspond roughly with the total average incidence of lesions in the various organs as given in the lowest line of the table.

While the incidence of lesions in the organs following injection of the strains isolated from such organs is high, as shown by these figures, the appearances at the necropsy are even more significant. In many instances in which the animals survive the injection for some time, no other focal lesions could be found except those in the organ in question; and when the animal died early, these lesions were the marked feature and the associated ones were relatively insignificant. Frequently the injection of a very small dose was sufficient to prove the elective localization. This elective property was shown not only by the cultures from tissues and foci but also by the bacteria contained in the foci, directly injected in other animals.

In many cases of both acute and chronic diseases the apparent atrium of infection was found to harbor streptococci having elective affinity; in the former usually only at the time of the attack, in the latter in some instances for months. The elective affinity, however, was less marked in the strains isolated from the supposed focus than in the strains isolated from the lesions in the various organs. The rather wide range of lesions, as indicated in the table, following the injection of the strains from herpes zoster and parotitis is due to the fact that often primary mixed cultures from tonsils and pyorrheal pockets were injected.

Attempts to find a method which would preserve the original tropic property, while only partially successful, have shown that it may be preserved for some weeks in the deeper colonies of the original shake cultures and for as long as seven months by keeping the suspensions containing sterile tissue in the ice chest, thus maintaining the bacteria in a condition of latent life.

The localization of the strains from appendicitis, ulcer of the stomach and cholecystitis as isolated, after cultivation and after animal passage, is of particular interest and will be discussed in a separate paper. It should be stated here, however, that these strains resemble one another very closely indeed in cultural and other respects. Those from appendicitis are the least virulent, those from ulcer occupy a middle position and those from cholecystitis are the most virulent. The virulence seems to be one of the factors that determines their place of survival after intravenous injection. Now if the localization is dependent to a certain extent on virulence, then the occurrence of ulcer and cholecystitis should become greater as the strains from the appendix are passed through animals, and appendicitis should occur oftener after the strains from ulcer and cholecystitis lose virulence from cultivation on artificial mediums. This is found actually to be the case (see figures in table). In this connection other facts should be mentioned. None of the strains from appendicitis produced pancreatitis. The strains from ulcer and cholecystitis as isolated (mostly those from acute cases) produced pancreatitis in 3 per cent. and 5 per cent., respectively, of the animals injected. After animal passage, pancreatitis occurred in 15 and 19 per cent., respectively, while after cultivation on artificial mediums pancreatitis in no case was obtained.

Lesions in the intestines, exclusive of the duodenum, were more common with the strains from cholecystitis and rheumatism than with those from appendicitis, and all the strains produced intestinal lesions (chiefly of the mucous membrane and lymphoid structures) quite commonly after they had been passed through animals, whereas, after cultivation for a time, no noteworthy lesions were found in the intestinal tract.

The streptococci studied by me from parotitis resemble the organism described by Herb[2] and, like hers, produced the characteristic picture of mumps in dogs when injected into Steno's duct. Intravenous injection of these organisms produced marked edema and hemorrhage in and surrounding the parotid. The affinity was so great that the streptococci were found in pure culture in the enlarged parotid in three of five full-time puppies removed from the uterus of a dog which was chloroformed during a marked parotitis following injection into Steno's duct. Antigens prepared from a number of these strains were found to bind specifically complement in serum from parotitis (Howell).

Lesions in the skeletal muscles occurred in 75 per cent. of the animals injected. The number of lesions in the muscles and myocardium in the animals injected with strains from myositis was often in proportion to the quantity injected, and occurred mostly in the tendinous portion and in the right ventricle.

Lesions in the kidney were especially common after injections of streptococci from rheumatic fever (39 per cent.) and from endocarditis (20 per cent.). These occurred chiefly in the medullary portion (Rosenow[3]) in the former and in the glomeruli in the latter.

Lesions in the lung, consisting usually of hemorrhages and edema, were rare following injection of the strains when isolated and after they were cultivated on artificial mediums but, just as was found previously (Rosenow[3]) they occurred oftener after the virulence was increased by animal passage.

That the streptococci are the underlying cause of the diseases from the lesions of which they were isolated is indicated further by the fact that they have elective affinity for the corresponding structures in animals. *Moreover, the fact that the same streptococcus may be made to localize in different organs is* in consonance with the knowledge that streptococci may cause diseases with different symptomatology. The *possibility, however,* that they are secondary invaders to some ultramicroscopic, filterable organism has to be considered. Filtrates of the streptococcal cultures from various diseases were injected intravenously. *In* some instances the filtrates produced lesions in the organs from which the strains were isolated; the lesions, however, were not due to living organisms because the broth which was inoculated and incubated *with the tissues* failed to produce any lesions. The results, while *inconclusive, may* be said to indicate that streptococci produce substances which cause injury specifically in the tissues from which the *strains* are isolated.

GENERAL DISCUSSION

The results obtained are in harmony with the facts that (1) "*septic sore throat*" is due to streptococci having peculiar properties;[4] (2) certain epidemics of throat infection, due to streptococci, are more frequently complicated by sinusitis than others; (3) distinct differences in the character of the lesion in the lung and mortality rate in pneumonia, as shown by Cole,[5] are due to pneumococci so nearly alike as to require sensitive biologic tests to differentiate them; (4) *hemolytic streptococci* frequently have a marked affinity for joints, and (5) Friedländer bacilli in arthritis show elective affinity for joints in animals when other strains do not (Dick[6]). The "organotropic" condition of streptococci is analogous to the affinity of the tetanus toxin for the motor ganglion cells, of the diphtheria bacillus for the faucial tonsils, of the meningococcus for the meninges, of the pneumococcus for the lung, of the typhoid bacillus for lymphatic tissues, of the virus of rabies for the central nervous system, of the organism of anterior poliomyelitis for the anterior horns of the spinal cord, of the malarial parasite for the red blood corpuscle, and of the *Trichina spiralis* for muscles. The results, moreover, are in accord with the well-known fact that chemicals when injected intravenously also localize unequally in various organs.[7] The changes in the distribution of lesions as the streptococci are altered by cultivation on artificial mediums or by animal passage are similar to the changes in localization of various chemicals or dyes depending on chemical constitution, as observed by Ehrlich.[8] In my experiments advantage was taken of the opportunity afforded to study the nature of selective action from the standpoint of living bacteria.

Flexner[9] has shown that the functioning organ may be especially favorable to the growth of *certain* bacteria although the organ extracts may inhibit their growth; hence the growth of bacteria in various organs may be related to function and blood supply. Streptococci of low virulence but highly sensitive to oxygen are found to produce lesions in tissues whose blood supply and therefore *oxygen* and food requirements are low (heart valves, tendinous portion of muscles and the structures about joints). Streptococci of greater virulence are found to produce lesions in tissues whose blood supply and therefore oxygen and food requirements are high (kidney, lung, etc.); hence localization and production of injury seem to be closely related to the amount of available oxygen in a given tissue. The fact that lesions occurred far more frequently in the right ventricle (containing venous blood) than in the left ventricle (containing oxygenated blood) is in accord with this hypothesis. Might not the predisposing *action* of *trauma* (locus minoris resistentiae), of exposure to cold and of a drunken bout, to *infection* be best explained on the basis of lack of oxygen?

The changes observed, as hemorrhage, cloudy swelling and necrosis, from a purely chemical[10] as well as from a colloid-chemical[11] point of view, are identical with the changes of tissue *asphyxia*. I have found that pneumococci when grown and autolyzed under anaerobic conditions produce a *much* larger quantity of toxic material than when grown or autolyzed under aerobic *conditions*. *Moreover*, pneumococcus extracts proved to be toxic to warm-blooded animals (guinea-pigs), have the same inhibitory effect on the development of fertilized eggs of arbacia as does lack of oxygen. Since bacteria and their products are powerful reducing agents,[12] one of the chief effects of the bacteria and their products very likely is interference with the normal cell respiration, and possibly the greater the virulence the more powerful this interference.

Although the circulation is an important factor in determining localization, the tissues themselves play an even more important rôle. The question whether the lesions in the organ for which a particular strain appears to have elective affinity are due to the lodgment of a larger number of bacteria here than in the other organs, or whether the bacteria lodged in equal numbers in the various organs but survive only in the one showing lesions, is now under study. The evidence already obtained, however, *points strongly* to the former mechanism. It appears that the cells of the tissues for which a given strain shows elective affinity take the bacteria out of the circulation as if by a magnet—adsorption.

This remarkable *tropic* condition tends to disappear quite promptly both on cultivating the streptococci on *artificial mediums and on passing them successively* through animals, and this may occur without demonstrable changes in *morphology*, grouping or character of chain formation. I have previously shown[13] that the ability of *Streptococcus viridans* and staphylococci to produce lesions in the endocardium is due partly to physical clumping. Evans[14] has shown that the action of vital stains of the benzidin group is related to the size of colloidal particles. A careful study of smears of the suspensions injected in these experiments revealed no constant relation between localization and clumping or size of the bacteria.

Individual variations in resistance to infection were found in the injected animals. The effects of these conditions in the host as determining factors in localization are important; they are probably expressions of differences in metabolism, oxidation rates, etc., which influence the soil for bacteria. The tendency of virulent bacteria, temporarily or permanently, to render this soil less favorable for their growth is well established. There is some evidence, on the other hand, which goes to show that certain bacteria of very low virulence (commonly found in chronic foci of infection) tend actually to make this soil more favorable. But, in the light of my results, it must be considered that differences in the host may afford the peculiar type of reaction, or that the individual harbors a particular form of focus of infection which is favorable for bacteria to acquire elective properties. The following facts support the latter view: (1) the common occurrence of certain noncontagious diseases, such as herpes zoster, ulcer of the stomach, etc., during definite age periods; (2) the fact that foci of infection afford opportunity for bacteria to grow under varying grades of oxygen pressure and in mixed culture, both of which have been shown to cause changes in virulence and other properties of bacteria,[15] including the streptococcus group;[16] (3) the occurrence of systemic infections such as rheumatic fever, appendicitis, ulcer of the stomach, etc., usually after the acute symptoms in follicular tonsillitis (hemolytic streptococci), have subsided, and (4) the finding in the focus and involved tissues at the time of the systemic infection, streptococci having elective affinity for these structures in animals.

Since different bacteria may acquire simultaneously affinity for the same tissue, diseases which resemble each other more or less closely, such as the different forms of arthritis, may be due to bacteria of different species each having elective affinity for the particular structures involved.

The figures in the lowest line of the table represent the results of numerous experiments (833) with streptococci (220) from a wide range of sources, and may therefore be regarded as an index of the liability of the various organs to infection. Thus, joint lesions occurred more often (27 per cent.) than lesions in other organs, corresponding to the frequent occurrence of spontaneous arthritis in man and animals. The occurrence of lesions in the stomach (20 per cent.), valves of the heart (14 per cent.), myocardium (12 per cent.) and skeletal muscles (12 per cent.) correspond in a general way to the occurrence of infection in these organs in man. The very infrequent involvement of the skin, tongue and the parotid in the animals is in keeping with the rarity of embolic infections in these structures. The character of the lesions and their occurrence simultaneously in the joints, heart, muscles and kidney, and the development of chorea (7 per cent. mostly in young rabbits) following injection of the streptococci from rheumatic fever, parallels quite closely the phenomena of rheumatic infection as observed in man. The strains from erythema nodosum resemble those from rheumatic fever, producing a relatively high incidence of arthritis, pericarditis and myositis, a fact which supports the view held by clinical observers,[17] that the causative agents of rheumatic fever and erythema nodosum must be similar.

The tendency to localize electively within a limited range, "monotropism," is most highly developed in the relatively nonvirulent strains isolated from chronic lesions. In the more virulent strains from acute lesions and after animal passage, this tendency is less highly developed, the lesions occurring over a wider range, "polytropism." The fact that the elective property is more highly developed in streptococci isolated from the organ involved, than in those isolated from the probable focus of infection, is in accord with the results obtained by Forssner,[18] who showed that when streptococci are grown in kidney and kidney extracts they acquire a special predilection for the kidney when injected intravenously. Since the bacteria which have grown in a given tissue acquire greater affinity for this tissue, the likelihood of these bacteria to involve other structures is relatively slight; hence the secondary focus, a cholecystitis, for example, would appear to be less important as a distributer of bacteria than the primary focus; if, however, the secondary focus happens to be in a joint, of which there are many, it may play an important rôle in causing extension to uninvolved joints and in preventing recovery.

The bearing that these results have on the specific treatment of these diseases is evident. The injection of a streptococcus vaccine or antistreptococcus serum without regard to the tropic condition of the infecting strain or the one used in their preparation is, in the light of these results, far from an exact method of treatment. However, the occasional, seemingly good result observed by some may be due to the use of a serum or vaccine made from strains in the same tropic condition as the one infecting the individual so treated.

The results detailed in this and in previous papers seem to bring the necessary experimental proof that chronic foci of infection play a most important rôle in causing systemic disease, a fact which has been observed and frequently commented on by different observers, but has been recognized in its full clinical significance especially by Billings.[19] A focus, such as a pocket in the tonsil which cannot heal for mechanical reasons and which is constantly filled with pus and necrotic material, teeming with bacteria, must be regarded in the light of these findings as a culture tube with a permeable wall affording abundant opportunity for the entrance of bacteria and their products.

INFLUENCE OF PEPTONE ON TOLERANCE OF THE BODY FOR HOMOGENOUS OVARIAN TRANSPLANTS*

LOUIS A. MITCHELL
MINNEAPOLIS

Much work has been done recently on the subject of the survival of foreign grafts, and interesting results have been obtained concerning the nature of the reaction by which the host destroys the engrafted tissue.

Tuffier[1] reports twenty-four attempts at homogenous grafts of ovarian tissue in man with failure in every case, the same technic being used by which uniformly successful results were obtained in autogenous grafts. He states that as a foreign body the graft is destroyed by macrocytes, and if the macrocytes could be prevented from attacking the graft, it might be possible to obtain success.

Castle and Phillips[2] conclude from experimental work on guinea-pigs and analysis of clinical results that homogenous transplantation of ovaries is not practical in domestic animals and man, unless the tolerance of the body to foreign tissue can be raised. Out of 141 guinea-pigs ingrafted with foreign ovaries, only three gave a functional result.

Davidson[3] reports success with autogenous transplants, but no permanent growth of homogenous grafts, and concludes, "It is a much more difficult thing to obtain permanent growth and function of homotransplants." Marshall and Jolly reached the same conclusions in working on animals.

Murphy has shown that the destruction of heterogenous tissue is brought about by the action of lymphoid tissue of the host,[4] and has had marked success in inhibiting the reaction against these foreign grafts[5] by the use of Roentgen rays and the injection of benzol (benzene, C_6H_6). (Repeated injections of benzol were quite harmful to the host.)

Leo Loeb[6] offers a very illuminating article on the behavior of tissues in a changed chemical environment. His conclusions are as follows: (*a*) In autogenous transplants, some of the tissue may live and grow, but in homogenous transplants only very rarely does this occur; and when it does, the metabolism of the graft becomes much altered in its new environment. (*b*) Different tissues may show different resistance to autotransplantation and homotransplantation, and different experiments may bring out variations of individual reaction between the tissue and the new host. (*c*) For the first week, there is little difference in the behavior of autotransplants and homotransplants; then a gradual destruction of the latter sets in, or the metabolic disturbance in the graft due to the shock of transfer may be great enough to prevent its ever recovering. (*d*) Destruction of the graft is brought about by a secondary reaction on the part of the host, and is accomplished by increased activity on the part of the connective tissue of the host. The action of the two factors is interdependent, but in a given case, one or the other predominates. (*e*) Function of corpus luteum is reduced after autotransplantation; in case of the latter, it is reduced by injurious action of the body fluids. Loeb further states that the toxic action of the body fluids of the host is not a factor in destruction of homografts. Ingebrigtsen,[7] in working with tissues in vitro, observed that normal autogenous serums offer better mediums for growth of tissue than similar serums which have been heated to a degree which causes destruction of complement (56 C. for 30 minutes), and that the reverse is true of foreign serums.

Carrel and Ingebrigtsen[8] found that the fluid of cultures in vitro containing a heterogenous serum has in five days acquired the power to hemolyze the red blood cells of the animal furnishing the heterogenous serum, while the serum of controls remains nonhemolytic. They attribute the development of hemolysis to the presence of antigen. This reaction of the graft is in turn met by the reaction on the part of the host, which we see manifested by a round-cell infiltration of the tissues of the graft, and which leads to the ultimate destruction of the graft.

Vaughan[9] also states that "any foreign protein (in this case ingrafted tissue) which can grow and multiply in the body of a given animal may prove pathogenic to the animal." He believes that some of the body cells in preparing for their combat with foreign protein develop a new function: that of elaborating a new and specific ferment which will digest and destroy the foreign protein.

In work done by Carrel[10] it was found that the limbs transplanted on an infected host were more apt to live than were those transplanted on an uninfected host. This would indicate that the action of the infecting bacteria had some inhibitory influence on the reaction of the host against the graft. Furthermore, since Besredka, Ströbel and Jupille[11] have shown that the action of complement on bacteria gives a substance which is identical in many of its physiologic actions to the substance obtained by the action of complement and peptone, it does not seem unreasonable to suppose that injections of Witte's peptone should have a similar effect on the reaction of the body against ingrafted tissues.

It was therefore thought that it might be profitable to undertake the following animal experiments in order to determine whether or not the repeated periodic injections of a solution of Witte's peptone would increase the tolerance of the body to grafts of foreign tissue.

TECHNIC

Operation.—The rabbits were operated on in pairs in order to make possible the immediate transfer of the grafts. The strictest aseptic technic was followed. A lower median incision was made through which both ovaries were completely removed. Great care was taken to leave no native ovarian tissue behind. The pedicle of the gland was clamped with

Kelly forceps and ligated below the forceps, and then cut between the ligature and forceps. Multiple simple grafts were used. One ovary was discarded and the other sectioned for grafts into the other rabbit. The ovary which was used for grafts was held by the pedicle and was not touched by instruments or gloves. The method of cutting the grafts differed and will be detailed later in each case, but the cardinal points observed were:

1. To minimize the traumatic shock and the danger of infection to the ingrafted tissue, by having it come in contact with nothing except the sectioning instrument, and the use of a very sharp sectioning instrument.

2. To minimize the time which the graft was in contact with the air between removal from the donor and implantation into the host.

3. To obtain good contact between the cut surface of the graft and a portion of peritoneum where the possibility of vascularization was good.

The grafts were left free in order to avoid trauma incident to suturing them in place. The abdomen was closed in layers with linen.

Peptone Injections.—Peptone injections were made at the time of operation and thereafter every four days until the animal was sacrificed for necropsy. The injections were made intraperitoneally under aseptic precautions, and the dose used was approximately 1 c.c. of a boiled 10 per cent. solution of Witte's peptone to each 100 gm. of the rabbits' weight.

The rabbits used as controls underwent the same operative technic as experiments, but received no peptone injections.

Following the peptone injections, the animals showed a reaction which was manifested by labored breathing, restlessness, and general bodily weakness similar to that described[11] as following the injection of an attenuated dose of peptotoxin which had been formed by the reaction of complement and peptone outside of the body. In every case after the animals had received from three to four injections, they showed a condition of reduced metabolism evidenced by a loss of body weight and marked thinning of the coat. This was not noticed in the controls, which were otherwise subject to similar conditions.

Ten rabbits were operated on; five were used for peptone injection and five for controls. The experimental rabbits and their controls in each case were operated on in pairs and subjected to similar conditions. The controls of Experiments 1 and 4 were lost through postoperative death.

SUMMARY OF EXPERIMENTS

Experiment 1.—Rabbit 1 (nineteen days' duration). Large en masse graft, consisting of one-half ovary, on mesentery of large bowel. At necropsy the graft had a large area of central necrosis surrounded by ovarian tissue which showed signs of beginning destruction. All of the ovarian tissue remaining was invaded by a new blood supply. The invasion by round cells had already taken place. This experiment was not controlled.

Experiment 2.—Rabbit 2 (controlled by Rabbit 3; six weeks' duration). Multiple small graft on mesentery. Grossly, the grafts in the animal injected with peptone had acquired a more profuse blood supply than those in the control in which no peptone had been injected, and were larger and felt more firm. On microscopic section it was found that destruction of ovarian tissue was complete in them, while there were small areas of ovarian tissue remaining in the grafts of the control. The invasion by round cells and connective tissue was more marked in the rabbit receiving peptone injections.

Experiment 3.—Rabbit 4 (controlled by Rabbit 5; eight weeks' duration). Multiple millet seed grafts in peritoneal cavity. These grafts were firm and healthy in appearance, and had a much more profuse blood supply than their controls; but microscopic sections showed all of their ovarian tissue to be necrotic, while there was still some ovarian tissue remaining in the controls. The cellular infiltration was more marked in the grafts of the injected animal.

Experiment 4.—Rabbit 6. Single en masse graft on broad ligament. Twelve weeks' duration. Twenty peptone injections. The graft had undergone complete destruction and had been almost entirely absorbed.

Experiment 5.—Rabbits 7 and 8; of only a few days' duration. Interrupted by the incidence of peritonitis, and the grafts had evidently lost their viability owing to the peritonitis, rather than to the usual reaction of the body against foreign tissue.

COMMENT

As has been seen, there are many references in the literature to the nature of the mechanism of the reaction by which homografts are destroyed. Tuffier explains the process by the action of macrocytes. Loeb believes that such grafts are destroyed by mononuclear invasion and proliferation of connective tissue. Murphy has shown that the presence of lymphoid tissue is essential before the host can destroy a foreign graft. In the foregoing experiments, the grafts were not attacked by macrocytes. Mononuclear infiltration and connective tissue proliferation were uniformly present. I can see no reason, however, to suppose that these evidences of reaction on the part of the host are the essential factors in the destruction of the graft. I am rather inclined to take exception to the further statement of Loeb that the toxic action of the body fluid of the host is not a factor in the destruction of these grafts. Several of the observations quoted above would indicate that the serum plays the primary rôle in the destruction of homografts.

1. Ingebrigtsen found that if complement was exhausted from foreign serum, it offered a better culture medium for tissues than normal serum, and that the reverse was true for autogenous serum.

2. There is no evidence of reaction against foreign tissues until just that period of time has elapsed after their introduction into the body which is necessary for the development of specific immune bodies. This led to the hypothesis that the tissue cells might be destroyed by a lytic action of the serum involving Erlich's side chain of the third order. The round-cell infiltration and connective tissue invasion, which was observed in all instances, may be explained as the usual reaction against any tissue in the body which becomes necrotic.

It was on the basis of this theory and the observation of Carrel that bacterial infection inhibited the reaction of the host against homografts that the foregoing experiments were undertaken, because Besredka, Ströbel and Jupille have shown that peptone exhausts complement from the serum and has a similar action to bacterial intoxication.

CONCLUSIONS

As the result of the experiments, we may reach the following conclusions:

1. Peptone injections, as they were made, tend to intensify rather than inhibit the reaction of the host against homogenous grafts of ovarian tissue.

2. Such injections of peptone produce a condition of reduced metabolism in the animal, but not to such an extent as to prove dangerous to life.

3. An abundant blood supply to the graft does not indicate that it is viable in its new environment, but may rather be evidence of an intense reaction against it on the part of the host.

4. The destruction of the graft is practically complete by the sixth week, both in animals injected with peptone and in those not injected.

5. The host primarily reacts to the presence of the graft by revascularization of its tissues, and the further reaction which evidently involves the destruction of the graft is evidenced by round-cell infiltration and proliferation of the connective tissue of the host.

6. The presence of peritonitis within a few days destroys the viability of intraperitoneal grafts.

DETACHMENT OF THE RETINA

WITH A PRELIMINARY REPORT ON A NEW OPERATIVE PROCEDURE *

EDGAR S. THOMSON, M.D.
AND
THOMAS H. CURTIN, M.D.
NEW YORK

Detachment of the retina is a condition of such seriousness, and its treatment is so unsatisfactory, that we feel justified in placing on record even a small number of cases.

There are three principal theories as to the causation of retinal detachment:

1. Von Graefe in 1854 assumed that a hemorrhage occurred behind the retina, basing his conclusion on the sudden appearance of the condition. Arlt considered that the fluid behind the retina was due to a secretion or exudation from the choroid pressing against the vitreous humor and thus bringing about its gradual absorption. The present theory, which has a large following, assumes a primary retroretinal exudation with compensatory diminution of volume in the vitreous.

2. Leber's theory, which embodies Müller's theory of fibrinous degeneration of the vitreous, and Iwanof's theory of detachment of the vitreous and shrinking, and Arlt's theory of rupture, or tear. Leber argued that given the shrunken fibrillary vitreous attached more extensively and firmly than normal to the retina, with its pool of fluid representing the amount of shrinking, the train is laid for an acute spontaneous detachment. A sudden rent occurs and through this the preretinal fluid rapidly becomes retroretinal and the detachment is accomplished.

3. Raehlmann's theory, which assumes a primordial alteration in the constitution of the vitreous, whereby, through the influence of osmosis, the watery constituents pass through the retina seeking to equalize with the juices of the choroid, which are rich in albumin.

Each of these theories has had its followers, but so far histologic examination has done little to establish any one of them. Our present point of view must rest on deduction and inference from well-known clinical phenomena. Speaking of retroretinal exudation, Schöbl[1] says:

> It is inconceivable that so large an exudation can be thus formed in a few moments, and even if this were possible and this exudation can overcome the normal pressure of the vitreous humor and press the retina inward, the intra-ocular tension must needs be enormously increased, and that is the condition that is hardly ever found in retinal detachment.

This point seems not to be well taken. Exudation from the choroid probably can occur rapidly. Intra-ocular tension depends not so much on excessive secretion as on the blocking of the outflow, so that even if we assume a choroidal exudation, increase in tension would not necessarily follow. Iwanof found in highly myopic eyes a detachment of the vitreous humor at the posterior pole, and his explanation of this fact was that the vitreous could not increase in volume as rapidly as the posterior part of the sclerotic was distended, and in consequence serum would have to fill the gap. If this were the active factor in myopic detachment, the lesion would invariably take place at the posterior pole, which is not the case. Also evidence goes to show that it is possible for the vitreous to increase rapidly in volume through imbibition of serum. This occurs in the rapid increase of tension during trephine operations in old glaucomatous eyes. Even if the anterior chamber is open, the pressure rises, and a prolapsed iris cannot be replaced. Also, after a loss of vitreous during cataract extraction, it is well known that almost all cases which heal up do not show detachment of the retina for some weeks, or even months. Such cases are invariably found with the eye plumped up to normal dimensions as soon as the wound is closed, generally on the following day. Iwanof thinks that the exudation behind the vitreous humor finally lacks room and must filter into the humor itself or pass backward through the retina and thus lift this membrane from the choroid. However, as Schöbl remarks:

> This explanation is incorrect and against all physical laws, since the fluid between the vitreous humor and the retina must exert an equal pressure in all directions and, therefore, could press the retina more firmly against the choroid, but could never detach it from this membrane.

A great deal of stress has been laid on rents in the retina, and it must be admitted that given a retinal rent it is conceivable that serous fluid might in such a case find its way through the rent between the retina and choroid. Many cases of detachment, however, show no demonstrable rents in the retina, and when one considers how much traction the retina can bear in old inflammatory conditions without showing any rent, it seems much too fantastic to assume the existence of a rent from traction when the most careful examination with the ophthalmoscope will not show any evidence of traction in the vitreous. In fact, most idiopathetic detachments have a sacculated, or rounded, appearance, which is suggestive of pressure from beneath, but has not the faintest resemblance to a condition which might be produced by traction bands in the vitreous. The commonest form of traction is that which occurs in the ciliary region from old inflammatory exudates, and while traction from exudates may occur, it is certainly very doubtful if it is in any sense a factor in the ordinary idiopathic detachment. The status of the so-called retinal rents has not as yet been

---

[1] Schöbl: Norris and Oliver's System, iii, 534.

satisfactorily established. A few have been observed in the periphery of the retina, but the causal relationship between rent and detachment is by no means settled. In one of our cases a well-defined "V"-shaped rent could be seen, across which ran a retinal vessel. As the direction of the retinal rent, which was roughly in the shape of a very obtuse angle, extended at right angles to the direction of greatest tension in the detachment, it seems more reasonable to assume that the rent was due to the pressure of the fluid from beneath and that it was a secondary feature.

The clinical course of many detachments is about as follows: The detachment occurs rather rapidly, and on our first ophthalmoscopic examination we find a perfectly clear vitreous with a sacculated spot in the retina and a vision which is reduced entirely out of all proportion to the local condition. One would think that a detachment which did not involve the macula and did not hang in front of it in the vitreous, would not reduce the vision. The vision is frequently very much reduced, however, and may become progressively worse in the early stages of the condition, so that the lymphatic derangement is far more serious than the local appearance would lead us to believe. In the detachment which occurs alongside of a sarcoma of the choroid, and which is manifestly due to the transudation of serum, the appearance and clinical characteristics are exactly the same as in the ordinary detachment, and these cases must be looked on as a still further proof of the distention theory. After detachment has existed for a certain length of time, floating bodies appear in the vitreous, and iritis and other inflammatory changes supervene. Traction bands may then form from degeneration of the vitreous. The diffusion theory "presumes differences in tension in two fluids, one of which is in front and the other behind an animal membrane. These conditions exist when the retina is detached. Behind the retina there is a relatively albuminous fluid, while in front of it in the vitreous chamber there is a fluid that contains but little albumin, the diffusion taking place more rapidly the greater the difference in density of the two fluids" (Schöbl).

Parsons[2] says:

> In most cases, according to some investigators in all, the retina is ruptured and fluid passes through the rent from the vitreous. It is certain that in many cases no rupture of the retina can be seen ophthalmoscopically, and it is probable that it is not an indispensable factor. If so, the fluid must be derived from the choroid or from the vitreous by a process of osmosis. Such experiments as have been made on the latter possibility have not been conclusive.

Vail[3] has recently written a comprehensive paper on the subject of treatment of retinal detachment which bears quotation in this connection. This paper is based on replies received from 281 oculists, 250 representing, according to the author's estimate, an average of twenty years of practice, and an experience averaging five cases a year, or about 25,000 cases in all, with the employment of every known line of treatment, "and not a single case of permanent cure in the lot." On the other hand, 31 oculists have secured cures; 25 each had a single cure; 4 secured 2 cures, and 2, 4 cures, making in all 41 patients reported cured. Two of these patients had detachment due to albuminuria in pregnancy, and they were cured after abortion. They should not be counted, as treatment is not applicable except in these unusual circumstances. This leaves 39 cures. In about one-half of this number the cure is not convincing from the records submitted, leaving, say, 20 cases, or less than 1 cure in every 1,000 cases. The author considers that these figures show conclusively that there is no proper treatment for this condition.

De Schweinitz, in a personal letter, says:

> The treatment that I have found most satisfactory has been posterior sclerotomy, with drainage of the subretinal space; rest in bed; and the injections subconjunctivally of saline solutions. In recent years I have added to this dionin, sometimes sweats, usually with pilocarpin.

Vail's theory is that there is a paralysis of the secretory function of the ciliary processes. This means that the secretion of aqueous is suddenly arrested. There being nothing wrong with drainage channels within the eye, the watery elements find ready egress, thus giving a minus tension. Leber found 90 per cent. had minus tension. The withdrawal of normal tension causes passive hyperemia of the blood vessels of the tunica vasculosa. This allows diapedesis and transudation. The vitreous contracts because it loses its percolating supply of aqueous, which soon drains off through the efferent channels which are wide open, and the fibers of the vitreous naturally contract like a sponge would after losing its water. The subretinal transudation is highly albuminous. The watery elements ooze away and are replaced by fresh serum, a poor substitute for aqueous. The tissue colloids and circulating colloids imbibe all the moisture they can. The reaction of the transuded juices becomes altered to a less than normal alkaline or an actually acid state. Vail further says that the causes of such a paralysis of the secretion of the ciliary body may be acute local and systemic, or chronic local. Acute local cases are from blows; certain drugs, like belladonna, when the patient has idiosyncrasy or a preceding equatorial choroiditis, or myopia. Acute systemic cases might arise from certain toxemias, like those of albuminuria, diabetes, etc., which have a paralyzing effect on the secretory function of the ciliary body. "Chronic local" from slowly progressive atrophy of the secreting epithelium of the ciliary processes. Vail's conclusions are that surgical treatment is not founded on scientific principles; that detachment of the retina is not a disease, but a symptom; that the disease is paralysis of functions of the ciliary processes, causing an arrest of aqueous secretion within the eye. The treatment should be the use of those measures, and only those, which have for their objects the reestablishment of the lost function of the ciliary processes. Vail rather advocates subconjunctival injections of sodium citrate, after M. H. Fischer's ideas.[4] This treatment is supposed to reestablish the aqueous flow by rendering alkaline the intra-ocular juices.

While this theory has a very attractive sound, it must be remembered that it is for the most part nothing more than a theory, and while it fits certain clinical aspects of the cases, so far as treatment is concerned, little benefit apparently has been secured. Sodium citrate injections, or any form of subconjunctival injections have given not the faintest glimmer of hope in our hands. We are, however, prepared to subscribe to the theory that the transudation of serum beneath the retina is but a symptom of a deeper intra-ocular disorder, but cannot altogether feel that it is a progressive degeneration. There is reason to believe that the actual detachment has something to do with lowering the nutrition of the eye and subjecting it to the well-known degenerative processes which supervene in a large proportion of cases—floating opacities of the vitreous, iritis and cyclitis, and later cataract. All these come on after the detachment has existed for some time, and are, as a rule, the more prone to occur the larger the detachment. The clinical course of the ordinary idiopathic detachment does not suggest a progressive degenerative process. If such were the case, there would be no reason why a detachment should not appear gradually and gradually enlarge. On the other hand, the detachment appears suddenly and, as a rule, remains approximately the same size until further degenerative symptoms set in. It seems, therefore, as if the exudate came from a sudden attack which subsides, leaving the exudate in situ, and that further degenerative processes are due to the presence of the detachment.

[2] Parsons: Pathology of the Eye, iv, 1166.

[3] Vail: An Inquiry into Results of the Established Treatment of Detachment of the Retina, and a New Theory, Ann. Ophth., 1913, xxii, 1.

[4] Fischer, M. H.: Glaucoma, Tr. Am. Acad. Ophth. and Otolaryngol., 1911.

We wish to record our belief that the clinical evidence is in favor of the choroid as an origin for the subretinal fluid. It may be asked that if the choroidal fluid filters into the subretinal space, why should it not also filter into the suprachoroidal space, and that is exactly what it does. As long ago as 1830, William Mackenzie in his treatise on Diseases of the Eye, said: "It has been ascertained by dissection that a watery fluid is sometimes present between the sclerotica and the choroid." This fact appears somewhat to have been lost sight of by later writers, as is perhaps natural, considering the fact that the condition cannot be discovered with the ophthalmoscope, and the ordinary puncture operations have simply allowed the fluid to escape without giving any light as to the true situation of the fluid. In trephining the sclera, it is in many instances found that a gush of fluid escapes before the choroid is punctured. The histologic examination of enucleated eyes for simple detachment of the retina is naturally rare. It will usually, however, be found that in the process of hardening, the anatomy of the detachment as observed during life is entirely obliterated. This is especially apt to occur in recent detachments before shrinkage and degeneration of the retina have occurred, and it is just in these cases in which such an examination would be of most value. We have not been able to find, in the limited number of cases examined, any definite adhesions, and definite localizations of the detachment by adhesion between the retina and choroid, nor any suggestions as to the origin or amount of the fluid.

Kuemmel[5] gives a very interesting account of the histologic examination of an enucleated eye with retinal detachment. He deduces some interesting theories, which to a certain extent harmonize with Vail's ideas, but the patient presented at the time of the enucleation a sharp atack of secondary glaucoma. Moreover, the fact that the process was an old one to a certain extent introduces elements which must be taken into consideration. He found inflammatory changes of a proliferating character in the iris, ciliary body, and choroid, and considers that these various changes are at the bottom of the choroidal effusion which leads to detachment. He further says:

> On account of these changes in the choroid and the ciliary body, disturbances must arise in the vitreous body, which, although it cannot be shown that they lead to disturbance of the fibrillae in an atrophic sense, still cause abnormal connections of this body with the surface of the retina, as is shown in the specimen. This is especially conspicuous in the anterior portion. On account of these unequal connections at the juncture of these two structures, there must arise differences in the tension, which must remain latent as long as the retina is connected.

He further argues that given a diminution of tension of the vitreous there must be a heightened tension in the choroid, which is made apparent by the increased blood supply. (If this principle were true, detachment of the retina should follow more frequently attacks of choroiditis, especially when accompanied by diminished tension.) Thus, a decrease of tension arises from the direction of the choroid to the vitreous body. He further says:

> We may accordingly assume that the retinal detachment arises by virtue of pressure from behind, due to the retroretinal transudate, as well as by traction on the part of the vitreous body from the opposite side.

Taking all of this into consideration, it seems to us that in the present state of our knowledge, we are not justified in assuming anything more than that retinal detachment occurs as the result of a lymphatic derangement leading to exudation from the choroidal vessels. It has been argued that in the cases of detachment following a blow, the degenerative condition predisposing to the detachment were already existent. This may be perfectly true, but, on the other hand, the manner in which traumatic detachment forms seems directly to support the theory of a choroidal effusion and directly to controvert the theory of vitreous traction. Traumatic detachments show at least that detachment can occur without participation of the vitreous body. It seems somewhat unreasonable to presuppose choroidal disease in traumatic detachments, for, if such were the case, we should have evidences of choroidal disease followed by later detachments in the fellow eye, which clinically do not occur. Cases of traumatic detachment have been observed for years, in which no detachment occurred in the fellow eye. This would not be the case if a degenerative uveal process were at the bottom of the detachment, for it is hardly conceivable that such a process as has been supposed to exist could occur in one eye alone. The clinical course of traumatic detachments also tends to support the idea that the secondary degenerations are due to the presence of the detachment. For secondary degenerations, uveitis, cataract, etc., occur in traumatic detachments just as they do in the idiopathic detachments. In myopia the question is a much more complicated one. It cannot be denied that the structure of the retina makes it less extensible on account of its rich connective tissue supporting the framework. And yet, as Schöbl has pointed out, if detachment was due solely to the lack of extensibility of the retina, it would occur invariably at the posterior pole. It seems probable, therefore, that the elongation of the myopic eye is merely a predisposing factor and that the exudation from the choroid takes place in these cases in somewhat the same manner as in the idiopathic and traumatic ones. It must, of course, be clearly understood that the class of cases in which disease of the choroid, or ciliary body, or both, lead to floating opacities in the vitreous, diminished tension, etc., that the detachment is apt to occur as a degenerative symptom from the general lymphatic disturbance, from the pulling of old organized exudates, etc.

---

[5] Kuemmel: Ann. Ophth., 1913, xxii, 437.

These cases, while bearing certain points of similarity, are clearly to be placed in an entirely different category from the ordinary idiopathic detachment. In other words, a clear distinction should be made between the cases in which the inflammatory symptoms antedate the detachment and those in which the detachment antedates the inflammatory symptoms.

It seems to us that we are justified in the two following assumptions: First, the presence of the detachment in itself leads to lymphatic disturbances and further complications of a degenerative nature. Second, the evidence on all sides, so far as it goes, is in favor of some operative procedure which withdraws the subretinal and suprachoroidal fluid. In the past when simple sclerotomy has been done and the fluid evacuated, it has been the rule to find a marked improvement in an attempt, however feeble, at reattachment. To be sure, when patients are allowed to get out of bed, the retina promptly redetaches, but this may be due to other factors. It seems probable to us that the fluid has not, in these cases, been removed completely enough to allow the retina to assume its normal position. The vision usually has improved, however, and the conditions have been promising for a time, and this has not been the case with any other means of treatment in our hands. With pilocarpin sweats, and rest in bed—in other words, a drastic elimination treatment—the fluid has at times undergone partial resorption, but this has never in our experience led to more than temporary relief, and has the serious objection of being greatly depressant, so that it has been abandoned by us, as by most surgeons within our knowledge. Good results have been reported by various surgical measures from time to time, but in all of these, puncture of the sclera occupies an important place, and he would indeed be venturesome who asserted that the scleral puncture was not the main, or perhaps the only cause of the improvement secured. Casey Wood[6] says:

> Scleral puncture seems to have held its own to the present time, and alone, or in conjunction with other forms of treatment, is practiced more frequently in detached retina than most of the surgical procedures about to be mentioned. Cures following its performance are not uncommon and when practiced within proper scleral areas, it is practically devoid of danger.

He also says (page 1356):

> Quite a number of brilliant and permanent cures have followed persistent treatment and a repetition of operations, in spite of these relapses. . . . No surgical intervention should be undertaken unless all parties to it are willing to have the patient submit to repeated operations as long as there is a chance of recovery. Deutschmann, for example, has finally succeeded in several cases of relapse, after operating a dozen times or more.

Acting on the foregoing ideas, we have endeavored to secure permanent drainage by means of a trephine opening in the sclera, through which the subretinal fluid could be completely removed by aspiration with a small syringe. This aspiration could be repeated several times, if necessary.

Trephining for detachment has also been done by Walter R. Parker,[7] and probably by others, with good results; but the incision of the choroid heretofore practiced seems likely to lead to reaction and vitreous hemorrhage, so that aspiration has been substituted.

It is a well known fact that the subretinal fluid in detachment tends to gravitate to the lower part of the globe. There are several points of doubt in connection with this phase of the subject, but it is probable that detachment is not a purely local process and that where several detachments occur, their shape is determined by more or less imperfect adhesions between the retina and choroid, and that the entire area beneath the retina is to a certain extent in communication. Frequently a detachment in the upper part of the field will subside, leaving the retina over the site of the old detachment apparently reattached, and the fluid will gravitate to the most dependent position—the lower part of the eyeball. It seems wiser, therefore, to select for the site of operation the most dependent position possible, which is within the area of the detachment, and this will usually be a point about equidistant from the external and the inferior recti muscles, or a corresponding point between the internal and the inferior recti. The trephine opening should be made as far back as possible, and this is naturally more easily accomplished when the operation can be done between the external and inferior recti muscles than on the opposite side. No speculum is necessary. An assistant inserts a strabismus hook and retracts the lower lid and tissues of the external canthus. A curved incision is made through the conjunctiva with the convexity in the direction of the cornea, and the tissues are taken up down to the sclera. It is wiser at this juncture to put in a single silk suture at the summit of the flap, as otherwise the capsular tissue underneath the flap is apt to be rolled up and the ultimate flap will then be composed of nothing but conjunctiva, leaving more or less thickening and adhesions in the episcleral tissues, which tends to seal up the trephine opening. The entire thickness of tissue is taken up, down as far as the sclera, and dissected well back. The assistant then holds this flap back by means of the suture. The trephine opening is then made with a 2 or 3 mm. trephine. We are of the opinion that a larger opening is better, but experience is necessary to decide this point. On the removal of the trephine button, there is in many instances a gush of serous fluid from the suprachoroidal space. Examination of the eye usually shows considerable subsidence of the detachment after this fluid has escaped. The flap is then sutured into place and the eye bandaged and the patient put to bed. It goes without saying that the pupil should always be well dilated with atropin before the operation, both for purposes of examining and to keep the eye as free as possible from the tendency to inflammation. There is usually very slight reaction after the trephine operation. In a week or ten days later, the patient is put on the operating table and the needle of a small aspirating syringe is inserted into the subretinal space through the conjunctiva and choroid. The subretinal fluid is then forcibly aspirated, after which the patient is put to bed for a day or two, as circumstances require. The aspiration operation is followed by practically no reaction and can be repeated as long as the trephine opening remains free. In this connection, it is very important to have the flap properly made, as, if capsular tags are allowed to roll up under the flap, it is difficult to see where the opening lies and to enter the needle requires a great deal of stabbing around in the dark. If the conjunctival flap heals properly, the trephine opening shows as a small dark spot, which is easily identified. It does not show, however, so plainly as a trephine opening at the corneal margin, on account of the greater thickness of the conjunctival and capsular tissues in the flap. In some of the cases presented, a single aspiration was sufficient, but in others there was reaccumulation of fluid and the aspiration had to be repeated.

[6] Wood, Casey: Ophthalmic Operations, Chicago, Cleveland Press, 1911, ii, 1,360.

[7] Parker, Walter R.: Tr. Am. Ophth. Soc., 1914, p. 661.

It is evident that this procedure, in order to be successful, must be undertaken before the detachment is old enough to have undergone degenerative changes. A shrunken and contracted retina will, of course, not fall back into position, even if the fluid be withdrawn; nor is there any probability of success if inflammatory changes have set in, especially if the intra-ocular tension has fallen much below the normal. It is, also, hardly conceivable that the operation would be successful in high degrees of myopia, although on this point experience is lacking. The rationale of the operation, however, is in recent traumatic or spontaneous detachments where there seems a likelihood that the fluid accumulation is acting to keep up the condition.

REPORT OF CASES

CASE 1.[8]—B., a bookkeeper, aged 21. Family history negative. Sept. 22, 1914, he noticed blurring in the sight of the left eye. September 26 he visited a hospital but did not receive any treatment. He visited Dr. Curtin, October 1. There was no history of trauma. Urinalysis, Wassermann and von Pirquet all negative. Blood pressure 128. R. V., 20/40. L. V., hand movements in the lower and outer parts of the field. There was low myopia in each eye. A large detachment of the lower and outer part of the retina was found in the left eye. The retina was bluish-white and thrown into folds with loss of the light reflex of the vessels. The disk was still visible, but the detachment extended nearly to the macular region. There were a few floating vitreous opacities. He entered the Manhattan Eye, Ear and Throat Hospital, October 2, and was put to bed, pupil dilated with atropin and pressure bandage applied. Pilocarpin sweats were given every second day. October 12, no improvement being apparent, he was operated on by Dr. Curtin. Under cocain, a button of sclera, 2 mm. in diameter, was removed by the trephine from under a conjunctiva flap over the site of the detachment and as far back as possible between the inferior and external recti muscles. The choroid and retina were not punctured. The conjunctival flap was united by two silk sutures and a moderate pressure bandage applied. He continued in bed until October 22, having had but a moderate amount of reaction. On that date, a medium-sized aspirating syringe was pushed through the conjunctiva and scleral opening and choroid, and 25 minims of serous fluid withdrawn. This subsequently was found to resemble serous fluids in general. The fundus of the eye was immediately examined and the retina was seen to have fallen back into place. The patient was returned to bed and kept there until November 4. The vision on the following day was found to be "fingers at 8 feet." There was hardly any reaction, and the eye did not even redden. The vision gradually increased. He was allowed to get out of bed November 4. November 16 his vision and retraction were as follows: Right, 20/40 : 20/20 with a minus 1.50 cyl. axis 180 degrees; left, 20/70 + : 20/40 with a minus 1.00 cyl. axis 180 degrees.

December 22, vision in the left eye was 20/30. January 27, the left lens was increased to — 1.50 cyl., which gave him vision of 20/20. At the time of writing (March 15, 1915) his vision has remained 20/20 with his correction. Externally the eye is normal in appearance, except that at the lower and outer aspect of the globe can be seen a small bluish circle, the site of the trephine opening. The conjunctiva is slightly chemotic over this area.

Ophthalmoscopically, the retina is entirely attached except in a small area in the lower and outer field, which is probably at the site of the scleral trephining. This can only be seen with the pupil dilated and the patient looking markedly downward. Small white striae can be seen in the retina in the lower macular region and lower parts of the fundus, the former site of the detachment.

There are a few floating opacities in the vitreous that can still be seen. The patient no longer observes flashes of light or disturbances in the eyes or contour of objects and readily reads the test type, in contradistinction to his earlier tests when he would deliberate and study the letters for a short time before pronouncing them.

As his record shows, his vision has gradually increased so that today it is slightly better than normal.

The patient has changed his occupation to that of salesman. He returned to work Nov. 23, 1914, and travels around the city on the various surface, subway and elevated trains, and has taken no special precautions regarding jarring, and his eye, to date, shows no indication of any redetachment.

CASE 2.—J. W., a clerk, aged 23. Family history good. He smokes and drinks moderately. Three years ago he had pneumonia. Nov. 13, 1914, he was accidently struck in the right eye by a companion. Immediately following it pained for about one-half hour. Two weeks later he noticed when going out into strong sunlight a black spot appeared before his vision. He tested the eye and noticed that day by day the vision was failing, so that by December 8, he could see very little. On this date he came to the hospital. Vision in the left eye was 20/20. In the right eye "fingers at 1 foot" in the upper field. Examination showed a large detachment in the upper and outer part of the fundus, with general edema of the entire retina, and with some slight detachment apparent below the macula. Three diameters to the nasal side of the disk, there was a patch of dark pigment, and through the center of this a whitish mass projected forward into the vitreous. Above this at the outer side could be seen grayish-white striae extending upward and inward, and down from this mass, which looked like a rather atypical form of retinitis proliferans, the retina was bluish-white and detached. The patient entered the hospital on December 12 and a scleral trephine was done by Dr. Thomson, between the inferior and external recti. December 22, the subretinal fluid was aspirated. At first there was no change in the vision, but after the aspiration the vision had increased to 20/200, and the field was enlarged. Twenty minims of fluid had been withdrawn. This was found to have the usual characteristics of serous fluids. He was kept in bed for a week, at which time the vision equalled 20/70 in a field extending to 50 degrees laterally on each side, 30 degrees above and 70 below. At present the retina is entirely reattached in the upper field. There is still a detachment below the mass. The vitreous is slightly hazy. The mass is apparently unchanged, except that at the apex can be seen a few small vessels, and several dark striae run to the posterior surface of the lens. Externally the eye appears normal. The pupil reacts to light, and the trephine opening can be seen through a slightly chemotic conjunctiva. Urinalysis, Wassermann and von Pirquet negative.

CASE 3.—J. Z., a baker, aged 42. About the middle of October he noticed the sight of the right eye was becoming dim. He did nothing until December 16, when the vision was so badly reduced that he could not count fingers. December 23 he came to the hospital. There were two large detachments occupying the entire lower half of the right fundus. The disk was partly obscured. The form field could not be made out, and the light field was obscure in the larger portion. The patient gave a history of chronic rheumatism, although his health had been good for the past two years. The tension was reduced in the right eye. Vision of the left eye was 20/20 —. Urinalysis, von Pirquet and Wassermann negative. The patient was put to bed with atropin and a pressure bandage. On January 5, Dr. Curtin did a trephine operation, making a 2 mm. opening between the external and inferior recti muscles. Very little fluid escaped when the trephine button was removed, so the needle of the aspirating syringe was entered through the choroid, and 20 minims of serous fluid was withdrawn. The following day the patient could count "fingers at 3 feet." His vision increased so that at the end of a week it was 20/200, and the field contracted only in the upper half. He was kept in bed a week, but after he got up the detachment increased and vision failed gradually to "fingers at 4 feet." January 16, 15 minims of fluid were again aspirated, without, however, securing a reattachment of the retina. February 4, 15 minims more of fluid were aspirated. Following this aspiration, the reaction was more severe and he was put to bed and iced cloths applied to the eye. A week later the ophthalmoscope showed that a hemorrhage into the vitreous had occurred and vision was reduced to hand movements. At present the eye is white. The trephine opening can be seen as a small bluish spot. The tension is normal. The vitreous is so clouded that details of the fundus cannot be seen. The field for light perception is good.

---

[8] The following case was reported in the Ophthalmic Record, February, 1915.

Besides these cases, about ten similar operations were done in old cases of detachment, most of which had lasted a year or more. It has not been thought worth while to report these cases in detail, nor was it to be expected that any marked success would be attained. However, a certain number of facts of interest have been determined.

The reaction seems entirely confined to the trephine operation and is very slight. The aspiration seems to cause no perceptible reaction, even when repeated at fairly frequent intervals, unless, as in one of the cases reported, a hemorrhage occurs following its performance. This accident seems rather unlikely to occur, however, and has not been noted in any other case.

The amount of fluid withdrawn seems to have very little influence on the amount of the reaction. In one case, 40 minims were withdrawn, and the following day the eye was hardly even flushed.

We have come to no very definite conclusion as to whether it is better to aspirate immediately or when the reaction has subsided. Where suprachoroidal fluid exists in any amount, which has been in more than half of the cases, it is perhaps as well to postpone the aspiration, but if when the trephine button has been removed no fluid comes away, showing that the entire amount is beneath the retina, it is probably as well to aspirate then and there. This course does not greatly increase the external redness of the eye, but it cannot be doubted that the lymphatic disturbance is greater when trephining and aspiration are done at the same sitting, and this point should, of course, receive due consideration.

In several of the cases, especially when the flap was not carefully dissected up in its entirety—that is to say, so as to include the conjunctiva and capsule of Tenon in one flap—the trephine opening was later found partially occluded and it was difficult to introduce the aspirating needle. In most cases, however, the opening can usually be found and the introduction of the needle is attended with but little difficulty. In conclusion, it must be emphasized that this procedure gives promise of results only in recent cases, when the light perception in the retina is still retained; when no inflammatory products are thrown out into the vitreous; when the tension is not materially reduced; and when a high degree of myopia does not exist.

A Favorable Death Rate.—Neither the state nor any of its municipalities should regard its death rate as favorable when about 50 per cent. of the deaths, according to present-day knowledge are preventable.—Rep. Pub. Health Com. Minnesota Pub. Health Assn.

SCLEROTREPHINE OPERATION FOR DETACHED RETINA

CLINICAL REPORT OF ELEVEN CASES *

WALTER R. PARKER, B.S., M.D.
DETROIT

After observing the results obtained by Colonel Elliot in treating glaucoma by his corneoscleral trephining operation, it seemed possible that scleral trephining might be utilized in the treatment of detachment of the retina.

May 19, 1913, the first operation was performed, and since that time fifteen operations have been made on eleven patients, all of which are included in this report.

Two operations were performed in Case 7, also in Case 8, and three in Case 9. In Cases 1 and 2, the sclera was trephined over the site of the detachment without incising the choroid and retina. In all the other cases, in addition to trephining the sclera, an incision with a cataract knife was made in the choroid or the choroid and retina, and the subretinal fluid, and, in most instances, a few drops of vitreous, were allowed to escape.

TECHNIC

The operation may be described in detail as follows: The conjunctiva and the underlying tissues are grasped with a pair of forceps at a point corresponding as nearly as possible to the lowest portion of the detached retina, and by a single cut with a pair of scissors, a triangular incision is made down to the sclera. Before losing the grip with the forceps a suture is passed through the apex of the triangular flap. This procedure not only enables the operator to include in the suture all the tissue incised, but affords a ready means of retraction. The suture can be held by an assistant, or a pair of artery forceps can be applied and so placed that the proper pull will be exerted to give a good view of the field of operation. After the sclera has been bared, a 2 mm. trephine opening is made, and the choroid, or choroid and retina incised in such a manner as to avoid injuring the large vessels. The free escape of the subretinal fluid may be followed by a few drops of vitreous. The needle on the suture previously passed through the apex of the flap is now passed through the subconjunctival tissues and the conjunctiva and the wound closed. A single suture on each side completes the operation. The after-treatment consists of rest in bed for ten days in such a position as to favor the replacement of the retina.

The cases are all from my service in the ophthalmic clinic of the University of Michigan, and are in no way selected.

A brief outline of the history of each case is as follows:

REPORT OF CASES

Case 1.—*History.*—The patient, N. N., female, aged 50, presented herself for examination in the ophthalmic clinic of the University of Michigan, May 12, 1913, complaining of failing vision for a year, and almost blindness for eight months.

Family history negative. Personal history, uterine prolapse and poor general health.

Examination.—Vision, right eye, 5/30; left eye, l. p., with poor projection. Tension normal in both eyes. Pupillary reflexes active to direct in right eye, and to consensual in left eye; feeble to direct in left eye and to consensual in right. Accommodative reflexes normal in both eyes. Transillumination negative.

---

* Read before the Section on Ophthalmology at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

* On account of lack of space this paper has been abbreviated for The Journal. It will appear in full in the Transactions of the Section and in the author's reprints.

Ophthalmoscopic Examination.—Right eye: Beginning nuclear cataract; otherwise no gross lesion. Left eye: Media clear, retina detached from opposite 2, around below and up to 10, upper border of detachment being on line of junction of upper and middle third of disk. Detached portion of retina fluctuates, and the vessels can be easily traced over it.

Visual Field (Fig. 1): Candle field, taken at distance of 1 meter.

Treatment.—May 19, 1913, trephine operation for detachment of retina performed. Stephenson's trephine used; 2 mm. disk removed. Choroid not incised. Almost no reaction followed. On the eighth day patient thought sight a little better, but the gain, if present, did not hold.

June 7. No improvement seen with ophthalmoscope. Vision l. p.

June 14, 1914. Patient returns with vision l. p. and loss of projection.

Result: Failure.

DISCUSSION

This case presented an uncomplicated detachment of the retina, and except for the extent of the detachment should have been favorable for operation. The absence of reaction was doubtless due to the fact that the choroid was not incised, thus making infiltration impossible.

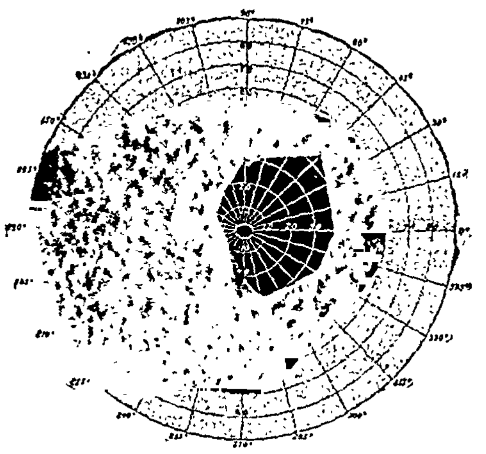

Fig. 1.—Case 1. Field before operation. May 13, 1913. Vision, light perception. Candle field. Left eye.

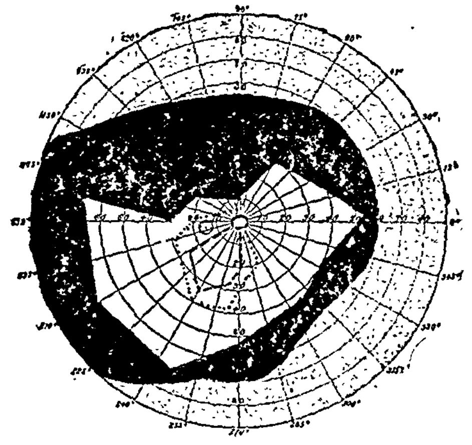

Fig. 2.—Case 2. Field before operation. Left eye. June 24, 1913. Vision, 2/60; 30 mm. object. In this and following figures solid line represents green, dotted line red, and dash line blue.

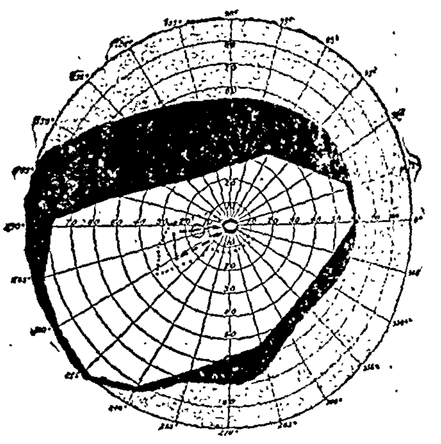

Fig. 3.—Case 2. Field after operation. Left eye. July 14, 1913. Vision, 2/60; 10 mm. object.

Case 2.—*History.*—E. T., male, aged 67, presented himself at the clinic June 23, 1913, complaining of cloud effect before the left eye coming on eight months previously. Vision now blurred; large floaters constantly present.

Family history negative. Personal history, hernia; gonorrhea thirty years ago. No history of trauma.

Examination.—Vision, right eye, 5/15; left eye, 2/60. External appearance of eye and conjunctiva normal. Pupillary reflexes active in both eyes. Tension normal. Transillumination negative. Wassermann negative.

Ophthalmoscopic Examination.—Right eye: Lenticular cortical opacities; many floating opacities in vitreous, both large and small, reticular and granular. Disk and retina edematous, foveal reflex faint; two corkscrew-like macular vessels; there were some slight atrophic changes in the choriocapillaris.

Left eye: Beginning lenticular cortical opacity; many floating opacities of vitreous, fine granular and reticular in character. Inferiorly, retina detached; nasally, detachment extends from a level above the disk slightly downward, following lower border of disk, thence temporally and upward at an angle of 45 degrees.

Diagnosis.—Right eye, incipient senile cataract. Left eye, incipient senile cataract and extensive detachment of retina, involving all except superior quadrant.

Visual Field. Field in left eye (Fig. 2) showed nearly all upper half gone, and peripheral contraction except down. Only small area below macula shows color perception.

Medical Examination.—Wassermann negative. Arterial sclerosis; blood pressure 166. Urine shows a few hyaline casts; otherwise negative.

Treatment.—July 3, 1913, trephine operation for detachment of the retina; choroid not incised.

July 11: No reaction followed the operation. No improvement in vision.

Ophthalmoscopic examination showed marked improvement in extent of detachment, the upper portion being two disk diameters below disk margin.

Form Field (Fig. 3): Slight improvement. Vision 2/60.

Result: Improvement in field. Vision unchanged.

DISCUSSION

This case presented a detachment of unknown origin of eight months' duration, complicated by degeneration of the vitreous. The choroid was not incised and no reaction followed the operation. While the vision remained the same, the visual field taken with a 10 mm. object was larger than the original one taken with a 30 mm. object.

Case 3.—*History.*—H. H.,[1] male, aged 46, came to the ophthalmic clinic of the University of Michigan September 23, 1913, complaining of a progressive loss of vision in the left eye, which began one year previously as a crescent-shaped shadow, convexity downward, in the upper part of the visual field. There had been no trauma, no pain, no photophobia.

Family and personal histories: Negative.

Examination.—Vision, right eye, 6/15; left eye, 4/60. Pupillary reflexes normal. Tension normal. No external pathology in either eye.

Ophthalmoscopic Examination.—Right eye: Some fine and reticular vitreous opacities; otherwise media clear. Physiologic depression present, lamina cribrosa showing faintly. Disk slightly edematous. Arterial reflex stripe most conspicuous in macular vessels. Arteriovenous compression with some distal dilation; foveal reflex present.

Left eye: Innumerable fine dust-like opacities in vitreous; few larger and rounded, all of same type, but variable in size. Disk hyperemic; physiologic depression present; lamina cribrosa faintly seen; scleral and choroidal rings blurred. Arterial reflex stripe conspicuous. Silver wire macular artery nearly developed just above fovea. Retina about disk hyperemic and swollen, whole retina edematous. Below fovea, retina is folded and floats free from choroid. Detachment extends from about one disk diameter below disk downward and outward as far as can be seen.

---

[1] Published in Archives of Ophthalmology, September, 1914.

Visual Field. Field (Fig. 4) showed marked contraction in superior nasal portion.

Medical examination negative.

Operation.—Oct. 16, 1913, scleral trephining operation performed.

Postoperative History.—During the night the patient complained of some pain and the conjunctiva became very much congested, swollen and edematous, the chemotic conjunctiva covering the limbus completely. The eye was iced for twenty-four hours.

After five days the swelling and chemosis were greatly reduced except at the site of operation, which showed bulging for five days longer, at the end of which time the eye was quiet and the stitches were removed.

Fundus examination made three weeks after operation showed many minute granular opacities in vitreous. Whole fundus slightly hyperemic; retina somewhat edematous. Arteriovenous compression present. Superior macular vessels showed silver wire characteristics. Very slight if any foveal reflex; macular region practically normal except slightly granular about the fovea. A glistening white spot with a bright annular whitish line nearly surrounding it was seen about three or four disk diameters temporally and about one disk diameter from the fovea. No area of detachment could be discovered, the retina being apparently completely reattached.

Three weeks after operation vision in left eye 6/15, and field for form and color nearly normal in extent.

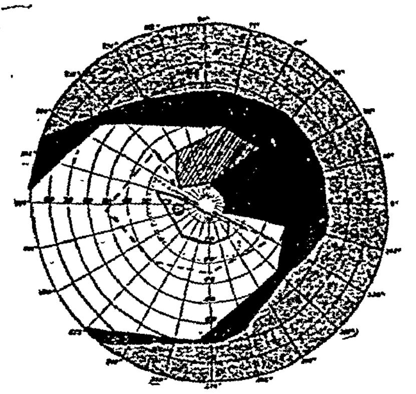

Fig. 4.—Case 3. Field before operation. Left eye. Sept. 23, 1913. Vision, 4/60; 10 mm. object.

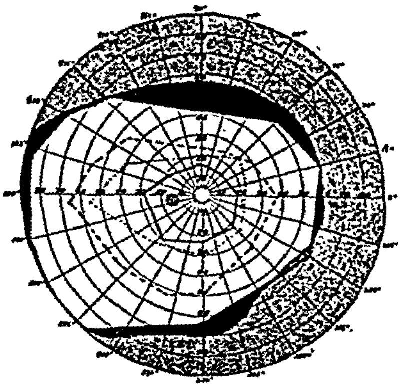

Fig. 5.—Case 3. Field after operation. Left eye. March 29, 1915. Vision, 5/7.5; 10 mm. object.

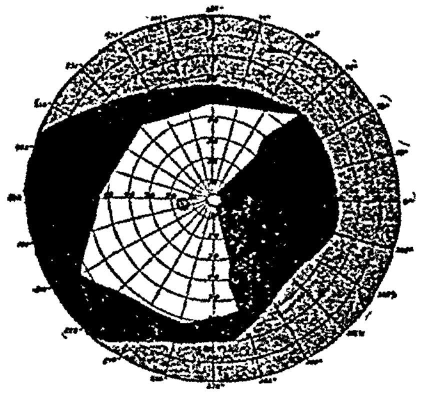

Fig. 6.—Case 4. Field before operation. Left eye. Oct. 28, 1913. Vision 1/120; candle light.

Refraction: Left eye + 0.50 sphere. Tension: Right eye, 20 mm. mercury; left eye, 20 mm. mercury.

The last observation, made seventeen months after time of operation, showed vision 6/7.5, tension 20 mm. mercury both eyes, and visual field nearly normal (Fig. 5).

Ophthalmoscopic Examination.—Same as three weeks after operation.

Result: Good after seventeen months.

DISCUSSION

The etiology in this case was unknown, although a well marked neuroretinitis was present, with many fine dust-like vitreous opacities. The detachment was of one year's duration and involved about the lower one-third of the retina. A marked reaction followed the operation and did not entirely disappear for ten days. Although there was an escape of a small amount of vitreous, no trace of an incision in the retina could be found. The vision improved from 4/60 to 6/7.5 pt. and the field to practically normal.

CASE 4.—*History.*—M. K., male, aged 62, entered the University Hospital, Oct. 15, 1913, with a history of having undergone an operation for cataract on the right eye seven years previously. On the third day a hemorrhage occurred, followed by an inflammation and loss of vision. The vision in the left eye has gradually diminished until on admission the patient was nearly blind.

Family History.—Father had cataracts in both eyes.

Personal History.—Negative.

Examination.—Vision, right eye nil, left 1/120; projection very poor. Tension, right eye, 8 mm.; left, 15 mm. Whole lens of left eye more or less granular and irregularly opaque. A well-marked iris shadow was present. Transillumination negative.

Oct. 16, 1913. Combined operation for cataract extraction. Moderate loss of fluid vitreous.

October 23. Pupil well dilated, coloboma free, eye quiet and in good condition.

Ophthalmoscopic Examination.—October 27. Left eye: Retina detached temporally and down; elevated 6 diopters; retinal vessels traced over detachment, which fluctuates with eye movements. Retinal vessels tortuous. Disk borders indistinct. Whole retina edematous.

Visual Field (Fig. 6): Large nasal and marked temporal contraction.

Nov. 21, 1913. Typical ophthalmoscopic picture of detachment of retina, including whole lower portion of globe. Transillumination negative.

November 24. Trephine operation for detachment of the retina opening in sclera, down and out. Choroid and retina incised with cataract knife after removal of scleral disk. Moderate amount of fluid escaped, followed by several drops of thin vitreous.

November 26. Slight reaction followed the operation; eye quiet.

Ophthalmoscopic Examination.—Detachment of retina more extensive.

March 29, 1914. Vision l. p. Candle field improved nasally; not changed temporally (Fig. 7).

The detachment in this case apparently followed the loss of fluid vitreous sustained at the time of operation for removal of cataract. The condition of the vitreous together with the rapid increase in the extent of the detachment from October 23 to November 21 made the case an unfavorable one for any operation.

CASE 5.—*History.*—M. B., female, aged 40, entered the hospital, Dec. 4, 1913, complaining of specks before right eye during past nine months, with progressive loss of vision. There had been no trauma, no pain or photophobia.

Family History.—Mother and one brother had cataracts.

Personal History.—Negative.

Examination.—Vision, right eye, fingers at 3 feet; left eye, 6/5. Pupillary reflexes normal; tension, right eye, 22 mm.; left eye, 24 mm. Transillumination negative.

Ophthalmoscopic Examination.—Right eye: Lens clear, many fine vitreous opacities, mostly posterior. Disk hyperemic, lower border blurred, elevated and continuous with detachment of retina. Localized area of proliferating retinitis just outside macula, with radiating folds and bands. Whole inferior half of retina detached and drawn into folds.

Left eye: Lens clear, floating opacities of vitreous, mostly long and thread-like; slight arteriovenous compression.

Visual Field (Fig. 8): Entire absence of right upper field, with marked peripheral contraction.

Medical examination, negative.

Operation.—Dec. 11, 1913, trephine operation for detachment; choroid and retina incised. December 15, marked chemosis, extending to fornix, followed operation.

December 25, eye quiet.

Ophthalmoscopic Examination.—Retina reattached, except immediately below macula and in extreme periphery. Fields (Fig. 9) show marked improvement, excepting large scotoma corresponding to area of proliferating retinitis. Vision, fingers 6 inches.

Result: Vision same. Marked improvement in fields.

DISCUSSION

The failure to improve the vision in this case could be accounted for by the nearly central proliferative changes in the retina.

Case 6.—*History.*—E. S., female, aged 36, entered the clinic Dec. 22, 1913, complaining of loss of vision in the right eye, especially below. First noticed four years ago when it was nearly as marked as at the present time.

Family history, negative.

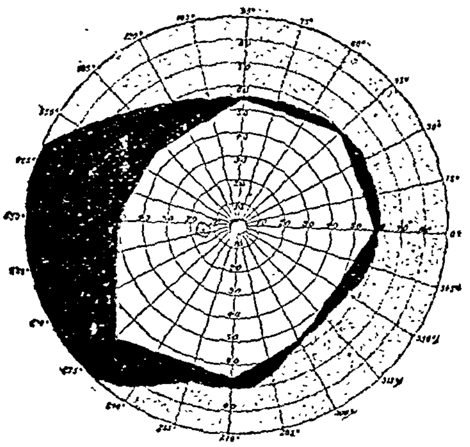

Fig. 7.—Case 4. Field after operation. Left eye. March 29, 1914. Vision, light perception. Candle field.

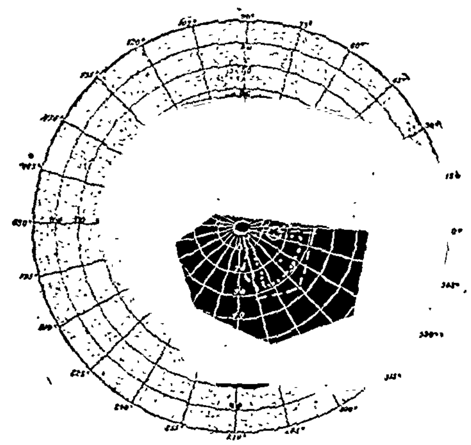

Fig. 8.—Case 5. Field before operation. Dec. 4, 1913. Vision, fingers at 3 feet; 10 mm. object.

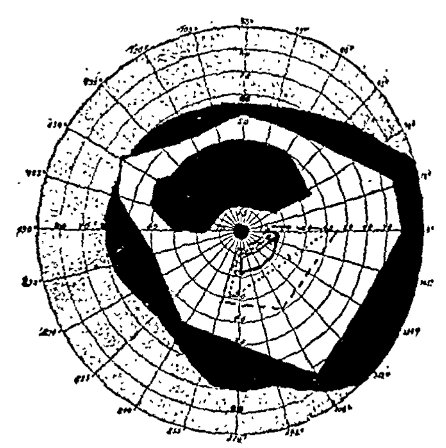

Fig. 9.—Case 5. Field after operation. Right eye. Vision, fingers at 6 inches; 10 mm. object. Dec. 22, 1913.

Personal History.—Struck in the right eye when aged 12.

Examination.—Vision, right eye, 1/60; left eye, 5/10. Pupillary reflexes normal. Tension, right eye, 16 mm.; left eye, 16 mm. Transillumination negative.

Ophthalmoscopic Examination.—Right eye: Media clear. Disk edematous. Arteries tortuous, arteriovenous compression present. Center of fovea shows cherry red spot surrounded by grayish ring which marks beginning of an area of elevation which extends downward and outward. Area of detachment retains nearly normal color and choroidal interspaces show temporally. Both choroid and retina appear to be detached in lower outer quadrant. Left eye: No gross lesion.

Visual Field (Fig. 10): Field taken with 10 mm. object shows marked contraction for form up and nasally, and slight contraction temporally. Color fields present only in outer lower quadrant.

April 2, 1914. Admitted to hospital. On ophthalmoscopic examination the findings were confirmed.

Operation.—April 6, 1914, trephine operation for detachment of retina performed. Choroid and retina incised. The escape of a moderate amount of fluid was followed by some loss of vitreous. Slight edema of conjunctiva followed the operation.

Postoperative History.—April 8, eye quiet. Pupil well dilated.

Ophthalmoscopic Examination.—Area of detachment somewhat diminished. Whole retina more edematous. Detached area grayish in color and distinctly tesselated. Choroidal interspaces clearly seen through retina, and elevated only 3 or 4 diopters.

Visual Field (Fig. 11): Visual fields taken April 23, 1914, showed nearly complete restoration of form fields and very marked increase in size of color field. Vision, O. D. 5/60, O. S. 5/4.

DISCUSSION

The marked improvement in the visual fields in a case of detached retina of four years' duration is of special interest.

Case 7.—*History.*—J. S., male, aged 64, entered hospital, May 8, 1914, complaining of loss of vision in both eyes for the past three years, following a kick in the face by a horse.

Family history, negative.

Personal History.—No constitutional diseases.

Examination.—Vision, right eye, fingers at 3 feet; left eye, l. p. Tension normal. Transillumination negative. Right eye, well advanced senile cataract.

Ophthalmoscopic Examination.—Left eye, large number of floating opacities in vitreous. Disk outline obscured at nasal border by fold of detached retina. Arteries small, veins tortuous, marked arteriovenous compression. Retina detached throughout with exception of upper outer quadrant.

Visual Field (Fig. 12): Candle field showed marked contraction up and in.

Operation.—May 15, 1913, trephine operation for detachment of retina; opening made down and out 12 mm. from limbus. Choroid and retina incised. On second day following operation, eye quiet. Fundus could be seen with S + 1.00 diopter lens. On fourth day, detachment had reappeared and could be seen plainly with S + 7.00 diopter lens. Candle field, taken on fifteenth day after operation, nearly identical with one shown in Figure 12.

May 29, trephine operation repeated; a moderate amount of fluid escaped.

June 12. Marked reaction followed operation.

Ophthalmoscopic Examination.—Many fine vitreous opacities. Disk blurred and edematous. Retina no longer overlaps disk border, whole detachment appearing less in amount. Form field, 10 mm. object. Figure 13 shows marked increase over candle field. Vision, fingers at 3 feet.

Result: Fields improved. Vision unchanged.

DISCUSSION

The condition of the vitreous alone could account for the failure to improve the vision in this case. The final field, taken with a 10 mm. object shows a decided improvement over the first, taken with candle.

Case 8.—*History.*—D. D., male, aged 28, presented himself at the hospital May 19, 1914, complaining of rapid failure of vision in the right eye for one year. Now nearly blind. Thirteen years previously the patient was struck in left eye, which resulted in immediate loss of vision in that eye. Later a cataract developed which was removed five years prior to admission without restoration of sight.

Family history, negative.

Personal History.—Treated for syphilis.

Examination.—Vision, right eye, l. p.; left eye, blind. Projection in right eye good. Tension normal. Pupillary reflexes: Right eye reacts moderately to direct, slightly to consensual stimulation. Left reacts to consensual only.

Ophthalmoscopic Examination.—Right eye: Beginning cortical cataract. Many vitreous opacities. Disk obscured, located only by convergence of central vessels. Retina detached throughout lower half. Detached portion of retina in folds with contraction bands present, both nasally and temporally. In places, detached portion of retina nearly normal in color, giving appearance of an associated detachment of choroid. Left eye: Lens absent. Total detachment of retina.

Visual Fields: Right eye (Fig. 14), form field, taken with a 20 mm. object, showed absence of nasal field with marked peripheral contraction temporally.

Medical Examination.—Positive Wassermann. Leukoplakia and adenopathy. Given salvarsan.

Operation.—June 1, 1914, trephine operation for detachment of retina performed. Opening in sclera made down and out about 12 mm. from limbus; choroid incised. No escape of fluid followed removal of scleral button, but a large amount of amber colored fluid followed incision of choroid.

Postoperative History.—Considerable reaction followed operation, but no complications. Twenty-eight days after operation the field (Fig. 15) taken with a 20 mm. opening, was more contracted than before operation.

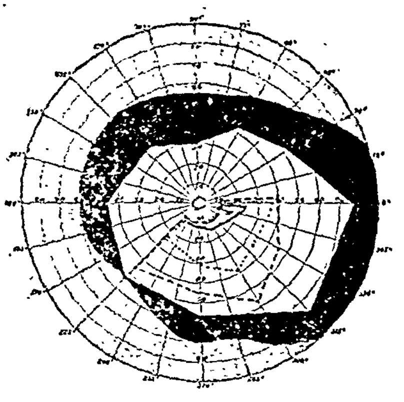

Fig. 10.—Case 6. Field before operation. Right eye. April 23, 1914. Vision, 5/60; 10 mm. object.

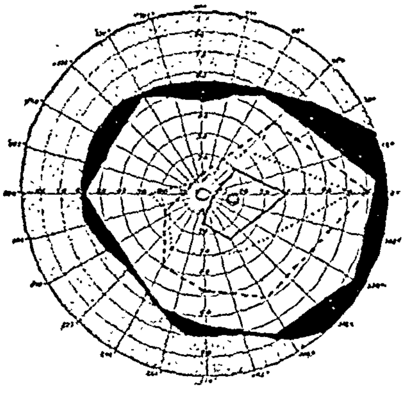

Fig. 11.—Case 6. Field after operation. Right eye. Dec. 12, 1913. Vision, 1/60; 10 mm. object.

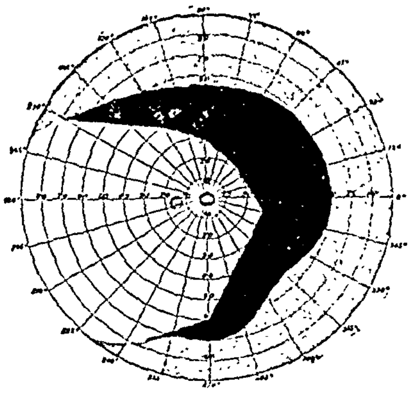

Fig. 12.—Case 7. Field before operation. Left eye. May 14, 1913. Vision, light perception. Candle field.

Nov. 12, 1914. Vision, l. p. Lens cataractous. Candle field (Fig. 16) about the same as field taken previously with 20 mm. object.

November 20. Trephine operation repeated. Marked reaction followed, but cleared up without treatment, leaving eye quiet after ten days, with the exception of some chemosis at site of trephine opening. Filtration good.

Dec. 20, 1914. Eye quiet. Vision, barely l. p. Field could not be taken, due to opacity in lens.

Result: Failure.

DISCUSSION

The condition of the vitreous, the presence of organized bands in the retina, together with the general condition of the patient, made this a most unfavorable case for operation. Apparently the formation of the cyclitic cataract was hastened by the operation.

Case 9.—*History.*—L. W., male, aged 14, presented himself at the clinic, May 19, 1914, with a history of loss of vision in left eye following blow on head three months previously. Was struck in same eye by fragment from dynamite cap three years previously.

Examination.—Vision, right eye, 5/5; left eye, l. p.; divergent, 20 degrees. Tension both eyes normal. Reflexes present, but restricted in left eye.

Roentgen-ray examination shows presence of foreign body posterior to sclera opposite superior temporal quadrant. Transillumination, negative.

Ophthalmoscopic Examination.—Right eye, normal; left, a few fine radiating lenticular opacities present. Two long organized bands (like retinal striae in appearance) hang from superior portion of vitreous; exact source not made out. Below disk several bands running downward in vitreous, similar to those seen above. Disk blurred, rings absent except down and out. Arteries contracted, veins engorged and tortuous. Central area blurred, obscuring all details. Down and nasally the retina and choroid detached 8 to 10 diopters, while down and temporally retina only detached.

Visual Fields (Fig. 17): Right eye normal. Left eye, marked contraction taken with 50 mm. object (20 mm. object not visible).

Medical history, negative.

Operation.—May 25, 1914, trephine operation for detachment of retina performed. Opening in sclera made directly down. Moderate outflow of clear fluid followed incision in choroid. Very slight reaction followed operation.

Postoperative History.—Thirteen days after operation, vision was 1/60. Field of vision (Fig. 18) much improved. Taken with 20 mm. object.

Ophthalmoscopic Examination.—Made sixteen days after operation. White bands observed at first examination unaffected. Temporally many vertical wrinkles and folds in retina. Along inferior nasal vein a striation apparent, not visible before operation. Detachment appreciably lessened below, especially temporally. Four weeks after operation detachment had same appearance as at last examination. Lamina cribrosa could be seen, however, and vision was 2/60.

July 3, 1914, thirty-nine days after operation, vision, 2/60. Field (Fig. 19) taken with 20 mm. object, more contracted above.

July 6, 1914, trephine operation repeated, opening being made down and out. Small amount of fluid escaped after incision in choroid.

July 10, 1914. Chemosis was slight.

July 25. Vision, 4/60. Field (Fig. 20) taken with 10 mm. object, much improved up and nasally.

Aug. 10, 1914. Vision, 5/60. Field (Fig. 21) taken with 10 mm. object, more contracted nasally, holding temporally.

November 8. Vision, 2/60. Detachment more marked below.

November 9. Trephine operation repeated second time. Sclera opened down and slightly cut. Moderate amount of fluid escaped after incision in choroid.

Dec. 1, 1914. Vision, 3/60. Field (Fig. 22) taken with 10 mm. object; marked contraction; somewhat smaller than first field taken with 50 mm. object. Eye quiet.

Ophthalmoscopic Examination.—Appearance same as after first operation.

Result: Slight improvement.

DISCUSSION

The organized bands in vitreous and retina made this case unfavorable from the first. The temporary improvement following the first operation led to the hope that some permanent gain might be made. The final improvement, however, was very slight.

Case 10.—*History.*—J. S., female, aged 21, presented herself at the clinic, Nov. 11, 1914, complaining of sudden total loss of vision in right eye nine days previously. After four days she could distinguish light; now sees objects. No trauma. No pain.

Examination.—Vision, right eye, fingers at 4 feet; O. S. 1/60, W. C. 6/15. Tension both eyes, normal. Pupillary reflexes: right eye, almost absent to direct, active to consensual. Left eye, active to direct, nearly absent to consensual. Both react in accommodation.

Ophthalmoscopic Examination.—Right eye: Many fine vitreous opacities. Disk indistinct, seen best with S — 12.00 D. Whole lower portion of retina detached, most elevated immediately below macular region seen with S + 5.00 D lens. Superiorly, fundus somewhat tesselated. Left eye: Media clear, disk vertically oval, seen best with S — 12.00 D. Myopic crescent along lower temporal border with myopic choroidal changes in macular region. Peripheral portion of fundus tesselated.

Visual Fields (Fig. 23): Candle field; contraction temporally and above.

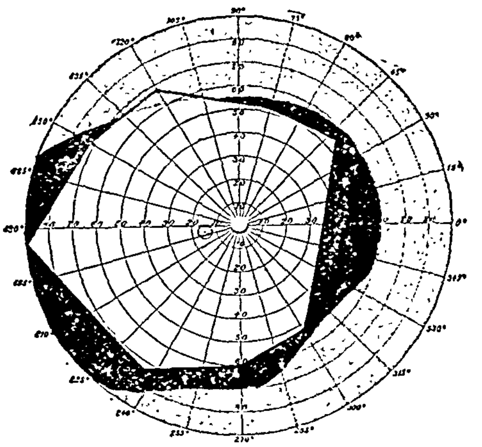

Fig. 13.—Case 7. Field after operation. Left eye. June 11, 1913. Vision, fingers at 3 feet; 10 mm. object.

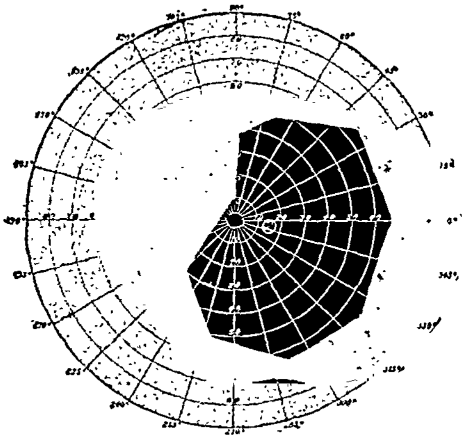

Fig. 14.—Case 8. Field before operation. Right eye. May 19, 1914. Vision, light perception; 20 mm. object.

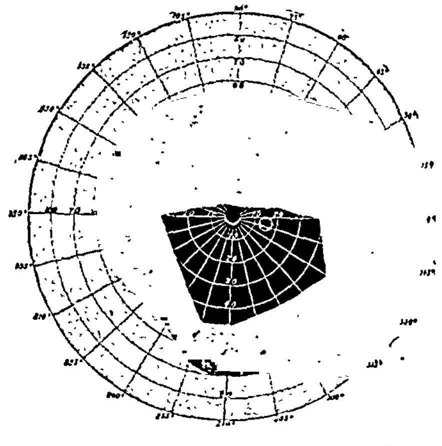

Fig. 16.—Case 8. Field after second operation. Right eye. Nov. 14, 1914. Vision, light perception. Candle.

Treatment, rest in bed.

Nov. 18, 1914. Vision, 4/60. Visual field, 10 mm. object, less contraction than former candle field. Small field for blue; red and green not attempted.

November 29. Vision, 6/40.

Ophthalmoscopic Examination.—Unchanged. Visual field not more contracted than at last examination.

Operation.—Nov. 30, 1914, trephine operation for detachment of retina performed. Scleral opening made down and out. Escape of yellowish colored fluid followed incision in choroid.

Postoperative History.—Slight injection and edema over trephine area. Twelve days after operation, eye quiet. Ophthalmoscopic examination showed marked improvement, retina replaced, excepting peripherally, down and in. Vision, 2/60.

Jan. 11, 1915. Vision, 5/60, with and without correction. Many thread-like and mossy vitreous opacities, apparently remnants of hemorrhage. Retina detached below. Fields, 10 mm. object. Practically the same as field shown in Figure 23.

March 26, 1915. Vision, right eye, fingers at 2 feet.

Ophthalmoscopic Examination. — Marked increase in extent of detachment now extending up and in, down to disk border, and up and out, to superior temporal artery, which seems to limit the detachment. Vitreous contains many fine and a few stringy opacities. Disk obscured.

Visual Field (Fig. 24): Field taken with a 10 mm. object shows marked loss in all directions, especially temporally.

Result: Failure.

DISCUSSION

The interesting feature in this case is the associated myopia. No other etiologic factor could be found as a possible cause of the detachment.

Case 11.—*History.*—M. W., female, aged 64, presented herself at the clinic, Feb. 8, 1915, complaining of loss of vision in left eye. Five months previously first noticed flashes of light before eye, which gradually disappeared. One month later, vision was practically lost for a period of from two to three weeks, when sight returned for objects, where it has since remained.

Examination.—Vision, right eye, W. C. 6/7.5. Left eye, fingers at 2 feet. External appearance of both eyes, normal. Pupillary reflexes, normal. Tension, right eye, 25 mm.; left eye, 22 mm. Transillumination negative.

Ophthalmoscopic Examination.—Right eye: Few striae in lens periphery. Few fine vitreous opacities. Peculiar flaky retinal changes of indefinite character over whole fundus. Otherwise negative. Left eye: Lens swollen and granular. Many fine reticular vitreous opacities. One large central opacity. Retina detached from just below disk border temporally and down. Peripherally detached portion of retina, grayish; centrally pale red.

Visual Fields: Right eye, slight contraction above; left eye (Fig. 25) with 30 mm. object, upper nasal half practically hemiopic. Marked peripheral contraction throughout.

Medical examination, negative.

Operation.—February 15. Trephine operation for detached retina performed. Several drops of straw-colored fluid and a small amount of vitreous followed incision of choroid and retina.

Postoperative History.—Considerable congestion and chemosis over trephine area. At end of ten days patient could see much better, counting fingers readily. No exact record made. On eleventh day, chemosis had disappeared. Apparently filtration had ceased. Vision much worse. Visual fields (Fig. 26) 10 mm. object larger than first taken with 30 mm. object. Most marked improvement nasally where hemiopic character of field had disappeared. Vision: Counts fingers at 3 feet.

DISCUSSION

The final field taken with a 10 mm. object showed a marked improvement over the first one taken with a 30 mm. object. The failure to secure a more marked improvement in vision could be accounted for, in part, at least, by the changes of the lens and vitreous.

SUMMARY OF RESULTS

Vision			Fields	
Improved	Unimproved	Made Worse	Improved	Made Worse
4	5	2	8	3

In three cases (3, 5 and 7) very good results were obtained. In Case 3 the vision was increased from

4/60 to 6/7.5 and the field almost completely restored. The last observation was made seventeen months after the time of operation. In Case 5 the field was almost completely restored except for a large central scotoma which corresponded to an area of proliferating retinitis, accounting for no increase in the acuity of central vision. In Case 7 the field was greatly improved, but the condition of the vitreous was such as to prevent improvement of vision.

The vision was made worse in two cases (4 and 10). Case 4 had a fluid vitreous, a portion of which had been lost one month previously during operation by me for the extraction of cataract. Case 10 had a high degree of myopia.

The field was made worse in three cases (1, 8 and 10). In Case 1 the detachment was very extensive and the choroid was not incised. Case 8 had contraction bands in the retina and a partial detachment of the choroid. There was also present a total detachment in the other eye and the Wassermann was positive. Case 10 had a high degree of myopia with a spontaneous detachment.

In three cases (6, 8 and 9) the detachment of the retina was associated with a partial detachment of the choroid. In Case 6 there was a slight improvement in the vision and a marked improvement in the field both for form and color. Case 8 was unfavorable for any operative procedure, while Case 9 showed slight improvement after the second operation in both vision and fields. The organized bands in the vitreous in Case 9, the result of a foreign body passing through the globe, made any marked improvement impossible.

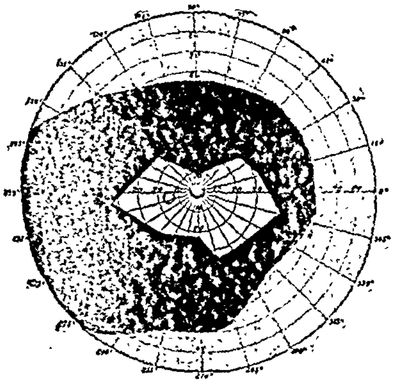

Fig. 17.—Case 9. Field before operation. Left eye. May 22, 1914. Vision, light perception; 50 mm. object.

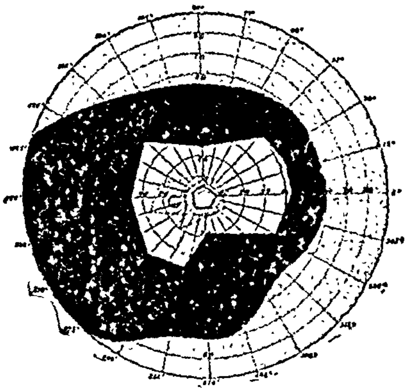

Fig. 18.—Case 9. Field after first operation. Left eye. July 7, 1914. Vision, 1/60; 20 mm. object.

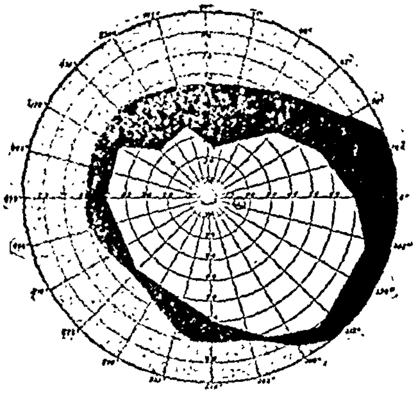

Fig. 23.—Case 10. Candle field before operation. Right eye. Nov. 29, 1914. Vision, 4/60; 10 mm. object.

In two cases (1 and 2) the choroid was not incised. In each case the vision was unchanged, while the field was slightly improved in one and made worse in the other.

The object of this operative procedure has been to secure an opening in the sclera and choroid which will allow free drainage of the subretinal fluid for a sufficient length of time to permit the retina to become reattached. If the secretory process is dormant, and all the subretinal fluid evacuated at the time of the operation, reattachment may occur without edema of the conjunctiva. But if the secretory process is active, or if any amount of the subretinal fluid is left behind, a certain amount of reaction must necessarily follow or the retina will again be separated from the choroid and failure result. In each of the cases in which a good result was obtained, the operation was followed by a marked edema which did not entirely disappear until the tenth day.

The procedure seems to be unattended by any danger, either of impairing the integrity of the globe, or, in uncomplicated cases, of increasing the extent of the detachment. On theoretical grounds at least it would seem desirable to drain off the subretinal fluid without injuring the retina. In the cases reported, however, the best results were obtained when escape of the subretinal fluid was followed by a discharge of a small amount of vitreous.

The results obtained in the eleven cases here reported, as compared with those obtained from any like number of cases previously treated, compel the author to look on the operation as one of distinct value in the treatment of detachment of the retina.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. THOMSON AND CURTIN, AND PARKER

Dr. Clinton T. Cooke, Seattle: I take direct issue with the statement that Vail's theory fits certain clinical aspects of the case. Has Vail shown conclusively that the hypotony is due to arrest of secretion and not to a free exit of aqueous through a patent ligamentum pectinatum? Minus tension is an undoubted fact. But has he shown the necessary connection between it and arrest of secretion? As to "Passive hyperemia with albuminous transudate, beneath the retina," does the assumption of the arrest of secretion and minus tension require us to assume also that the subretinal albuminous fluid is transudate, brought about mechanically, and is not an inflammatory exudate of toxic origin? It is possible for contraction of volume of the vitreous to occur in at least three ways; by a general loss of its water, by a formation of circumscribed areas or cavities in its substance, by a liquefaction of its peripheral portion, from a diffusion to it from the choroid of a toxin, or by reason of an interference with its supply of nutriment plus liquefaction. In either case its place is taken either by aqueous or by transudate or exudate, or else the sclera contracts on it. If this latter does not occur, room is afforded for the subretinal accumulation if the channels for aqueous escape are unblocked. How an albuminous transudate of choroidal origin is to bring about diffusion of water from the vitreous to the choroidal side of the retina in the face of an alleged acid reaction, I fail to see. Vail's treatment by sodium citrate is based on its alleged acid reaction. Fischer finds that even a slight acidity causes a rise in tension equal in certain concentrations to an amount sufficient "to burst the great sclera" and that the change or reaction is a most important factor in producing a rise in tension in glaucoma. I think Vail does not follow Fischer. Furthermore, I think that Fischer's work effectually disposes of Vail's theory. In my opinion, the theory of Drs. Thomson and Curtin is vastly preferable. With the rest of the paper I am in agreement, particularly where they call attention to the not infrequent association of a subchoroidal exudate with the subretinal fluid; that is, of a choroidal detachment. This accords with a case recently observed by myself and operated according to the technic of Dr. Walter Parker, in which I trephined over the site of detachment and observed the gush of fluid before puncture of the choroid. This patient secured increase of vision and partial reattachment of the retina. In the future I contemplate following the technic of the authors of this paper, although I see no reason, even in the cases of subchoroidal exudate, to defer aspiration of the subretinal fluid to a subsequent time.

Dr. Vard H. Hulen, San Francisco: The operation presented by Dr. Parker, and that described by Dr. Curtin are the same excepting the aspiration, which does not appeal to me. We are distinctly in need of some method of treatment for detachment of the retina which is really hopeful. Nothing heretofore, in my experience, has been of that nature: Dr. Parker performed his first operation within a few days of the date on which I had recommended the same procedure to a patient, the idea having occurred to me independently some time before as it probably had to others.

I have one experience only to report and it appears favorable to this operation. This patient, female, aged 46, came to me in July, 1911, stating that she had noticed a blur over her right eye for four or five years or longer. At this visit her vision was 20/70. The field, irregular, roughly; nasal 30 C.; temporal, 50 C.; up, 20 C.; down, 30 C. The eye appeared normal except that the ophthalmoscope revealed a small, typically appearing detachment of the retina above and to the temporal side, 8 diopters in elevation. While the location was not usual for detachment and the outlines exceptionally clear cut and its height rather great for its area, I proposed the usual treatment for simple detachment. Later, no constitutional or local cause having been discovered, I mentioned a growth as a possible cause of the detachment. Negative results having followed nonoperative treatment, scleral punctures were proposed. The vision having dropped to 16/200 I suggested in June, 1913, the operation as now described by Dr. Parker. The tension has always been normal and conditions unchanged excepting some increase in the detachment with floating opacities in the vitreous. Many months elapsed and then the patient returned and said great failure of vision had recently followed a pelvic operation under ether. I then found the entire lower half of the retina detached. May 10, 1915, I trephined the sclera below and to the temporal side 10 mm. from the limbus. A large quantity of typical subretinal fluid escaped on the withdrawal of the trephine. The lower detachment was completely dissipated, but the first "detachment" remained unchanged. As no reaction followed and the vision was now 10/200, I suggested as a final measure the same procedure over the site of above and this was done June 9. In sharp contrast to my first experience, the trephining was followed by the loss of no fluid, and incising the dark object through the opening caused merely a little oozing of blood and there was a feeling of resistance. I now thought the diagnosis of sarcoma of the choroid confirmed and proposed immediate enucleation. To date this has been declined though strongly urged in addition by two of our most skilled confrères. Neither of them, however, will make a positive diagnosis of tumor from their examination of this eye. The retina below remains attached, media and "tumor" unchanged, eye quiet, but the contrast in appearance of the two trephined areas calls for radical and immediate action. My experience with this case encourages me to try this operation again in cases of simple detachment. One point in the technic recommended by Dr. Parker's comparatively large experience I feel should be accepted with caution, for it may be a mistake to puncture the retina as a routine procedure. To evacuate the subretinal fluid by trephining, without injuring the retina or the loss of vitreous, the eye, I believe, has been put in the most favorable condition for recovery.

Dr. G. C. Savage, Nashville, Tenn.: Let every man bear the consequences of his own sins. I bear reproach myself for using the citrate of sodium subconjunctivally. I want to say in defense of Vail that I believe his theory is the only one that should appeal to us. Any change in the eye that will lessen the contents of the vitreous body would predispose to the detachment of the retina. The watery constituents of the eye go into the vitreous and aqueous chambers and are emitted slowly as a secretion. Any other fluid such as a transudation of serum in the eye would make the eye opaque. The ciliary glands, like any other glands of the body, might fail in secretory power, and thus fail to keep the chambers of the eye properly filled. Not knowing about Vail's line of thought I promptly wrote him that I had never cured a case. About that time a young man came from Vanderbilt University complaining of loss of vision in one eye. The diagnosis was easily made—simple detachment of the retina. I said to him if I knew the reaction of the detaching fluid I might be able to do something for him. His vision was practically nothing. He said: "Take advantage of your guess that it is acid and do whatever you want to do for me. I do not want to lose my eye." I gave the citrate of sodium by subconjunctival injection, with marvelous improvement within twelve hours. These were repeated frequently, improvement continuing. It has been about three years, and that man is now able to read ordinary print. The injection of citrate of sodium was what brought about the improvement. I concluded that something ought to be done to improve the nutrition of the eye so I gave him 1/100 grain of mercuric chlorid and 1 grain of potassium iodid after each meal. I then wrote Vail again that I was curing a case. Later I found that his theory and my practice fitted into each other perfectly. In the past three years I have had more cases of detachment of the retina than in all my other years of prac-

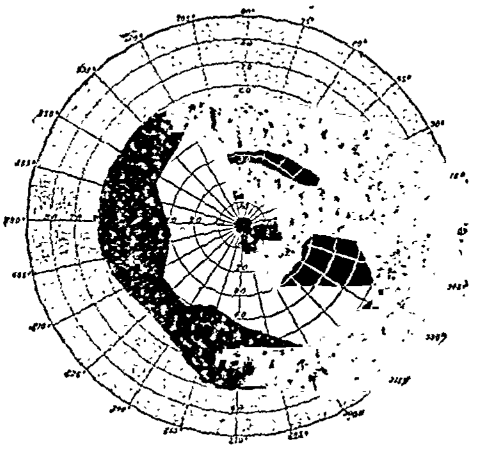

Fig. 24.—Case 10. Field four months after operation. Right eye. Vision, fingers at 2 feet; 10 mm. object.

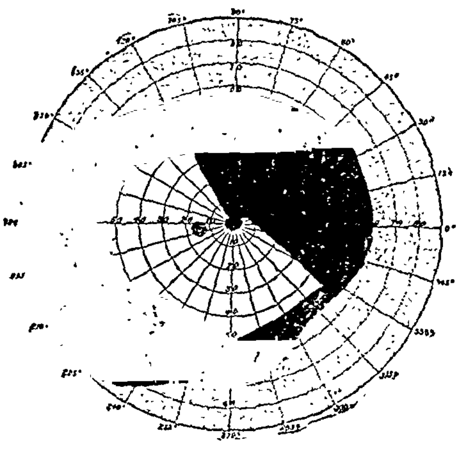

Fig. 25.—Case 11. Field before operation. Left eye. Feb. 12, 1915. Vision, fingers at 4 feet; 30 mm. object.

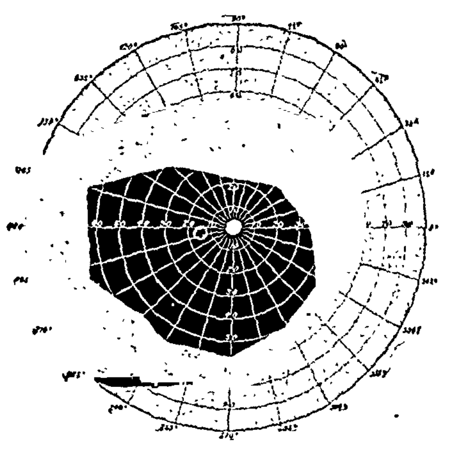

Fig. 26.—Case 11. Field one month after operation. Left eye. March 4, 1915. Vision, fingers at 3 feet; 10 mm. object.

tice. Some cases have not improved at all. Cases that had clear vitreous improved. Some improved very remarkably, others less remarkably, and I believe all patients with clear vitreous would have gotten well if they had persisted in the treatment, including the agents that I believe are best for improving the nutritive power of the ciliary body. Vail in his theory of causation is right.

Dr. Milton K. Thompson, Muskogee, Okla.: I had a peculiar case. I want to make this report and get the opinion of the elders such as Dr. Savage and others. The patient suddenly went blind. The ophthalmic examinations showed a distinct retinal detachment of a rounded character, but we did not know what nature of a tumor it was. Several of us decided it was a tumor. On questioning the young man we found that he had a specific history. We put him on treatment with neosalvarsan and inside of a month's time the tumor had gradually gone down and he had very good vision, except central, at the point of tumor where the choroidal scar showed. Now I want to know why that did that way and what condition existed?

Dr. Kaspar Pischel, San Francisco: I would like to express my gratitude to Dr. Parker for the very accurate table he has presented. He shows his failures there along with his successes—the bad as well as the good. The results are good enough for us and we should all try it. I shall certainly do so at my first opportunity. Naturally I will use the trephine or trepan in connection with the dental engine which I showed this morning. The trepan on the dental engine works so much faster and, with my stop, is so much safer that I will never return to Elliot's original hand trepan.

Dr. Thomas H. Curtin, New York: Dr. Thomson and I wish to apologize for simply recording three cases, but we have recorded only those cases which we thought were applicable for this operation, namely, recent cases of spontaneous or traumatic origin. We have operated in ten or twelve cases, however, in which from the outset we expected no results, although we have, even in these cases, had improvement in the fields of vision. Just before I left New York a patient with myopic detachment with vague light perception in the upper field, after being operated on twice, had a vision of fingers at 4 feet. In answer to Dr. Cook, I wish to say that we do not try to defend Dr. Vail's theory and have founded our belief as to the causation of retinal detachment on the results of our own clinical experience. I want to say, regarding the operation, that we think it is a bad plan to puncture the retina in any operation for the cure of retinal detachment. Holt, in 1911 in the *Transactions* of the Ophthalmic Section at Heidelberg, did trephining for myopia with and without detachment. He came to the conclusion that patients who had tears in the retina gave no results from the trephine operation. In regard to subconjunctival injections, as has been stated in the paper, we have consistently and conscientiously used them. We have tried various solutions, saline, dionin, citrate of soda, cyanid of mercury and glycerin and none of them has given us the least result.

Dr. Walter R. Parker, Detroit, Mich.: Cases of detachment of the retina due to intra-ocular tumor were not included in my report. Dr. Savage has been more fortunate in his results from subconjunctival injection than many others. Certainly if medical treatment will cure detachment of the retina, surgical interference should not be thought of. Personally I have never permanently cured a case of detachment, except by the method described in my paper. Trephining the sclera alone has been done before, but the results were unsatisfactory. My suggestion is to combine an incision of the choroid with the trephine operation.

Authority to Compel School Inspection.—The objection that the state has no right to permit or require medical inspection of the children in the schools will not bear close scrutiny or logical analysis. The authority which has the right to compel attendance at school has the added duty of insisting that no harm shall come to those who go there.—*Wisconsin State Board of Health Bulletin*, April-June, 1915.

METHODS OF WEIGHING PARTS OF THE LIVING HUMAN BODY *

C. D. SPIVAK, M.D.
DENVER

The problem which I essayed to solve can be better understood if I recite the course of reasoning I followed: A man weighing 150 pounds is placed on a certain diet and he gains 10 pounds. The question arises, How can we locate the gain? In other words: How have the 10 pounds distributed themselves over the body? Have they spread themselves uniformly through the body or not? If the additional mass has not been distributed uniformly, is there a definite relative increase in the various sections of the body? Have 3 pounds been added to the upper extremity and 7 pounds to the lower extremity or vice versa? The same question is, of course, applicable to a man who has lost 10 pounds. As far as I could trace in the available literature, not only has there never been made an attempt to solve this problem, but it has never even been propounded.

The student of metabolism differentiates between the increase in the mass of the body which takes place during the period of growth and the increase in the mass of the body which takes place after the period of growth has terminated. The first growth is a fundamental biologic property implanted in the race and transmitted by heredity. It is involuntary. The second, the increase in mass after growth has ceased, is wholly artificial and may be influenced by diet, exercise, environment, etc. It is to a great extent under control and therefore voluntary. I am concerned with the latter only.

Now, the increase in mass manifests itself in two ways, in weight and in measure. The result of the added 10 pounds has hitherto been measured by means of the scales and the tape measure. Neither of these methods is capable of throwing light on our problem. The scales show an increase in the body of 10 pounds, but they do not show where they are located. The measurements made by the tape, no matter how carefully made and how numerous, will not give even an approximate idea of the increase in the bulk either of the entire body or of a part of the body.

As the development of the art of measurement is older than the art of weighing, so has the solution of the problem dawned on me first through the glimmering light of measure.

Having evolved a method of measuring the bulk of the whole human body and of its certain parts and sections by means of the volumometer, and having also suggested the use of a new ponderal index in anthropometry,[1] I naturally turned my attention to the actual weighing of parts of the living human body. Here the difficulties, mechanical, physical and mathematical, confronted me at every step, and I have made but slow progress. I have consulted physicians, engineers and mathematicians. They all became attentive and interested, and, to use a hackneyed expression, sat up and took notice. But alas, they gave me only much warmth and but little light.

---

* Because of lack of space this article is abbreviated in The Journal. The complete article appears in the Transactions of the Section and in the author's reprints.

[1] Spivak, C. D.: The Specific Gravity of the Human Body, Arch. Int. Med., April, 1915, p. 628.

I have constructed scales for weighing parts or sections of the living human body which consist of (*a*) a board, (*b*) a stand and (*c*) two ordinary platform scales.

The board is 7 feet long and is provided on its lower surface with two transversely grooved steel bars running alongside of its margins.

The stand is made of an iron frame, the upper surface of which ends in a knife-like projection which fits into the grooves of the bars and serves as a fulcrum.

The board is placed on the fulcrum in about its middle portion, and the two scales are so placed that each of the two extremities of the board rests on or is suspended over their platforms. The scales on which the longer arm of the board is resting will indicate a certain amount of weight, and, by shifting the board to the right or to the left, one is able to adjust it so that neither of the scales will indicate any weight. The board then will be balanced, or in other words, the center of gravity of the board will have been determined. The scales represent a lever of the first order.

Now when a man weighing, say, 150 pounds, is placed on the balanced board, the upper extremities in the anatomic position, one or other of the scales will indicate a certain amount of weight. By shifting the subject to the right or to the left we are able to adjust it so that neither of the scales will indicate any weight, or, in other words, the center of gravity of the man in the horizontal position will have been determined. We then mark on the body of the subject the line of the center of gravity. We shift the subject a distance (*a*) to the right of the fulcrum, and we note the amount indicated on the right hand scales, and then we shift the subject a distance (*b*) to the left of the fulcrum, and we note the weight indicated on the left hand scales. From the known quantities (1) the weight of the entire body, (2) the center of the gravity, (3) the distance *a* and the distance *b* and (4) the two weights when the body is shifted to the right and to the left, we should be enabled to find the unknown weight of the part of the body on either side of the fulcrum. Dr. I. J. Schwatt, professor of mathematics at the University of Pennsylvania, to whom I submitted the problem was kind enough to prepare the following four equations:

Given the four equations:

$$(1)\quad W(1-d) + P_1x = W_1d + P_2y$$
$$(2)\quad W(1-d-a) + P_1(x-a) = W_2(d-a) - P_2(y+a)$$
$$(3)\quad W(1-d+a) + P_1(x+a) = W_3(d-a) + P_2(y-a)$$
$$(4)\quad P_1 + P_2 = P$$

Required to solve for the unknowns, P_1, P_2, x and y.

SOLUTION[3]

First, eliminate y, as follows:

Add (1) and (2).

$$(5)\quad \therefore W(1-d) - Wa + 2P_1x - P_1a = d(W_1 + W_2) - W_2a - P_2a$$

Add (2) and (3).

$$(6)\quad \therefore 2W(1-d) + 2P_1x = (d-a)(W_2 + W_3) - 2P_2a$$

Second, eliminate x, as follows:

Subtract (5) from (6).

$$(7)\quad \therefore a(W + P_1) = \frac{d}{a}(W_3 - W_1) - a(W_2 + W_3) + a(W_2 - P_2)$$

Solve (7) for P_1.

$$(8)\quad \therefore P_1 = \frac{d}{a}(W_3 - W_1) - (W + W_3 + P_2)$$

Substitute (8) in (4).

$$\therefore \frac{d}{a}(W_3 - W_1) - (W + W_3) - 2P_2 = P_1$$

$$\text{i. e., } P_2 = \frac{1}{2}\left\{\frac{d}{a}(W_3 - W_1) - (W + W_3 + P)\right]$$

Substitute this value for P_2 in (8).

$$\therefore P_1 = \frac{1}{2}\left[\frac{d}{a}(W_3 - W_1) - (W + W_3 - P)\right]$$

Hence from (6)

$$x = \frac{a\,[d(W_1 + W_2) - 2W(1-d) + a(W - W_2 + P)]}{d(W_3 - W_1) - a(W + W_3 - P)}$$

And from (1)

$$y = \frac{a\,[d(W_2 - W_1) + a(W - W_2 + P)]}{d(W_3 - W_1) - a(W + W_3 + P)}$$

In conclusion, I desire to beg of you to consider all that I had to say in reference to the weighing of parts of the living human body as merely preliminary. I may be right and I may be wrong. I may be wending my way to the land of the Eureka, or I may be drifting into a fool's paradise. I do not know.

1421 Court Place.

ABSTRACT OF DISCUSSION

Dr. T. Brailsford Robertson, Berkeley, Calif.: I would like to ask Dr. Spivak whether, in order to measure his new ponderal index, it is necessary totally to immerse the subject?

Dr. Joseph Erlanger, St. Louis: I would like to know how much of a factor in the measurement of the mass of the body changes in the distribution of the blood in the body may be, and also how much of a factor variation of the gaseous content of the cavities of the body may be, and whether these factors have been taken into account by Dr. Spivak?

Dr. C. D. Spivak, Denver: The new ponderal index which I recommend is made up of the old ponderal index, which represents the ratio between the height and the weight of the body in air, and the volume of the body measured in water. The new ponderal index takes cognizance of the specific gravity of the body as one of the trinity of measurements. The problem of weighing parts of the human body is to be solved by engineers and mathematicians and may be represented as follows: Given a mass of homogenous consistency, we can judge the weight of any of its parts by measuring or weighing the amount of water which that part displaces. Given a mass that is not symmetrical and not homogenous in consistency, wanted to find the weight of certain sections of that body: I claim that mathematics and mechanics will jointly come to our assistance and give us, if not the exact weight of such parts, at least an approximate weight.

The question of the specific gravity of the body has been studied very carefully, mainly by the Germans. There is an article in English by an American, a teacher of swimming, who studied the question from his particular standpoint. Professor Spitzig of Cleveland informs me that he and Rev. Frederick Odenbach of St. Ignatius College of Ohio City have carried on investigations and they have arrived at the conclusion that the specific gravity of the human body is so low that it takes only a little bit of buoyancy to keep it afloat, which is in perfect accord with my findings. The question as to whether the air in the lungs has any influence on the specific gravity has received due consideration at the hands of German investigators. It was found that the volume of air in the lungs equals the volume of air in the intestines, and consequently there is a perfect balance between the specific gravity of the two halves of the body—that above and that below the diaphragm.

[3] The solution was kindly prepared by Dr. G. E. F. Sherwood, Professor of Mathematics, School of Mines, Golden, Colo.

CHRONIC RETENTION OF URINE IN CHILDREN [*]

EDWIN BEER, M.D.
NEW YORK

During the past five years a number of children[1] suffering from chronic vesical urinary retention have come under my observation. Invariably the condition had been unrecognized, and the children were steadily deteriorating in health. As the picture presented by these cases seems to be quite characteristic, even though the etiology of the condition may vary from case to case, I have thought it well worth while to report this series and to call attention to the syndrome.

The picture presented by these cases is very suggestive of chronic interstitial nephritis. The patients become pale and pasty. Frequently they are apathetic. Usually there is some difficulty in urination. The little patients complain of pain, or their parents note that they take a long time to complete the act. In some cases the straining is so great that the patient shows collapse symptoms with excessive pallor and weakness. On physical examination a globular mass is felt in the hypogastrium; it varies in size, but never disappears spontaneously. If infection is present, the mass may be tender. When a catheter is passed, this tumor vanishes. There is regularly residual urine. The walls of the bladder are hypertrophied, though this may not be evident late in the disease when excessive dilatation takes place. On palpation one may feel the bladder contract and become hard, behaving like the pregnant uterus. If no infection has set in, the urine may be clear, suggesting the urine in chronic interstitial nephritis. Eventually all the patients seem to become infected. As a secondary and constant development, the ureter openings become patulous and the ureters dilated. Unilateral or bilateral hydronephroses develop, and the enlarged kidney or kidneys become palpable. With infection setting in, the kidneys partake of the trouble, and infected hydronephrosis with or without multiple abscesses develops.

Neurologic examination of these patients frequently shows nothing abnormal; in others, distinct evidence of a cord or of a brain lesion is found. Even in cases in which the most complete examination fails to reveal a definite disturbance in the nervous system, postmortem examinations (three cases) have shown definite cord lesions.[2] Many of the cases without neurologic signs so closely simulate those with definite neurologic symptoms, as well as those adult cases of contracture of the neck of the bladder, due to some neuromuscular disturbance (arteriosclerosis of the cord, poliomyelitis, etc.), that, reasoning from analogy, one feels compelled to view these cases as due to neurologic disturbances, provided no local physical obstruction is present.[3]

In some cases a local examination may demonstrate an obstruction at the prepuce or in the urethra (stricture, folds, new growth). This should regularly be excluded, if possible. A minute meatus may be associated with a neuromuscular disturbance and, as in one of the following cases (Case 3), have nothing to do with the retention. The ready passage of an instrument into the bladder probably precludes the possibility of a mechanical obstruction, whereas, in conditions of sphincter spasm, such as most of these cases probably are, no obstruction is usually felt. This corresponds to the adult cases as well as to similar spasms in other parts, notably cardiospasm.[4] That the condition is frequently one of spasm (or perhaps better disharmony between the detrusor and sphincter muscles or relative hypertonicity of the sphincter) can frequently be demonstrated by passing a good-sized bougie into the bladder after the patient has voided. As soon as the sphincter is well stretched and the bougie is withdrawn, the bladder may be emptied voluntarily (except in cases with a diverticulum, etc., as Case 2). Again, that the detrusor is not paralyzed can be readily proved by starting the stream by forcible expression. After the sphincter spasm has been overcome the patients may void in a good stream.

Roentgenographic studies of these cases with silver salts will regularly show a fair-sized bladder and dilated ureters, provided the condition has lasted a sufficient time. If the cause of the retention is a diverticulum (Case 2), the Roentgen-ray cystograph will readily assist in making the diagnosis.

From the foregoing it is clear that these cases present a definite clinical picture due to varied etiologic factors. Before reporting and analyzing the series here brought together, it would be well to tabulate the etiologic factors:

1. Mechanical obstructions:
    - A. Extravesical, as congenital folds and strictures, including tight prepuce, small meatus, etc.; new growths.
    - B. Intravesical, as diverticulum of bladder, vesical stone.
2. Neuromuscular:
    - A. Brain disease.
    - B. Spinal cord disease.
    - C. Spasticity of sphincter without definite neurologic signs;[2] probably disease of sacral cord.

The cases due to extravesical obstruction are well known, and in the literature there are many examples of such cases.

Case 1.—*Chronic retention of urine; congenital stricture in penile urethra; dilatation. Cured.*—Boy, aged 7 years, since the age of 2 has been dribbling urine. Has no pain. No trauma or local disease. Physical examination shows a large, tense globular mass filling the hypogastrium. On catheterization this disappears. The meatus of the urethra is small. No neurologic symptoms are present, and no evidence of a neuromuscular disturbance can be detected. The urine is cloudy, albumin is present, also an occasional hyaline cast, and many pus and red blood cells. The Roentgen examination shows no calculus.

Meatotomy was performed, and 1½ inches behind the meatus a stricture was detected. This was stretched and kept open with an indwelling catheter (No. 12 French). October, 1913: After catheter had been used in this way for fourteen days, patient was able to empty his bladder and was discharged.

---

[*] From the Mount Sinai Hospital Surgical Service.

[1] The opportunity to study three of the following cases, I owe to Drs. A. G. Gerster and H. Koplik, for which I take great pleasure in thanking them. In addition to the nine cases included in this series, I have seen several other cases belonging in this group, but as they were not adequately studied, they have been excluded from the report.

[2] Blum, V.: Zur Kenntnis der Harnretention im Kindesalter und zur Frage der Pyocyaneussepsis, Wien. med. Wchnschr., 1907, lvii, 2257.

[3] The series of cases has been so arranged as to emphasize this interpretation, which I trust will convince even in those mentioned in Legueu's paper (Arch. urol. de Necker, 1913-1914, i), where the changes in the urinary tract in these cases are attributed to a probable congenital anomaly or malformation of the ureters, etc. In Bransford Lewis' recent analysis of similar cases in adults (Prostatic Obstruction and Vesical Atony, Ann. Surg., March, 1915) he announces the same conclusions which I have reached.

[4] The analogy between cases of cardiospasm and those under discussion is quite striking. An esophageal probe, stomach tube, etc., can be passed over a silk thread (Mixter technic) through the spastic cardia without the operator detecting any obstruction. Here, too, the obstruction leads to dilatation of the passage above, and the dilated hypertrophied esophagus may assume enormous proportions.

Much rarer are cases of chronic retention due to intrinsic conditions, as diverticula, which is well illustrated in Case 2.

Case 2.—*Chronic retention of urine; diverticulum of bladder; excision; reimplantation of left ureter. Cured.*—Boy, aged 10 years, five or six days before admission had slight terminal hematuria and pain on urinating. He feels that he cannot empty his bladder. Has some pain in hypogastrium. The patient is markedly pale. The hypogastrium is filled by a globular mass which does not disappear completely after urination. There are a penile hypospadias and slight right lumbar tenderness. The neurologic status is negative. The urine is turbid, and contains a heavy trace of albumin, much pus and many epithelial cells. The residual urine is between 60 and 90 c.c. Phenolphthalein test shows 45 per cent. excretion in two hours.

March, 1915: Argyrol cystograph shows a well-developed diverticulum of the bladder and a dilated right ureter. The diverticulum is as large as a peach, and appears to be a little to the left of the midline and behind the bladder.

March 24, 1915: Cystoscopy shows that the right ureter meatus is patulous. Near site of left ureteral meatus is the opening of the diverticulum. The left ureter seems to open into the diverticulum close to the mesial lip, as indicated by the discharge of indigocarmin in good concentration. The right kidney excretes a good stream well colored at fourteen minutes.

March 27, 1915: Extraperitoneal excision of diverticulum of bladder and reimplantation of left ureter in bladder. The bladder was exposed in the usual way through a suprapubic incision, and dissected free from the peritoneal covering. The bladder was gradually drawn into the wound, and the diverticulum found to lie between the trigon and the rectum. As the lower 1 inch of the left ureter was intimately adherent to the diverticulum, it had to be sacrificed and excised with the inflamed diverticulum. The position of this pouch was such that, whenever it was full, it compressed both ureters, and in that way induced bilateral hydro-ureter (and nephrosis). At operation both ureters showed evidence of this, and the left was found markedly dilated. (Roentgenoscopy revealed condition on right side.) The ureter (left) was implanted in the posterior wall after ligating the neck of the diverticulum and burying it in the bladder wall. A suprapubic Kader cystostomy for drainage was made, and when the drainage tube was withdrawn, the cystostomy opening (valvular) closed at once without leakage.

April 26, 1915: Urine is clear. Bladder is completely emptied and patient is absolutely well.

May 12, 1915: Cystoscopy shows excellent function of the ureteroneostomy, which looks like a small, red, nipple-shaped protrusion of mucous membrane on posterior wall, and through its central lumen an intense stream of indigocarmin is emitted in normal fashion.

As illustrative of the neuromuscular group of cases with retention of urine due to a definite discoverable lesion in the nervous system, let me cite the following case under Group 2 A, due to cerebral disease:

Case 3.—*Retention of urine; Little's disease; spastic sphincter of bladder.*—Boy, aged 6 years, complained of difficulty in urinating. Patient was born by face presentation, asphyctic, remaining so for one and one-half hours. Anuria followed, lasting a week (?), and thereafter dribbling. At 2 years of age there was pain on urination. At 3 years of age he began to walk. Parents noticed that left side of body was weak. Patient must urinate frequently and strains so hard as to cause weakness, pallor and general distress. He was an underdeveloped, pale, pasty-looking boy, suggesting chronic nephritis.

Local examination showed a small meatus. In hypogastrium was a hard tumor, extending well up to the umbilicus. It disappeared on catheterization. Meatotomy was performed without changing the condition. Kidneys were negative.

Neurologic examination revealed weakness of left side of body, bilateral Babinski, apparently the residue of a Little's (or left cerebral hemiparesis).

Cystoscopy May, 1912, revealed a trabeculated bladder. Delayed excretion of indigocarmin in feeble concentration.

A diagnosis of retention of urine due to neuromuscular disturbance (sphincter spasm of cerebral origin [Little's]) was made. Diminished kidney function (beginning bilateral hydro-ureter and hydronephrosis).

An attempt was made in this case to overcome the spastic sphincter by progressive dilatation with bougies. After these had been passed, the patient was able to empty his bladder. This was kept up for some time, No. 18 French being used.

March, 1915: Patient was again seen. He had the peculiar pallid appearance of a nephritic. Bladder was two-thirds to umbilicus, and on straining the patient could void only one-half ounce of urine, which was perfectly clear. Neurologic signs of left hemiparesis persisted.

The following case illustrates very satisfactorily the group in which the chronic retention is associated with a well-marked and readily detectable spinal cord lesion, or Group 2 B.

Case 4.—*Retention of urine; incomplete transverse myelitis.*—Boy, aged 11 days, was born by foot presentation, and was delivered by traction (midwife). On the eleventh day parents noticed that he failed to pass urine. Physical examination showed a large globular hypogastric mass which disappeared on catheterization.

Neurologic examination revealed both lower extremities paralyzed. The flat muscles of the abdominal wall, especially on the right side, were paralyzed. Bilateral Babinski and exaggerated knee jerks were readily elicited. Examination of the spine was negative. Subsequent Roentgen examination of the spine was also negative.

Owing to absolute retention, the little patient had to be catheterized every twelve hours for several weeks, when some urine (overflow?) was voided. Catheter always entered without striking an obstruction. When the patient was 3 months old there was slight improvement in the neurologic symptoms, but no marked change in urinary retention. The bladder was always palpable, filling the hypogastrium; it contracted firmly under the palpating hand, and on pressure urine could be expressed. As soon as the stream was started, that is, the spastic sphincter overcome, the baby was able to void in a good stream. The urine up to date shows no sign of infection of the urinary tract.

In my experience, by far the largest group of cases of chronic retention of urine in children shows no other symptoms referable to the nervous system, though in the only two cases hitherto recorded which have come to complete necropsy, the sacral segments of the spinal cord showed definite lesions:

Case 5 (v. Blum, Frankl-Hochwart).[2]—Boy, aged 13 years, wets himself day and night. When 3 years old he had acute attack with tonic and clonic spasms, unconsciousness and urticaria. This lasted one day. He was always weakly and nervous. In the fifth year, he fractured his frontal bone above the right eye and had concussion. Then he was four weeks in bed. Subsequently he had scarlet fever. No disturbance in urination was noted until tenth year, when increased frequency and urgency developed. When 11½ years old, there was hematuria with pains in kidney regions. This disappeared after rest, but ever since there has been incontinence with dribbling and hypogastric pain.

Physical examination, Jan. 21, 1907, reveals an underdeveloped boy, looking about 6 or 7 years old. Pallor of skin and mucous membranes. In hypogastrium there is a rounded protrusion extending above umbilicus, produced by a full bladder. No obstruction to catheter's passage through urethra (No. 14 French). Urine is clear, no albumin, specific gravity 1.006; microscopically, many leukocytes and flat epithelial cells.

Neurologic status is negative except for exaggeration of knee jerks and ankle clonus. On passing catheter into bladder, patient voided 200 c.c. under good pressure, and on withdrawing catheter, patient voided another 40 c.c. in good strong stream.

Patient became infected and died of pyocyaneus sepsis.

Necropsy showed no obstruction in the urethra, cystitis, bilateral infected hydro-ureters and hydronephrosis together with other septic foci.

In the spinal cord (Professor Obersteiner) definite changes were found in the lower sacral segments (see original). These consisted of pathologic changes in the anterior cornua as well as of a congenital anomaly of the central canal.

Case 6 (Frankl-Hochwart).—Boy, aged 15 years, antecedents psychopathic. Patient weakly, underdeveloped? As a child had enuresis. Since one year, pains in glans penis and incontinence. Bladder was chronically distended and was expressible. Uremia led to death.

In posterior urethra, necropsy revealed a moderately developed *semilunar* fold (apparently out of proportion to the symptoms). Trabeculated bladder, dilatation of both ureters and pelves of kidneys. Spinal cord shows moderate dilatation of central canal and definite degenerative changes in the anterior cornua, second to fifth sacral segments.

The close analogy between these cases and those which follow, as well as the observation of similar spastic sphincter activities in adults in connection with spinal cord disease, suggests very strongly that the cases of Group 2 C are due to isolated disease of the sacral cord (sympathetic centers?).[5] Until we obtain more necropsies of these cases, the final proof will be lacking. Unfortunately, up to date I have been able to obtain only one cord (but no peripheral nerves, etc.) in this type of case (Case 8), and though this was not complete, the evidence it offers is very striking and corroborative of the foregoing point of view.

The end-result of all these cases, if nothing is done to relieve them, is infection of the kidneys and death. Under this Group, 2 C, I wish to describe briefly five cases. The first case presented some signs of a neurologic disturbance, and serves as a good link between Group 2 B and Group 2 C.

Case 7.—*Chronic retention of urine; bilateral pyonephroses; uremia.*—Man, aged 23, was very small at birth ("as long as a spoon") and was blue. Great efforts had been made to keep the patient alive. He was always very feeble. For fifteen years prior to his death his urine had been milky. Examinations showed this due to pus. Of late there had been some pain on urination and some bleeding. During the six months prior to his death, he began to show signs of failing kidney function, increasing pallor, drowsiness, weakness and apathy.

Patient was admitted in wretched shape. Respirations were exceedingly frequent and fairly deep and noisy. Pulse very feeble. Mind perfectly clear. General twitchings; very little urine secreted. Blood pressure 145 mm. Blood urea markedly increased. Cerebrospinal fluid was clear. Urine was full of pus; no sugar and no acetone.

Neurologic examination revealed both knee jerks markedly exaggerated; there were bilateral ankle clonus, left-sided Babinski and bilateral Kernig. Wassermann positive.

The patient soon became unconscious and died uremic.

Necropsy showed marked hypertrophy of the bladder, which was trabeculated and inflamed. The ureter openings were patulous, and both ureters and kidneys distended and infected (bilateral infected hydronephrosis). Careful examination of the urethra showed no mechanical obstruction. Unfortunately, the cord could not be examined.

Case 8.—*Chronic retention of urine; pyo-ureteronephrosis.*—Boy, aged 4½ years, has always had bladder trouble, more or less retention and dribbling. Hypogastric mass noted two weeks before admission. Passes urine frequently and has marked thirst. Two weeks ago fell down and after that parents first noted distended bladder.

Physical examination reveals a pale, underdeveloped child, with aged facies. In hypogastrium an ovoid mass, tense, elastic, feeling like a full bladder. Urine can be expressed by pressure on mass.

Neurologic status is negative.

Temperature is from 102.4 to 103.8 F.

Roentgenoscopy of spine for *spina bifida occulta*[6] was negative.

To relieve condition, patient was catheterized regularly, and from 250 to 450 c.c. were obtained.

Repeated attempts to relieve the spasm at the bladder neck with papaverin (from one-fifth to one-half grain) failed. Residual urine remained between 4 and 5 ounces.

Patient began to have higher temperatures, and a permanent catheter had to be inserted. No obstruction was encountered at any time in passing catheters. Subsequently patient developed right costovertebral tenderness, and urine became more and more turbid. Phenolphthalein test 15 per cent. in two hours.

Patient lost ground rapidly and died within two weeks of admission, despite permanent catheter and bidaily or daily irrigations.

No complete necropsy was permitted, but a small part of the lower spinal cord was obtained and examined by Dr. I. Strauss, who reports as follows:

There is a degeneration of both pyramidal tracts. The sections are about third, fourth and fifth sacral segments. Sections of the cauda equina show no root degeneration.

Case 9.—*Chronic retention; hypertrophied bladder; bilateral hydronephroses.*—Boy, aged 15 months. Physical examination reveals a globular tumor mass in the hypogastrium. It is always present except when emptied by a catheter, that is, distended, hypertrophied bladder. In left lumbar region is a mass corresponding to the position of the kidney. This is probably a hydronephrotic organ. No neurologic symptoms were elicited.

Cystoscopy (February, 1912) reveals bladder trabeculated, otherwise normal. No obstruction in urethra. Indigocarmin does not appear until four and three-quarters hours after injection, which suggests a bilateral kidney involvement.

Diagnosis of chronic retention, hypertrophied bladder, bilateral (probably) hydronephroses, due to spasm of vesical sphincter.

Case 10.—*Chronic retention of urine; pyonephrosis.*—Boy, aged 5½ months. Normal birth in 1910. Globular tender mass presented in hypogastrium, a trifle more marked on right side than on left. With the impression that this was an abscess (appendicular), an exploratory incision was made. This incision demonstrated that the tumor was a full bladder, and it was emptied with a catheter. The bladder filled again and remained distended throughout our observations; residual urine approximately 60 c.c. Later a mass developed in the *left kidney* region which proved to be an infected pyonephrosis.

No neurologic symptoms were elicited.

Case 11.—*Chronic retention; bilateral infected hydro-ureters and hydronephroses.*[7]—Boy, aged 5 years, had a fever four months before admission. Shortly thereafter there were blood in urine and in stools (prolapse?), and pain in right lumbar region. Condition had gradually become worse.

Physical examination was negative. No neurologic symptoms were elicited. Urine contained pus and pyocyaneus bacilli.

---

[5] In patients who have had infectious diseases, for instance, diphtheria, in making the diagnosis the possibility of a detrusor weakness due to chronic peripheral neuritis should be borne in mind.

[6] Compare case of Muchamisky: Urolog. Jahrb., 1913, p. 403.

[7] This case has been rather fully reported by Henry Heiman: A Case of Bilateral Hydroureter, Chronic Pyocyaneus Infection, Arch. Pediat., November, 1913, and by Leo Buerger: Congenital Hydroureter and Hydronephrosis, Internat. Clin., iv, Series 24.

Aug. 16, 1911: Cystoscopy and bilateral ureter catheterization. Bladder full of purulent urine washed clean before introduction of small cystoscope. Left ureter opening is patulous and seen to discharge purulent urine (infected hydronephrosis, tuberculosis?). Right ureter meatus is slit-shaped, normal. Indigocarmin excretion is negative in forty-five minutes, speaking probably for a bilateral renal involvement. Both ureters catheterized. Urine from right kidney was clear, from left, many pus cells, no tubercle bacilli, no growth on culture mediums.

As repeated examinations failed to show tubercle bacilli, the patient was treated with bladder irrigations, and urine became less purulent. Autogenous vaccines (from bladder urine) were also employed.

In August, 1912, the child was again admitted. There was a residual urine of 4 or 5 ounces, and urine was turbid with pus.

Almost fourteen months after the first cystoscopy, the second examination was made (Dr. Buerger), and it demonstrated that the condition had progressed. Both ureter openings were now patulous. The left orifice was enormously dilated; the right was also very much enlarged, although it still retained some of the natural outline of a normal ureteral orifice.

The development of the same condition on the right side as had existed fourteen months earlier on the left suggested bilateral hydronephroses and hydro-ureters, and with the aid of an argyrol roentgenogram, this was beautifully verified. At no time did we obtain any evidence of obstruction in the urethra, as all instruments passed into the bladder readily.

The condition of the patient gradually became worse, and in July, 1914, he died.

Necropsy (incomplete) showed bilateral infected hydronephroses. The left kidney was more enlarged than the right and was full of pus. The ureters were also markedly distended and tortuous. Both meatus were much dilated. The bladder was very much dilated, looking like an enormously enlarged adult bladder, and its walls were thinned. The urethra showed nothing abnormal.

Before saying a few words concerning the therapy in these cases, the question arises as to whether a unilateral renal involvement may obtain in this condition. Judging from the cystoscopic examination as well as from the urinary and necropsy findings in Case 11 as well as the course of Case 10, it would seem that the process for a time might be limited to one side or asymmetrically developed. This is of importance in trying to understand a case recently reported from Zuckerkandl's clinic by Bachrach:[8]

Case 12 (Bachrach).—Woman, aged 27, since childhood never urinated normally. Had to strain and wait at times one-half hour before finishing the act. After exposure, developed cystitis with right kidney pains.

Physical examination showed feeble, atrophic patient. Bladder extended 3 inches above symphysis. Catheter entered easily.

Cystoscopy revealed bladder inflamed, and trabecular hypertrophy with multiple diverticula. Left ureter meatus was normal, whereas the right ureter meatus was patulous. (No neurologic status mentioned.)

Collargol cystograph showed ascent of silver into right dilated ureter and pelvis.

Diagnosis: Infected hydronephrosis and hydro-ureter with "atonic" (Schlaffer) dilatation of vesical orifice.

This case showed what appears to be, but is not definitely proved to be, a unilateral involvement ascribed to atony by the author, basing his interpretation on J. Israel's conception of dynamic as opposed to mechanical obstructions. And this, despite the fact that he states that Israel believes such dilatations follow the repeated futile attempts of the contracting bladder[9] to empty itself in a normal way. The increased intravesical pressure forces one or both ureter openings: ureteral dilatation develops. Superimposed vesical infection probably hastens the process. In Bachrach's case, strange to say, no neurologic data are given. A survey of the essential facts of this incompletely described case will demonstrate a close similarity to the cases reported under Group 2 C. The second case reported in Bachrach's paper, also without neurologic status, presented a picture similar to my cases with bilateral hydro-ureter and hydronephrosis, and seems to belong in this group.[10]

Case 13 (Bachrach).—Girl, aged 16. Up to fourteenth year nocturnal enuresis. Since beginning of menses that has ceased, but there is difficulty in urinating. After exposure, urine became turbid and frequency developed (every ten minutes).

Physical examination reveals signs of incomplete urinary retention in bladder. Urine is cloudy with pus. Combined kidney function is lowered. (Indigocarmin in thirty-five minutes.)

Cystoscopy reveals trabeculated, inflamed bladder with numerous diverticula. Both ureter openings are widely patulous. Catheterization of ureters reveals a residual urine of from 100 to 120 gm. (partly reflux?).

Roentgenoscopy with collargol reveals ascent of silver salts into dilated ureters and pelves from bladder.

Diagnosis: Bilateral infected hydronephrosis and hydro-ureters with atonic dilatation of ureters.

THERAPY

When we come to treatment of these cases, a distinction must be made between Groups 1 and 2. In cases belonging to the former group, much can be accomplished. Mechanical obstruction, intrinsic and extrinsic, can usually be obviated. If such strictures cannot be reached through the bladder or the perineum, which will be seldom, if ever, a temporizing cystostomy operation will be in place. In cases belonging to Group 2, therapy is pretty well baffled. Medicinal treatment, for example, potassium iodid, perhaps mercury, and antispasmodics (papaverin) will have to be tried, together with dilatation of the sphincter; and if all attempts fail, a cystostomy will be indicated, perineal or suprapubic, with section of the bladder's neck. This operation should be done to save the progressive changes in the ureters and kidneys. Should a kidney become infected, it should be nephrotomized rather than taken out, whenever feasible, in view of the usual symmetrical development of the disease.[11]

[8] Bachrach, R.: Ueber atonische Dilatation des Nierenbeckens und Harnleiter, Beitr. z. klin. Chir., 1913, lxxxviii.

[9] Frequently seen in various types of cystitis as well as in neuromuscular disturbances.

[10] There are a number of other cases in the literature which appear to fall into Group 2 C, for example, J. Daland's case cited by Osler, in his Practice. From personal communication, Jan. 29, 1915, I learn that no obstruction was found, and the patient had the usual bilateral hydro-ureteronephroses. Unfortunately, no cord examination was made. E. Holt (Diseases of Infancy and Childhood, 1898) describes 8 cases of hydronephroses in 726 consecutive necropsies. In a series of 10 cases, in 7 only the left side was affected, and in 3 both sides. He says this condition is due to obstruction in ureter, bladder, urethra or prepuce, but in only 3 cases could sufficient or adequate obstruction be demonstrated. Double hydronephroses of congenital type result in death within the first year.

A STUDY OF IMMUNITY FOLLOWING THE USE OF TYPHOID VACCINES AND SEROBACTERINS

W. E. RICHARD SCHOTTSTAEDT, A.B., M.D.
FRESNO, CALIF.

In order to gain more information regarding the immunizing value of the various sensitized and nonsensitized typhoid vaccines in use at the present time, a series of experiments on rabbits was undertaken. Following the inoculation with such vaccines, blood was withdrawn at regular intervals, and estimations of the opsonic index and the agglutinating and bactericidal powers were made.

HISTORICAL

Clinicians are generally agreed regarding the immunizing value of typhoid vaccines and serobacterins, and such reports as those of Major Russell, of the U. S. Army, and the numerous data from other armies and institutions are convincing. Occasional failures to obtain immunity, as reported by Trowbridge, Finkle and Barnard,[1] may perhaps be explained by the use of a vaccine improperly prepared or improperly administered.

There is a discord in the opinions of men treating typhoid with vaccines. On the one side we have Elmer[2] and others condemning, and on the other Krumbhaar and Richardson[3] (who collected reports of 1,806 cases) and others recommending their use.

No good index of immunity exists, but a great deal of careful work has been done to throw light on the subject. Estimations of the immune bodies in the blood following the injections of vaccines have been made. In man, Wollstein[4] shows the height of the bactericidal power, and Moon,[5] Wade and McDaniels,[6] and Dyer[7] the height of the agglutinating power to be about two months after the first dose of vaccines. Some serums were negative as early as four months after the first injection, and most of them negative within one year. Still, we know that immunity usually outlasts this period. This resistance is probably due to a degree of sensitization of the body cells. It is also known that persons who have had typhoid fever previously react severely to immunization with typhoid vaccines, probably for the reason just given.

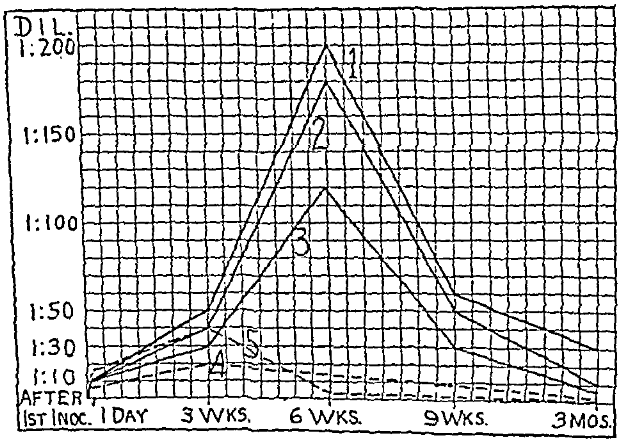

Chart 1.—Agglutinins.

Animal experimentation, though small, has largely borne out the foregoing data obtained from human serum. Freshly isolated cultures of *Bacillus typhosus* do not agglutinate as readily as subcultures, but McIntosh and McQueen,[8] and Gay and Claypole[9] found that inagglutinable strains, when injected into animals, led to the production of typhoid agglutinins which had no action on themselves but agglutinated heterologous strains freely. Johnston[10] found an increase in the bactericidins and a rise in the opsonic index to 4.7 following typhoid vaccination in rabbits. Thus, although there is of necessity a difference in the reactions found in human as opposed to rabbit blood, there is also an analogy.

It has been found by Cecil[11] and Stone[12] that vaccines killed by the addition of phenol (carbolic acid) or tricresol are more potent than those killed by exposure to heat. Cecil[11] also found that sensitized typhoid vaccines when injected *intravenously* have only one-third the virulence of nonsensitized typhoid bacilli, probably because the former undergo phagocytosis and bacteriolysis more rapidly.

The Besredka sensitized living typhoid vaccine is apparently most active. It does not produce typhoid fever or typhoid carriers if the strain is an old one, as shown by Nichols,[13] Castellani,[14] Metchnikoff and Besredka,[15] the latter having been unable to immunize chimpanzees except with this type of vaccine. In 745 persons whom they vaccinated, no carriers and no cases of typhoid developed.

Nègre,[16] working with rabbits, found that after the use of ether-killed vaccine the serums showed a very high agglutinating power with low bactericidins and antibodies, whereas the living sensitized vaccine produced low agglutinins but high bactericidins and antibodies. Typhoid vaccine killed by heat produced high agglutinins and low bactericidins.

MATERIALS AND METHODS

For this study, twelve rabbits from two litters of about the same age and weight were taken. Two rabbits served as controls, and the remaining ten were divided into pairs, one rabbit from each litter, and were injected *intravenously with the following* vaccines:

Vaccine 1: This vaccine was prepared by growing typhoid bacilli on agar slants for twenty-four hours, washing off the growth with salt solution, and then killing and standardizing in 0.6 per cent. phenol.

Vaccine 2: This vaccine was made as Vaccine 1, but killed by heating at 56 C. (132.8 F.) for one hour, and then standardized in 0.4 per cent. phenol.

Vaccine 3: This vaccine was made as Vaccine 2, but before the bacilli were killed they were washed till the filtrate gave a biuret negative test.

These three vaccines were made from the same strain of typhoid bacillus and standardized by the hemocytometer method, the Helber blood-platelet counter being used. Injections of 500 million, 1,000 million and 1,000 million were given at weekly intervals.

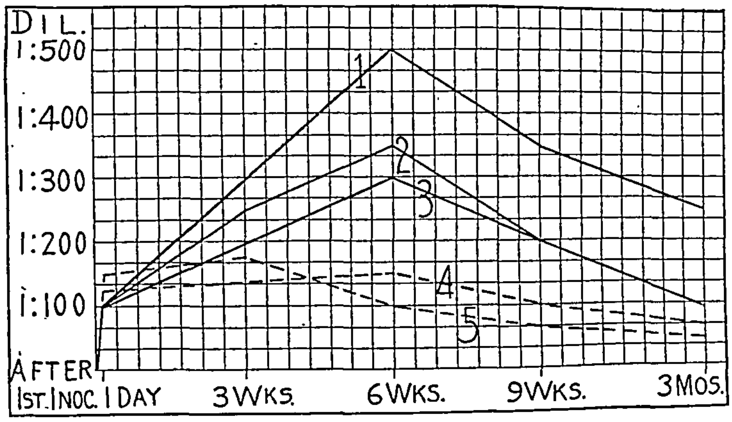

Chart 2.—Bactericidins.

Vaccine 4: This vaccine was kindly furnished by the California State Board of Health. It is sensitized vaccine made according to the method of Gay and Claypole, and given according to their directions in three doses of approximately 750 million typhoid bacilli every other day.

Vaccine 5: This vaccine was the Typho-Serobacterin Mulford immunizing package, bought in the open market. It was administered according to the directions accompanying the package.

The rabbits were kept separated and were fed alike. Rectal temperatures were taken and blood collected at regular intervals. The rabbit's ear was flipped vigorously for a few minutes, washed with xylene and alcohol, and one of the marginal veins punctured; in this way sufficient blood for the test was easily secured. The bacteriologic tests were made on the same day that the blood was drawn.

General reactions, such as a fever of from 2 to 2.5 degrees and loss of appetite for two or three days, occurred in all four rabbits receiving Vaccines 1 and 2, but only after the first injection. There was a slighter reaction in one of the rabbits receiving Vaccine 3, and in the other rabbits receiving the same vaccine the reaction was mild, extending only over the day of administration of the vaccine. There was no general reaction after any succeeding doses, neither was there any sign of general reaction in the rabbits receiving the sensitized Vaccines 4 and 5. The serums were tested with the same cultures of typhoid bacilli from which Vaccines 1, 2 and 3 were made. The agglutinins were tested according to the usual microscopic methods, with a time limit of thirty minutes.

The bactericidins were tested by making progressive dilutions of serum, mixing them with equal parts of a twenty-four hour culture of bacilli, and incubating at 37 C. (98.6 F.) for fifteen minutes. This was plated, and the number of colonies estimated after twenty-four hours. The opsonic index was made according to Wright's method, and 100 cells were counted.

It was found that none of the rabbits before the injection had agglutinins to typhoid, and that the bactericidins were not present above a dilution of 1:5.

The results of the tests for agglutinins, bactericidins and opsonins are given in the accompanying charts; the numerals refer to the vaccines used and are the same as those used above in describing the preparation of the vaccines.

1. Nonsensitized vaccine killed by the addition of 0.6 per cent. phenol.
2. Nonsensitized vaccine killed at 56 C. standardized in 0.4 per cent. phenol.
3. Nonsensitized washed vaccine.
4. Sensitized vaccine, Gay and Claypole method.
5. Sensitized vaccine, Typho-Serobacterin Mulford, Immunizing.

No negative phase was observed in this series. Taken as a whole, both the agglutinins and the bactericidins in this series were lower than those obtained by the majority of other workers. These individual variations can largely be accounted for by the use of different strains of bacteria and some differences in the methods used. The aim of this study has been toward simplicity. It may be possible that the apparent lack of immunity after the administration of sensitized vaccines is due to the fact that the serums were tested with a culture different from that used in the manufacture of the vaccine, that is, the culture from which Vaccines 1, 2 and 3 were made, and with which the serums were tested.

SUMMARY

There is a slight reaction following the injection of nonsensitized vaccines in rabbits, which is absent following the injection of sensitized vaccines.

Vaccines killed by heat seem to be less active than those killed by the addition of phenol only.

Washing the vaccine does not seem especially to influence its immunizing value.

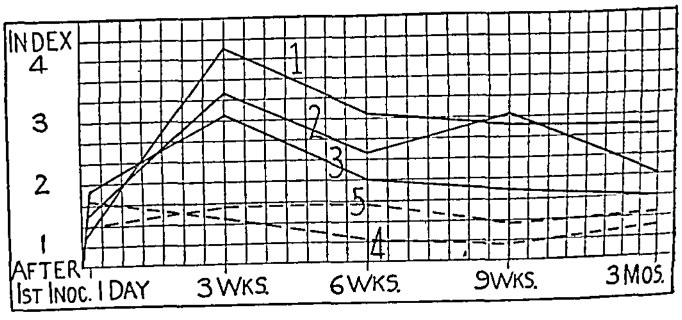

Chart 3.—Opsonins.

The height of the immunity curves occurs earlier after sensitized than nonsensitized vaccines, but the former appear to be only about one fourth as potent.

The agglutinins practically disappear within three months after the first injection, while bactericidins and opsonins can be detected much longer.

Opsonins increase more quickly than do agglutinins and bactericidins.

Opsonins and bactericidins remain more permanent than agglutinins, and immunity is more likely due to the former than to agglutinins.

Sensitized typhoid vaccines are less potent than nonsensitized typhoid vaccines, probably because the bacteria of sensitized vaccines undergo phagocytosis and bacteriolysis more rapidly.

CONCLUSIONS

In conditions in which a prolonged reaction is desired, as in conferring immunity, the nonsensitized vaccines seem preferable.

In conditions in which no general reaction is wanted and a quick response of the protective powers desired, as in active typhoid fever, a sensitized vaccine would seem preferable.

THE ACETONE BODIES IN DIABETES MELLITUS

INFLUENCE OF LOW AND HIGH PROTEIN INTAKE ON THE EXCRETION OF ACETONE, DIACETIC ACID AND BETA-OXYBUTYRIC ACID

JACOB ROSENBLOOM, Ph.D., M.D.
PITTSBURGH

INTRODUCTION AND REVIEW OF LITERATURE

I have frequently noted that the administration of increased amounts of protein to diabetics often increases the amounts of acetone, diacetic acid and beta-oxybutyric acid excreted in the urine. Magnus-Levy[1] has had a similar experience, and asserts that the increased excretion of the acetone bodies does not mean that they have been formed from the protein but on account of the high protein content of the diet, which makes an extra tax on the oxidizing powers of the body and diverts these from the combustion of the acetone bodies.

It is now firmly settled that the acetone bodies are mostly derived from the fats and especially from the fats composed of the lower fatty-acids.[2] Knoop,[3] Ringer[4] and others have shown that in the catabolism of fatty acids the carbon chains are broken down by the oxidation of the third carbon atom from the end, that is, in the beta position, and the two end carbon atoms are then split off. It follows that two carbon atoms are separated at a time, and therefore every fatty acid which contains an even number of carbon atoms can be converted into beta-oxybutyric acid.

TABLE 1.—RESULTS OF TESTS *

Normal fatty acids which contain an odd number of carbon atoms cannot yield beta-oxybutyric acid.

The acetone bodies might readily be formed from proteins, by separation of the NH_2 group from the amino-acids.[5] It was formerly thought that they could be formed from carbohydrates, as is the closely related lactic acid, but we now know that this is not true.[6] It is to be remembered, therefore, that theoretically the acetone bodies may be formed at the expense of proteins or fats, but that usually they are formed from the fats and in severe diabetes from the fatty acids produced by the deaminization of amino-acids.[7]

TABLE 2.—COMPOSITION OF OX MEAT

Arginin	7.47
Histidin	1.76
Lysin	7.59
Ammonia	1.07
Tryptophan	Present

It has been asserted by several observers[8] that sugar produced from protein can inhibit the formation of acetone bodies just as well as carbohydrate can. This statement is based on the fact that with an increase of protein catabolism the acetonuria is lessened, if at the same time the protein given does not drive up the glucosuria and thus do away with the inhibitive action that the protein sugar would exert.[9] In health the catabolism of large quantities of protein can dissipate acidosis on account of its partial conversion into sugar, but in diabetes protein does not act so, as the sugar is not burned up.

Borchardt[10] found that protamin, histon, egg albumin, pancreas and casein, which contain monamino-acids, increasing in the order named, when given to healthy subjects, showing acidosis from carbohydrate starvation, produced different effects on the amount of the acetone bodies excreted. Protamin increased the acidosis, while casein reduced it. Rosenthal[11] found that when meat, casein, egg albumin or thymus were added to a high protein diet they all increased the acetonuria. He thought the higher the glycogen-producing quantity of the protein and its content of monamino-acids, the less is its ability to produce acetone. Lüthje[12] asserted that calf thymus reduced diabetic acidosis, while casein increased it. Labbé,[13] Cammidge,[14] von Noorden,[15] and Hugounenq and Morel[16] have all shown that a high protein feeding to diabetics has a ketogenic influence which in time may be of serious import. Moorhouse, Patterson and Stephanson[17] have recently shown that in experimental diabetes in dogs the course of the acetone excretion bears a close relation to the protein metabolism, and they think that the acetone excretion depends on the character of the proteins fed, as they found that when feeding erepton, the acetone excretion was high. On feeding caseinogen, the amount of acetone excreted fell, and on feeding gelatin the acetone was markedly diminished.

METHODS

The standard strict diets of von Noorden[18] were used in this work. The increased amount of protein added to the diet was always given as meat. The glucose was estimated by Benedict's[19] method, the acetone and diacetic acid by Folin's[20] method, and the beta-oxybutyric acid by Shaffer's[21] method.

EXPERIMENTAL

Table 1 presents the results obtained in this study. All of the five cases studied show a marked increase in the amounts of the acetone bodies excreted in the urine when the protein intake was increased; and when the protein intake was lowered, the amount of the acetone bodies excreted was lessened.

TABLE 3.—COMPOSITION OF GELATIN

	Per Cent.
Glycocoll	16.5
Alanin	0.8
Valin	1.0
Leucin	2.1
Isoleucin	..
Phenylalanin	0.4
Tyrosin	0
Serin	0.4
Cystin	..
Prolin	7.7
Oxyprolin	3.0
Aspartic acid	0.6
Glutamic acid	0.9
Tryptophan	0
Arginin	7.6
Lysin	2.8
Histidin	0.4
Ammonia	0.4

These results may also explain partially the remarkable effects of the so-called green days and oatmeal days in lessening the amount of acetone bodies excreted in the urine. As both of these diets contain very little protein (typical green days 30 gm., and typical oatmeal days 51 gm.), it may be that part of the lessened excretion of acetone bodies is due to the lowering of the protein intake.

It is most likely that the increased excretion of the acetone bodies produced by increasing the protein intake is due to the fact that some of the amino-acids present in the protein act as ketogenic substances. In Table 2 is given the most complete analysis of ox meat.[22]

It is well known that of these constituents the *leucin*, *tyrosin* and *phenylalanin* are ketogenic, and it may be that the increased excretion of the acetone bodies is due to the presence of these amino-acids in the increased amount of meat protein ingested.

22. Osborne and Jones: Am. Jour. Physiol., 1909, xxiv, 438.

Another reason to suspect that this is the case may be found in the results obtained by Moorhouse, Patterson and Stephanson. They found that, of the various proteins studied in regard to their effect on the excretion of acetone in dogs rendered diabetic, gelatin produced a marked diminution in the excretion of these bodies. I think the explanation of this result is due to the fact that gelatin contains very small amounts of *leucin, tyrosin* and *phenylalanin,* as may be seen from the analysis[23] given in Table 3.

The importance of restricting the amount of protein in the diet in diabetes has long been well known in regard to the sugar excretion.[24] I present in this paper data showing the importance of restricting the protein intake in diabetes in relation to lessening the amount of excretion of the acetone bodies in the urine. It is possible that by selecting proteins free from those amino-acids that are ketogenic we may be better able to control the formation of the acetone bodies in this disease.

THE PREVENTION AND TREATMENT OF RINGWORM AND FAVUS OF THE SCALP

J. E. LANE, M.D.
NEW HAVEN, CONN.

In a recent case report of "Two Favus Families,"[1] I illustrated some of the results of neglecting to attend properly to every case of favus of the scalp as soon as it is discovered.

Ringworm and favus of the scalp are not common diseases in many of our smaller cities and towns. The importance, therefore, of properly caring for the early cases, in order to prevent their spread, is often insufficiently appreciated by the health authorities and physicians of such localities.

In addition to this, the profusion of drugs recommended for these diseases, as well as the lack of detailed information of the method of carrying out the treatment and of what is expected from it, leave the physician, who is unfamiliar with these diseases, uncertain what to do.

As ringworm and favus are closely related, and as their treatment is similar, they may well be considered together. Both are children's diseases and preeminently diseases of the school age. Ringworm of the scalp heals spontaneously at the approach of puberty, and is almost never found in an adult. Favus almost always begins in childhood, but unlike ringworm, does not usually heal spontaneously until it has destroyed all the hair of the scalp, which frequently is not until late in life.

These diseases do not affect the general health, and their importance consists chiefly in the loss of education to the individuals affected, as the children are usually excluded from school. In the case of favus this exclusion generally includes the whole school life of the child, if he is not properly treated.

The objects to be sought in the management of these diseases are the prevention of their spreading to others and the cure of the affected individuals.

In order to prevent their spread:

1. All cases should be reported to the health authorities, who should have the power of supervising them. Diseases which are excluded from this country by the federal government are not too unimportant to be noticed when they are found here.

2. Whenever a case is discovered in a school, all the children in the room should be examined. This is more necessary in the case of ringworm than in that of favus, as it is much more contagious than the latter, which is usually contracted only by members of the immediate family.

3. Whenever a case is found, it should be ascertained whether there are other children in the family or house, and if there are, all these children should be examined, for it is the exception for only one child of a family to be affected in the case of ringworm, and in the case of favus more than one are frequently affected. This is easily understood, as both diseases are especially found in unhygienic and crowded quarters.

4. Houses in which cases have been found should be thoroughly disinfected after the disease is cured or when they are vacated.

Other precautions for the prevention of the spread of the diseases naturally come under the head of treatment and will be considered there.

The modern and only satisfactory rapid method of curing these diseases is by the use of the Roentgen ray, but as it can be employed only by a skilled roentgenologist who has had an opportunity of previously seeing its application, and as it is not practicable in localities in which there are only a few cases to be treated, it will be simply mentioned in this place.

Strickler[2] of Philadelphia recently reported good results in ringworm with a vaccine treatment, which will be of great value if further use confirms his results.

Before considering the treatment in detail, it will be well to consider some of the difficulties to be contended with. In the first place the fungi are extremely tenacious of life when removed from the scalp. Ringworm can ordinarily be produced from crusts which have been preserved for from three to six months, and instances of successful inoculation have been known to take place after eighteen months, though the spores are always dead after two years. The life of the fungus in the hair is longer, and spores in removed hairs will usually grow after fifteen or eighteen months. Favus spores have been found living in scutula after two years.

In locations in which they can be reached by antiseptics, the fungi are easily destroyed, but in both diseases a large number of the fungi are buried deeply in the hair follicles and in the interior of the hairs. When we consider the fact that in the case of ringworm "soaking the hair in absolute alcohol for as long as twelve hours will not inhibit the growth of the fungus," we are not surprised that "the resistance of the parasite in the hair follicle has up to the present time remained almost absolute to all chemical agents." This statement may be extended to include the Roentgen ray, which does not kill the parasites.

[2] Strickler, Albert: The Vaccine Treatment of Ringworm of the Scalp, The Journal A. M. A., July 17, 1915, p. 224.

From these facts is easily seen the futility of all treatment by antiseptics alone, in whatever form they may be used. They are necessary but, without the removal of the deep-seated fungi, they are unable to effect a cure of either disease. In this connection it may be well to quote Sabouraud,[3] to whom all who say anything about these diseases must acknowledge their indebtedness. He says that "the frequent observations of favus cured without depilation by various applications must assuredly be ranked as fables," and that "when an author claims to have cured a tinea tonsurans in three weeks, he evidently does not know what he is talking about, and the only reply that can be made is, that it takes at least six weeks to affirm that it is cured."

TREATMENT

1. The hair should be cut short over the whole head, but it should not be shaved, as this would prevent effectual depilation. This is essential in all cases of favus and in all cases of ringworm, except those of very limited extent. In these the hair must be cut well around the edges of the affected area. The purpose of this is cleanliness, prevention of the spread of the disease, easier discovery of new patches, and facilitation of the treatment.

2. When crusts are present they must be removed. This is best accomplished by soaking the head with oil for a day or two to soften them. Cottonseed oil, to which 1 per cent. of betanaphthol has been added, serves the purpose admirably. The head is then washed with an antiseptic soap for which the following formula may be used:

℞	Betanaphtholis	3 parts
	Sulphuris praecipitati	10 parts
	Saponis mollis	q. s. ad 100 parts

3. Depilation is the most important as well as the most difficult and tedious part of the treatment, except when the Roentgen ray is used. The most satisfactory method of depilation is still that of the thumb forceps, although many easier and quicker methods have been tried. In extensive cases of favus, the whole head must be depilated and redepilated as fast as any hair grows, for at least three months. In early cases with small areas involved the depilation may be limited to the affected areas and a circumference of half an inch. In the case of ringworm, depilation of the patches cannot be completely accomplished, as many of the hairs are broken off and the rest are so fragile that they break when this is attempted. But all patches should be kept as completely depilated as possible, together with the surrounding area, as in the case of favus.

4. The value of antiseptic applications lies in the destruction of the superficial fungi and in preventing the spread to other spots and to other individuals. They also serve the additional purpose, in the case of ringworm, of irritating and causing some inflammation in the affected areas, which facilitates the expulsion of the stumps of the broken hairs that cannot be pulled out. The affected areas are painted daily with:

℞	Tincturae iodi	20 parts
	Alcoholis	80 parts

and the following ointment applied to the whole head:

℞	Hydrargyri praecipitati flavi	1 part
	Sulphuris praecipitati	1 part
	Resorcinol	1 part
	Olei cadini	10 parts
	Adipis lanae	10 parts
	Petrolati	10 parts

5. The head should be washed daily or every other day with the antiseptic soap for which the formula has been given. If crusts persist in forming they are softened and removed as often as necessary.

6. The following additional precautions should be taken: It is hardly necessary to say that individual toilet articles should be used. Keeping the hair cut short removes any necessity for the use of comb and brush. Affected children should sleep alone. Other children should not be allowed to wear the hats of the patients. The heads should be isolated as well as possible, and for this purpose there is nothing better than a tight-fitting cotton cap which can be boiled or thrown away when soiled. The scalps of persons affected with these diseases bear irritation remarkably well, and there is usually no occasion for interrupting the treatment. However, if the heads become sore from it, it is stopped for a few days, and petrolatum applied till it is resumed.

If these steps are carried out faithfully for a long enough period of time, the diseases will be cured and their spread pretty well limited. In extensive cases, the time necessary for cure is not likely to be less than two years, except in some of the rarer varieties of ringworm. When a case after vigorous treatment is apparently cured, treatment should be suspended for a month or six weeks. If there are no signs of recurrence at the end of that time, the patient should be examined occasionally for another six weeks before he is pronounced cured. If, in the meantime, any unhealed spots become visible, treatment should be at once resumed.

This is not an easy way to cure these diseases, but the more thoroughly it is realized that, with the exception of the Roentgen ray, there is no easy way of curing them, the better shall we take the precautions necessary for preventing their becoming so numerous as to present a serious problem.

The applications mentioned are no better and no more efficient than many others. They may be varied ad libitum with perfect confidence that many others are just as efficient in keeping the surface clean, and just as inefficient for affecting the disease in the hair follicles.

The difficulties encountered in the treatment of ringworm have been well stated by Martin[4] as follows:

1. The multiplicity of treatments proposed.
2. The confusion in the diagnosis of the different varieties.
3. The certainty of an ultimate spontaneous cure.
4. The depth of the anatomic seat of the lesion.
5. The difficulty of diagnosis, especially of an early diagnosis.
6. The difficulty of diagnosis of cure.
7. The difficulties of prophylaxis.

All of these difficulties are considerable in the case of ringworm, and for the most part equally so in the case of favus.

I have avoided adding to the confusion by mentioning any new drugs or combination of drugs that are still constantly being suggested with claims for the remarkable results referred to by Sabouraud as "fables." A few of the statements made here are not strictly applicable to some of the rarer varieties of ringworm, but it seemed best not to complicate the subject by calling attention to exceptional cases.

NEPHRITIS

A NEW SERIES OF CASES WITH A REVIEW OF RECENT LITERATURE *

W. OPHÜLS, M.D.
SAN FRANCISCO

RESULT OF AUTHOR'S INVESTIGATION

The material for this investigation has been collected since the reading of my first paper. On the whole the method of investigation and the class of cases covered has been the same, but in this instance the anatomic research has been supplemented by a careful study of the clinical histories.

The material comprises eight cases of amyloid disease associated with chronic parenchymatous nephritis, thirty-four cases of general arteriosclerosis with cardiac hypertrophy, in which the kidneys were slightly involved in twelve and moderately diseased in twenty-two cases. In addition there were eight cases of general arteriosclerosis with more extensive renal lesions of the type described in my first paper as arteriosclerotic nephritis. The most interesting group was that of thirty-two cases of glomerulonephritis of which four were acute, eight subacute, seventeen chronic; in addition, belonging to the last group, there were three cases in children which it was difficult to classify on account of the peculiar mixture of subacute and chronic lesions in them.

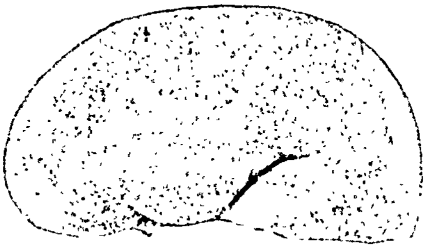

Fig. 1.—Case XVII, 188, acute glomerulonephritis; one-half normal size.

SUBACUTE AND CHRONIC PARENCHYMATOUS NEPHRITIS

These cases certainly, of themselves, form a separate group, both anatomically and clinically. They represent the "nephroses" of Volhard and Fahr.[4] Their most characteristic feature, histologically, is the extensive epithelial degeneration with granular change and development of double refractile lipoid droplets. The diseased tubules are usually full of casts. Amyloid was found again in all my cases, although in some the amount of amyloid in the glomeruli was not very large. In all cases amyloid was also found in the spleen or liver or both. The etiologic factors in all of them were the usual causes of amyloid disease (chronic tuberculosis in three, chronic syphilis in one, malignant tumor in one, chronic suppuration in three).

From the very beginning, as emphasized in my previous paper, these cases show inflammatory lesions in and about the glomeruli. In the early stages there may even be a very heavy infiltration of the glomeruli and of the interstitial tissue with polymorphonuclear leukocytes. Connective tissue proliferation sets in early and eventually may lead to considerable shrinkage of the kidneys, which at first are very large and white. On account of these inflammatory changes, the occurrence of which in the later stages is acknowledged by Volhard and Fahr, I believe that their appellation "nephrosis" is faulty and I still prefer the term acute, subacute or chronic parenchymatous nephritis with, or possibly without, amyloid.[5]

Clinically these cases are characterized by very pronounced urinary findings (much albumin, many casts), marked edema (although very emaciated cases may remain "dry"), absence of hypertension and a small heart.

GLOMERULONEPHRITIS

1. Acute glomerulonephritis: Figure 1 shows a characteristic gross specimen of this condition and Figure 2 is a photomicrograph taken in a typical case. The kidneys in these cases are usually considerably swollen, hyperemic, edematous, somewhat opaque.

Petechial hemorrhages are frequently found in the cortex, but they vary considerably in number. The best descriptive term to apply to these kidneys is large variegated kidney, because their discoloration contrasts strongly with the extreme pallor of the amyloid kidneys (large white kidney).

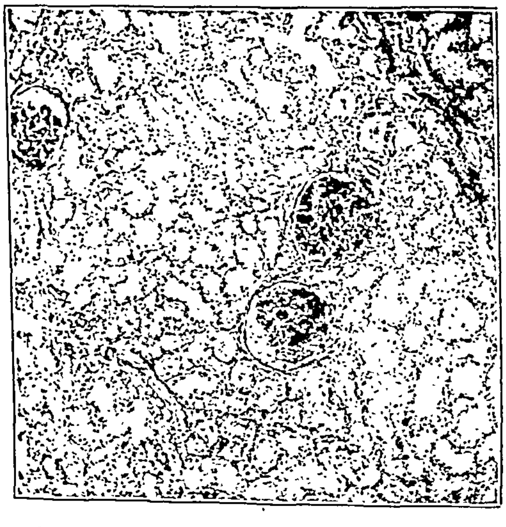

Fig. 2.—Case XVIII, 158, acute glomerulonephritis; magnified 57 times.

The histologic features of the process are acute inflammatory lesions in and about the glomeruli, inflammatory hyperemia, and edema of the interstitial tissue, blood, leukocytes and casts in the tubules. The epithelium is more or less degenerated. The presence of numerous neutrophilic and of some eosinophilic leukocytes in the affected glomeruli and in the tissues plainly show the inflammatory character of the condition.

The urinary findings are very pronounced; there may be edema. Blood vessels and heart are still normal except for accidental lesions.

The condition is caused by septic infection, usually with streptococci, and the death of the patient is due to the overwhelming infection, the nephritis playing a minor part in the clinical symptom-complex.

Even at this early stage a certain degree of anemia may have developed on account of the underlying septic infection.

In three of our cases the acute *diffuse* glomerulonephritis was the result of a final exacerbation of a chronic diplostreptococcus endocarditis.

* Because of lack of space the review of the literature has been omitted in The Journal. The complete article appears in the Transactions of the Section and in the author's reprints. A copy of the latter will be sent by the author on request.

[4] Volhard and Fahr: Die Brightsche Nieren-Krankheiten, Berlin, 1914.

[5] In this consideration I have eliminated the purely toxic forms of nephritis like the corrosive sublimate kidney, etc., on account of lack of suitable material.

2. Subacute glomerulonephritis: In these cases the kidneys are also large, more or less opaque and variegated. Some of them are studded with minute hemorrhages (Fig. 3) others are more pale as in Figure 1. Histologically the glomeruli show hyaline necroses of some of their loops, intracapillary and extracapillary proliferation (Fig. 4). The tubules are in the same condition as in the acute cases. The infiltration of the interstitial tissue with neutrophilic and eosinophilic leukocytes is often very severe and there are evidences of a beginning diffuse proliferation of the connective tissue. The blood vessels locally and generally are still normal except in the late cases, when a local involvement of the blood vessels may be noticed. The blood pressure rises gradually to 180 to 200 and there may be seen at necropsy a commencing hypertrophy of the left ventricle.

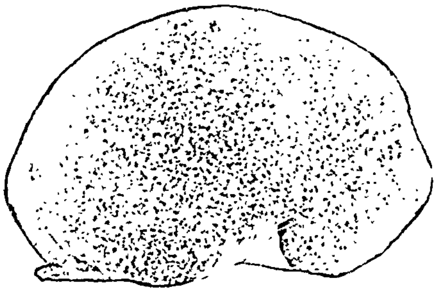

Fig. 3.—Case XVIII, 166, subacute glomerulonephritis; one-half normal size.

The urinary findings are very marked and in one of our late cases there was evidence of a beginning polyuria. The anemia is also more noticeable.

The etiology in all cases is very evident in a comparatively recent history of tonsillitis, rheumatism and other forms of streptococcus infection with or without endocarditis. The latter was present in four of our eight cases. One of our cases, a very pronounced diffuse subacute glomerulonephritis in a baby of 2 months, was remarkable on account of the absence of streptococcus infection. In this case the lesion must be attributed either to a severe colon bacillus pyelitis or possibly to congenital syphilis, of which there was definite clinical and anatomic evidence.

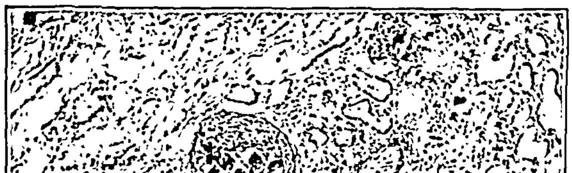

Fig. 4.—Case XIV, 34, subacute glomerulonephritis; magnified 57 times.

Edema is often marked, but is not always present. One late patient in whom the condition had been running for about six years had an albuminuric retinitis and died in uremic coma. Most of the patients, however, died within one year of the infection, but there were three late patients who lived thirteen months, four years and six years, respectively. In several of these late subacute cases the symptoms of the original infection had more or less subsided and the symptom-complex was dominated by the nephritis.[6]

In both acute and subacute cases diplostreptococci can often be found in the urine.

3. Chronic glomerulonephritis: In chronic glomerulonephritis the kidneys show marked evidence of contraction which is either diffuse, and then the surface of the organ remains smooth (Fig. 5), or irregular, producing a granular (Fig. 6), or sometimes even coarse, nodular, surface. The capsule is thickened and adherent. The color varies from dark red with numerous hemorrhages to a pale putty color. Quite often one notices a distinct brownish tinge on account of hematogenous pigmentation of the epithelium and other tissues. Some of the kidneys are more or less cystic. The cortex is narrow and the markings on the cut surface are indistinct.

The microscope (Fig. 7) shows a marked diffuse proliferation and fibrous transformation of the connective tissue with atrophy of many tubules. Other tubules may remain large or even become hypertrophic. Many of them still contain leukocytes and red blood corpuscles. There may be much epithelial degeneration and many casts. The glomeruli become more and more fibrous and eventually are transformed into small solid nodules of hyaline connective tissue. Even at this stage, however, one usually encounters at first many, later few, glomeruli with subacute lesions; which finding materially assists in the histologic diagnosis.

The blood vessels in the kidney show most remarkable differences. In some very old and far-advanced cases they remain practically normal, in others they show intense lesions very early. These vascular lesions develop into extreme degrees of endarteritis both in the small and in the larger arteries. The disease of the blood vessels remains localized in the kidneys and the renal arteries in the majority of cases (ten in our series of fifteen with marked vascular lesions) but there are some in which a very pronounced degree of general arteriosclerosis develops eventually.

The blood pressure is always elevated and runs up to 200, more rarely to 250. The heart is usually enlarged, but within moderate limits. The wall of the left ventricle, however, may show a very evident concentric hypertrophy. There were three cases with normal or even small hearts.

The urine continues to show considerable albumin, more or less constantly. Casts may be present at all times or in showers. Red blood corpuscles and leukocytes are found frequently. Practically all our cases showed a marked polyuria and some definite hyposthenuria. The phenolphthalein excretion when measured was always found considerably diminished and sometimes almost entirely suppressed.

Edema is a very common symptom, but there are "dry" cases. Uremia is often observed (eleven cases out of seventeen); retinitis albuminurica more rarely (three out of seventeen).

Anemia, with very few exceptions, is well developed; it being very common to see a reduction of red blood corpuscles and hemoglobin to one half or less. The character of the anemia is that of a severe secondary anemia.

It is natural, that in these old cases it is much more difficult to detect the original infection which caused the nephritis, unless it persists palpably in the form of an old endocarditis or, as in one of our cases, in the shape of an old septic infarct of the spleen, full of influenza bacilli. A careful study of the clinical record, however, usually reveals a very definite history of repeated attacks of tonsillitis, rheumatism or other septic troubles, and it is suggestive that the better the record the more commonly is there note of such conditions. In some cases it may be possible to discover the old septic focus at necropsy, although this may not always be an easy matter. In some cases the urinary tract itself may afford a hiding place for the streptococci, they being found more or less constantly in the urine, and at necropsy in smears from the slightly inflamed renal pelvis or urinary bladder. The more intensive study of this series of cases has greatly strengthened my previous conviction that all these cases are due to septic and mostly streptococcic infections in the last resort, and also the idea that it is the continuance of this infection in more or less hidden foci which keeps the process in the kidneys going.

---

[6] Volhard and Fahr distinguish between a more severe form of subacute glomerulonephritis with much extracapillary proliferation in the glomeruli and a milder form with intracapillary lesions only. I believe this is an unnecessary refinement, but there is no question that the cases with much extracapillary proliferation are the severer ones.

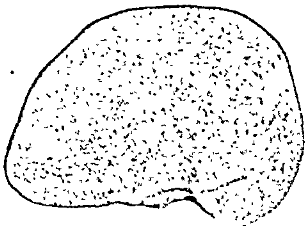

Fig. 5.—Case XVI, 10, chronic glomerulonephritis; diffuse contraction with smooth surface; one-half normal size.

4. Subacute and chronic glomerulonephritis in children: This small separate group of three cases of glomerulonephritis in children is especially interesting for several reasons. The etiology was very evident in all three cases, in one a general diplostreptococcus sepsis with an infectious aneurysm of the abdominal aorta without history of tonsillitis, in another repeated attacks of tonsillitis and in the third, a boy of 6 years, nephrolithiasis with development of a large calculus in the bladder and streptococcus infection of the urinary tract.

The rise of blood pressure in these three cases was well marked (about 150) and the cardiac hypertrophy very definite, in fact, more pronounced than in adults, as one would expect in the youthful organism. This in the absence of all signs of general arteriosclerosis and in one case of all local vascular change in the kidneys definitely proves that the hypertension in nephritis is not the result of arteriosclerosis. In two cases there was very marked local arteriosclerosis in the diseased kidneys without any further involvement of the arteries elsewhere, proving also that the arteriosclerosis in the kidneys in these cases is purely the result of local conditions.

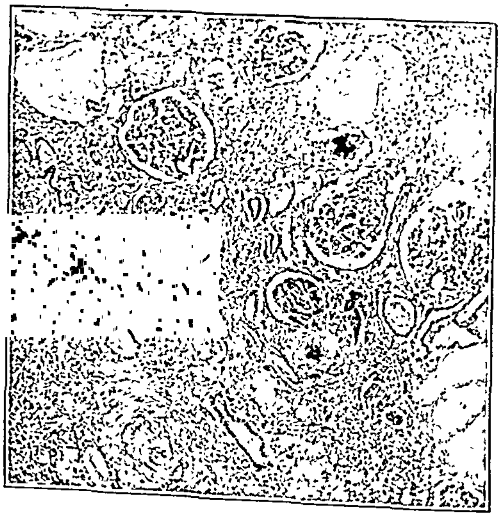

Fig. 7.—Case XVIII, 19, chronic glomerulonephritis; magnified 57 times.

5. Focal hemorrhagic glomerulonephritis (Löhlein): In subacute or chronic bacterial endocarditis, Löhlein[7] has described glomerular lesions which he believes to be essentially different from those in true glomerulonephritis. Baehr,[8] who studied the kidneys in twenty-five cases of bacterial endocarditis, found this condition in twenty-three of them and gave a very complete description of the process. The characteristic feature appears to be a hyaline necrosis of a circumscribed portion of a certain number of glomeruli, associated with hemorrhage. The hyaline material is later organized and replaced by fibrous tissue. Löhlein suggested that the condition might be of embolic origin, due to the detachment of very small pieces of septic thrombus from the heart valves, but he was unable to find any bacteria in the hyaline material which fills the capillaries of the glomeruli in these cases. Since then Baehr has actually demonstrated the diplostreptococci in the affected loops in five of his more acute cases, in specimens that were fixed in alcohol. The bacteria, however, seem to disappear very rapidly in the lesions; as Baehr says: "In the later stages of the lesions, bacteria were never found; apparently they underwent destruction during the early stages when the glomerular structure was disintegrating." Inflammatory lesions in and about the affected glomeruli are usually absent or much less intense than in ordinary glomerulonephritis, but when the condition involves the major part of a glomerulus and is associated with a more intense reaction, as sometimes happens, it is difficult to distinguish it from true glomerulonephritis. The focal character of the disease also varies a good deal in different cases, sometimes a few glomeruli being affected, at other times a great many. If a great many glomeruli are involved rather severely, it becomes difficult to distinguish this form from diffuse glomerulonephritis both histologically and clinically, and I believe, in the descriptions laid down in literature, one can find all intermediate stages between focal and true diffuse glomerulonephritis. The differences are purely quantitative in character and I cannot help but feel that this focal hemorrhagic glomerulonephritis is merely an abortive form of true glomerulonephritis.[9] The knowledge of the frequent occurrence of this type of disease in subacute and chronic endocarditis is of considerable practical importance, as it will prevent the clinicians from diagnosing a serious *diffuse* glomerulonephritis merely on the basis of possibly transitory urinary findings.

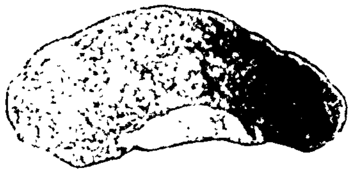

Fig. 6.—Case XVII, 68, chronic glomerulonephritis; granular contracted kidney; one-half normal size.

---

[7] Löhlein: Pathologische Anatomie der haematogenen Nephritis, Ergebn. d. allg. Path. u. path. Anat. (Lubarsch und Ostertag), 1910, xiv, No. 2, p. 874.

[8] Baehr: Glomerular Lesions in Subacute Bacterial Endocarditis, Jour. Exper. Med., 1912, xv, 330.

[9] Löhlein's statement that in true diffuse glomerulonephritis *all* glomeruli must show evidence of disease, is certainly an exaggeration. The lesions usually affect a majority of the glomeruli, but all subacute and chronic cases show clear evidence of a more gradual involvement of glomeruli, apparently in repeated crops.

Cases of this kind have been found not only in diplostreptococcus endocarditis but also in ordinary streptococcus infections and even in colon bacillus sepsis.

It is interesting to note that in the three acute cases of diffuse glomerulonephritis of our series which were the result of chronic diplostreptococcus endocarditis, old focal lesions of the character just described were found in all. Evidently in these cases, for a considerable time, the kidneys were involved to a minor degree only, until a sudden recrudescence lighted up the process and caused more acute *diffuse* lesions and incidentally the death of the individual.

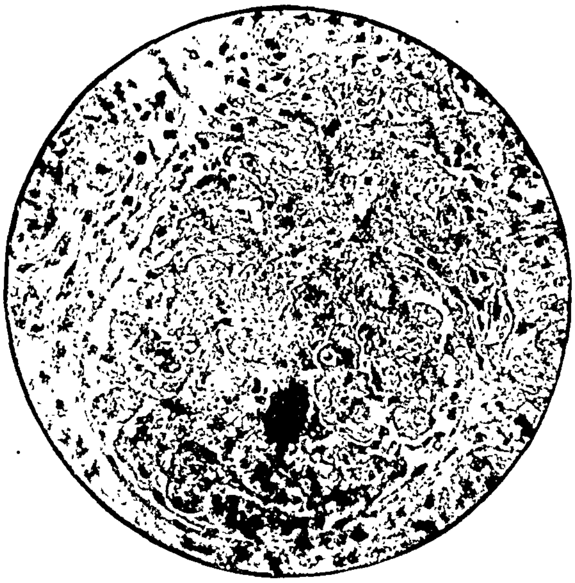

Fig. 8.—Case XVI, 212, hyaline deposit and degeneration extending beyond glomerulus along vas afferens; magnified 210 times.

6. Histogenesis of glomerulonephritis: There remain to be discussed a few problems connected with the histogenesis of glomerulonephritis. There are especially two important questions which arise naturally: first, How are the so important lesions produced in the glomeruli? Second, Is there any explanation for the later involvement of the blood vessels?

As stated before, Löhlein had postulated an embolic origin for the lesions observed in focal glomerulonephritis, and his deductions seem to have been confirmed by the actual finding of bacteria in the early stages of the condition both by Baehr[8] and by Fahr.[9] I do not see any reason why this idea could not be extended to all cases of glomerulonephritis or at least to the majority of them. In practically all my cases during the more acute stages, some and often many loops of the affected glomeruli are more or less completely filled with peculiar hyaline masses[10] which have been described by many previous investigators, and the wall of these capillaries undergoes a peculiar form of hyaline necrosis with karyorrhexis of the nuclei of the endothelium and other cells. The origin and meaning of this peculiar form of thrombosis has been the source of much discussion. From a study of the early cases I have become convinced that this thrombosis and subsequent hyaline necrosis of the capillary wall precedes all other changes in the glomeruli, which is in full agreement with the opinion of previous investigators. The only difficulty in the way of assuming an infectious, embolic origin for these lesions is the fact, which I can confirm from my own experience, that in spite of the most careful search one cannot find any bacteria in these masses. The detection of isolated bacteria is, however, made somewhat difficult by the numerous small fragments of chromatin scattered through the hyaline material. Still, in the embolic focal glomerulonephritis we encounter the same difficulty and the assumption is made, and I believe justly, that in the majority of instances it is the rapid destruction of the bacteria which accounts for their absence.

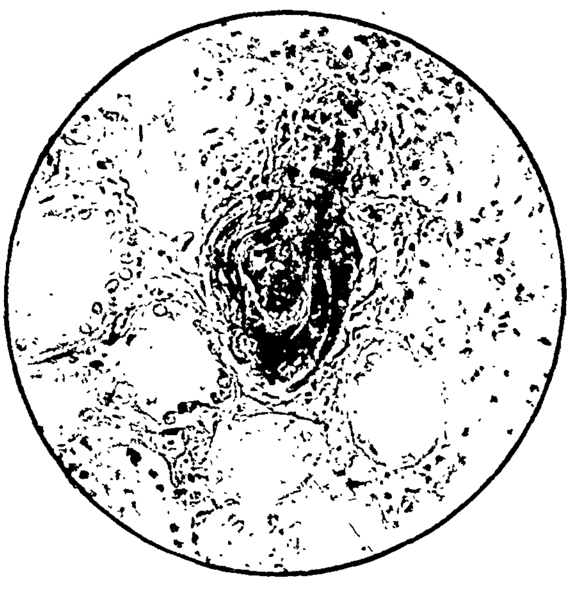

Fig. 9.—Case XVIII, 70, hyaline thrombosis of a small artery with complete obstruction; magnified 210 times.

When one considers in addition that in these cases of chronic septicemia, especially when they are associated with endocarditis, small clusters of bacteria necessarily must be in the circulation all the time, the mere fact that they cannot be found in the glomeruli is, to my mind, a strong argument for the belief that they must be destroyed in them because similar material in other cases is so apt to be found lodged in these structures. This line of reasoning suggests itself especially in those cases in which bacteria can be demonstrated easily in other capillaries of the same kidney but not in the glomeruli. Among my series there are several such cases in which many of the ordinary capillaries are full of diplostreptococci, but in which the diseased glomeruli are free from them.

In view of the actual finding of the bacteria in focal glomerulonephritis in which the reaction is less intense, I believe that we are justified in developing the following hypothesis: In cases of chronic septicemia the endothelium of the glomeruli gradually acquires strong bacteriolytic properties. When in such cases suddenly large numbers of the bacteria are thrown into the glomeruli, an explosive bacteriolysis takes place which liberates large amounts of bacterial toxins. These cause blood destruction resulting in hyaline thrombosis, hyaline necrosis of the wall of the capillaries and the inflammatory reaction about them.[11]

This theory, if true, would solve many difficulties which we otherwise encounter in an attempted explanation of the renal lesions. If we believe that the affection of the kidneys is purely toxic, it is difficult to understand how the poisons could ever become so concentrated in the blood that they would produce these intensely inflammatory conditions in the kidney, and in no other organs, but even more difficult to explain in case of a general intoxication would be the fact that all glomeruli are not affected similarly and simultaneously.

---

[10] I wish to state here positively that these masses have nothing whatever to do with amyloid, as I was misled to assume in my previous paper.

[11] An experimental confirmation of this idea is at present being attempted in our laboratory.

The relation of the disease of the small arteries to the rest of the renal lesions has also been the subject of much contention. It is evident from our specimens that the endarteritis cannot be the direct result of the inflammatory changes in the tissues about them, because, in some cases, the arterial lesions are early and extensive, in others the inflammatory changes in the connective tissue may be far advanced and the arteries remain practically normal. The great question here, as in other forms of arteriosclerosis, has always been whether the condition was due to toxic or to mechanical causes.

The careful study of some of my cases suggests what I believe to be a new and better solution of this question, so far as the arterioles are concerned. It brings the lesions in them into close connection with those in the glomeruli. The occurrence of peculiar hyaline masses in the wall of the diseased arterioles in chronic nephritis has been emphasized by several previous investigators. These hyaline masses were especially well marked in one of my cases (XVI, 212) of early chronic glomerulonephritis, and in this instance the relation of the arterial lesion to that in the glomeruli was especially evident. Many of the glomeruli were the seat of a very extensive hyaline necrosis which involved the vasa afferentia at their point of junction with the tuft, but differently from what one sees in the loops of the tufts—the hyaline material in the small arteries did not occlude the lumen entirely, but left a small open space in the center as shown in Figure 8, and could be followed back in the wall of the artery for quite a distance.

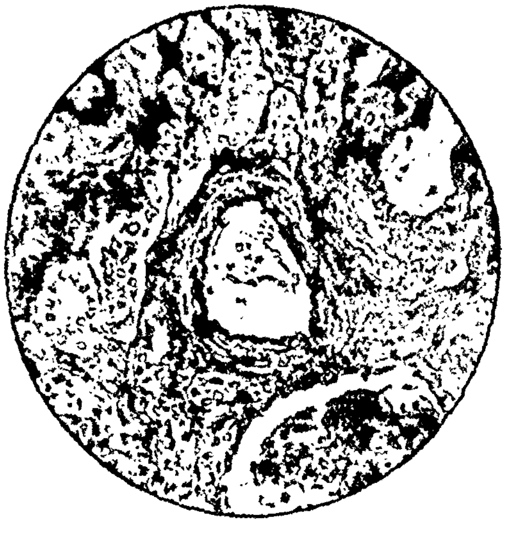

Fig. 10.—Case XVIII, 61, thrombotic masses containing leukocytes and red blood corpuscles underneath endothelium in small artery; magnified 210 times.

Sometimes the lumen of the arterioles is entirely closed by this process, as shown in Figure 9; most commonly, however, a small central lumen remains open. This lumen is either merely spared out of the heavy masses of hyaline fibrin deposited on the wall, or in many cases a more or less perfect layer of endothelial cells can be demonstrated on the inner surface of the fibrin. In some way the coagulable material must get in behind the endothelium. That this material is really derived from the contents of the blood vessels is shown by the fact that blood corpuscles, white and red, are carried behind the endothelium, as shown in Figure 10, in which several groups of red blood corpuscles are seen between the endothelium and the inner elastic layer. The same idea is borne out by the fact that the material which transudes into the tubules from the glomeruli partly coagulates in the form of ordinary fibrin, partly in the form of similar hyaline masses as shown in Figure 11.

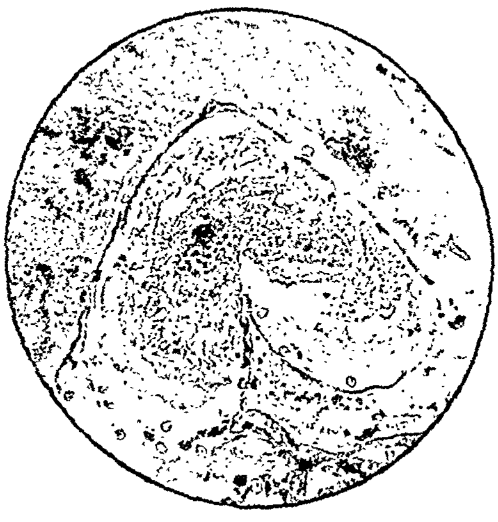

Fig. 11.—Case XVIII, 70, fibrin both thready and hyaline in tubule; magnified 210 times.

This hyaline material in the arteries is gradually organized (Fig. 12) and eventually it is entirely replaced by fibrous tissue in which gradually elastic fibers develop as is clearly shown in Figure 13. The process, then, in the arterioles in this and in several other cases of my series, is evidently the result of the organization of a hyaline material furnished by a peculiar form of lateral thrombosis, and I imagine that such must be the case in other instances.

So far I have not been able to collect any data in explanation of the gradual extension of the disease from the arterioles to the larger arteries. That similar thrombotic processes in small and even large arteries are not uncommon in cases of chronic glomerulonephritis is evident in several of my cases.

In some of them, scattered small anemic necroses in the kidneys are shown; in others, anemic necroses and later scars in the heart muscle. These lesions in the heart muscle may give rise to clinical symptoms of myocarditis.

In one case (XVIII, 61) in addition to these myocardial changes there was clinical evidence of similar disturbances in the arteries of the brain (hemiplegia) and in the arteries of one leg (dry gangrene of the foot). Unfortunately we were not permitted to determine the exact condition at the necropsy.

PRIMARY ARTERIOSCLEROTIC CONTRACTED KIDNEY

I may be very brief on this point, as my subsequent experience entirely confirms the result of my previous observations. In these cases the general arteriosclerosis is the principal feature. The renal disease is more or less incidental and varies in intensity, anatomically, almost independently of the clinical conditions, although naturally an extreme involvement of the kidneys will aggravate the clinical symptoms.

The clinical signs are those of hypertension and of secondary circulatory disturbances. The urinary findings are comparatively slight and transient and the patients have no "kidney" history. There is little or no anemia. The development is insidious and the disturbances usually set in with cardiac distress and edema. None of my cases showed any definite uremic symptoms, although, of course, if the destruction of the kidneys is unusually extensive uremia might supervene. The etiology is entirely obscure.

These are the cases which show *very high blood pressure* and extreme cardiac hypertrophy; nevertheless, it must be emphasized again that there is by no means any direct correlation between the extent of the lesions in the arteries anatomically, the severity of the clinical symptoms and the amount of circulatory disturbance developing eventually.

Very interesting to me were two cases in women, in whom long-continued hypertension of 200 and more had been observed for years and *still* there was no cardiac hypertrophy detectable at necropsy.

COMBINATION FORM (VOLHARD AND FAHR)

I have reserved to the last a short discussion of the important problem whether, from an anatomic standpoint, there is any justification for the establishment of an additional group of cases of nephritis which would correspond to the combination form of Volhard and Fahr. It is the conception of these authors that there is a definite group of cases which develop primarily insidiously on an arteriosclerotic basis, but which eventually develop signs, both anatomically and clinically, of true nephritis. These cases, however, as Volhard emphasizes, from the beginning show a more rapid progress and a more malignant development than the ordinary cases of arterial hypertension. This fact alone would suggest that, from the very beginning, they cannot be entirely identical with them; in other words, that they do not commence as cases of uncomplicated arteriosclerosis.

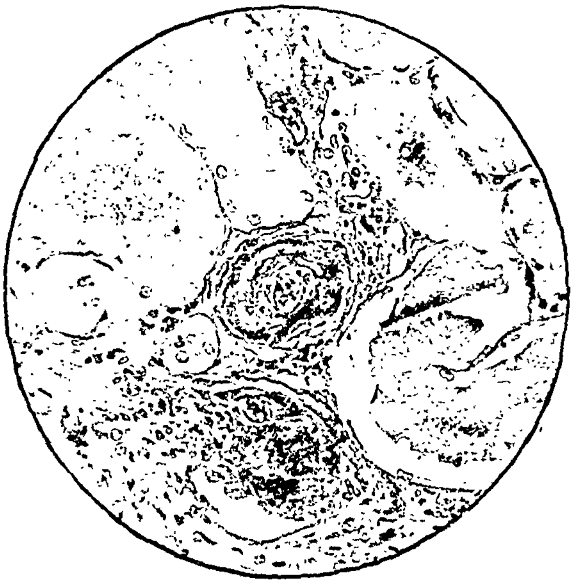

Fig. 12.—Case XVIII, 70, lateral hyaline thrombotic deposit in small artery in process of organization; magnified 210 times.

The difficulty, of course, resides in the fact that in these more chronic cases which come to necropsy, when the destruction of the renal tissue is practically complete and all acute lesions have subsided, it is very difficult to decide in which way the process actually developed, whether on an arteriosclerotic basis or as an unusually chronic form of glomerulonephritis with extensive arterial involvement.[12]

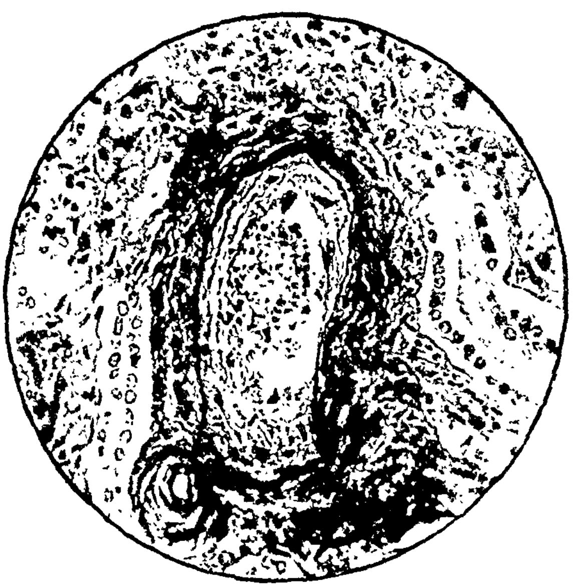

Fig. 13.—Case XVIII, 70, thrombotic deposits in small artery, completely organized. Beginning formation of elastic fibers; magnified 210 times.

In fact, it has been claimed again and again by eminent authority, that such a distinction eventually becomes impossible as it would be impossible, for instance, in a burnt-out building to find out how the fire originated. Among my series naturally there were several such puzzling cases and it was not until after repeated effort and considerable hesitation that they were eventually placed in one or the other category. I may say here that the segregation was made always on anatomic grounds without regard to the clinical history.

In some of these cases I was at first misled by the belief that the structure of the fibrous remnants of the glomeruli afforded some clue as to the nature of their mode of destruction, in this way, that in arteriosclerosis the glomerulus itself merely collapsed and became necrotic, which process was followed by a more or less crescentic fibrous thickening of the capsule; whereas in glomerulonephritis, on account of the more diffuse connective tissue proliferation, a much less definitely defined, diffusely fibrous nodule resulted, in which there often might be seen remnants of the original hyaline material. This is certainly true in the majority of cases, but I eventually recognized that this is by no means a reliable guide. My mind was first disabused of the correctness of this assumption by a study of a case (XV, 120) in which in spite of the fact that in a *child of 6 a general arteriosclerosis* was very unlikely and was actually absent, the glomeruli in the old lesions showed the "arteriosclerotic" picture. It became clear to me that when the glomerulonephritis is largely capsular, eventually a picture is produced exactly like that in arteriosclerosis. Having once clearly recognized this fact it became much easier to place the cases, and subsequent study only helped to confirm my growing belief that all cases in which one could detect definite inflammatory lesions in the glomeruli, even in a few of them only, belonged from the beginning in the group of glomerulonephritis.[13]

In these cases the *finding* of granular leukocytes, especially eosinophils in the interstitial tissue, the presence of neutrophilic leukocytes in the tubules, the occasional hemorrhages, the nature of the changes in the arterioles, the sometimes apparent etiology, all pointed in the same direction, and also the fact that once included in the series of chronic glomerulonephritis, it became *impossible* to sift them out again by repeated reviews of this series.

The fact that in this way all cases showing severe renal symptoms eventually became included in this class and none which had a cardiovascular history may also be looked on as corroborative of the correctness of the classification.

---

[12] How little one can depend in making this distinction on the points of difference laid down by Jores between true arteriosclerosis and endarteritis is shown in very many of my specimens. In one and the same section some of the arteries may show the *picture* of "endarteritis" and others of *true* "arteriosclerosis" according to Jores' definition, and it is very evident, from a careful study of such specimens, that the age of the lesion has much more to do with the histologic appearances than the *nature* of it. The older the lesions the more the picture of Jores' true arteriosclerosis is approximated.

[13] A careful review of the specimens on which I based *my first paper* has convinced me that in the group of arteriosclerotic nephritis in this publication there are a few cases which I now would classify as chronic glomerulonephritis. The same is true *of several* of the cases reported in Gaskell's paper.

Whether it will appear advisable, on the basis of more elaborate clinical observation, to subdivide the cases in this group of chronic diffuse glomerulonephritis into two subdivisions, a more acute and a more chronic one, is, of course, another question beyond the reach of my experience. I can only emphasize that from an etiologic and anatomic point of view such a subdivision, at present, appears uncalled for.

In conclusion I wish to emphasize that I do not look on acute, subacute and chronic glomerulonephritis as different stages in development but as different forms of the same disease.

The following is a brief summary of my findings:

1. Nephritis from an anatomic point of view may be best subdivided into: *a*, acute, subacute and chronic *parenchymatous nephritis* which is very frequently associated with amyloid; *b*, acute, subacute and chronic *glomerulonephritis* to which class belong most of the cases with continued definite urinary findings, renal hypertension, uremia and other definite symptoms of renal disease.
2. Hypertonic cardiovascular disease may involve the kidneys more or less extensively, often causes certain functional disturbances in the kidneys, may cause contracted kidney, but should be segregated entirely from true nephritis.
3. The cause of true nephritis is continued bacterial septicemia, and the lesions in the kidneys are probably due to rapid bacteriolysis and incidental liberation of large doses of toxic material in and about the affected glomeruli.
4. The lesions in the arterioles, in at least some of the more chronic cases, are due to the organization of a hyaline (thrombotic?) deposit on the inner surface of the arteries which at times is found underneath the endothelium.

ABSTRACT OF DISCUSSION

Dr. Joseph Von Werthern, San Francisco: I would like to ask Dr. Ophüls if there is any danger in the use of vaccines of having a disastrous effect on the kidney from the introduction of a large amount of such preparations at various times?

Dr. Lawrence Selling, Portland, Ore.: May I ask Dr. Ophüls' opinion on the combination form of Volhard and Fahr?

Dr. William Ophüls, San Francisco: So far as the vaccine is concerned, I really could not answer that question. I have no data on which to base any answer. So far as the combination form of Volhard and Fahr is concerned, it is discussed in my paper, which I abstracted, and I may say that I believe that the cases which they classify as the "combination form" are true cases of nephritis of a particularly slow and insidious type, and that on this account the clinical picture resembles more that of the cardiovascular cases. In these very chronic cases, if you have a good clinical history, you will often find evidence of a preceding infection, sometimes as long as twenty or twenty-five years. Frequently clinical evidence of such infection has recurred at intervals, and when you study the cases histologically, carefully, you find very convincing proof of *old* inflammatory lesions in the kidneys. I may say that I hesitated quite a little in some cases, whether I should classify them under the arteriosclerotic group, or within the inflammatory group. But after I had once made up my mind to put these cases into the inflammatory group, I could not get them out any more. I mean to say that I have gone over the chronic cases of the inflammatory group at least half a dozen times, trying to find cases that could be separated from the rest of them, but it was absolutely impossible. I was perfectly willing to follow Volhard and establish a combination form, but in my series it did not seem to work out that way.

RAYNAUD'S DISEASE

REPORT OF A CASE OF SYMMETRICAL GANGRENE OF UNUSUAL SEVERITY

ARCHIBALD L. HOYNE, M.D.
CHICAGO

Whether the condition known as Raynaud's disease is to be considered of rather frequent occurrence or whether it is to be regarded as an extremely rare affection must necessarily depend on one's conception of this disorder. That many cases have been reported in which the diagnosis rests on an unstable foundation, there is no doubt.

Raynaud,[1] in his famous essay, makes three classifications of the disease which bears his name. He states there may be merely local syncope which usually has a brief existence though it is likely to be recurrent; (2) there may be local asphyxia which is not necessarily preceded by local syncope or (3) there may be symmetrical gangrene. Any one of these conditions of the extremities may occur without being followed or preceded by one of the others.

In local syncope the fingers or toes—more frequently the former—become blanched, presenting a white, waxy, swollen appearance. There is a sensation of burning or tingling in the parts affected and pain even may be extremely severe. This type is practically identical with the condition sometimes found in chilblains and is not infrequently described as "dead fingers."

The second stage, or local asphyxia, appears to be a severer degree of the same pathologic condition, but, as the name implies, the parts assume a cyanotic aspect. As a rule the skin first becomes a reddish purple and then it may return to normal or continue to darken until a blue-black color is attained. As in the first stages, pain may be troublesome and hot applications may afford relief.

The third stage, symmetrical gangrene, is the one with which this paper is chiefly concerned. And in order to put a check on the reporting of miscellaneous conditions as Raynaud's disease, it might be advisable to limit that title to this particular type. In this connection I quote Riggs[2] who says that "the occurrence of local syncope and local asphyxia, either separate or associated, constitutes what is known as 'Raynaud's phenomena,' but the additional element of gangrene is necessary to justify a diagnosis of Raynaud's disease." Now if we are to accept Riggs' definition, and also Raynaud's original view that symmetry of the lesions and absence of demonstrable changes in the blood vessels are two essential features, then in fulfilling those requirements for a diagnosis, it will be found that extremely few cases of Raynaud's disease have been reported in this country. In England, France, Russia and Germany, however, symmetrical gangrene of the extremities seems to be much more frequently encountered.

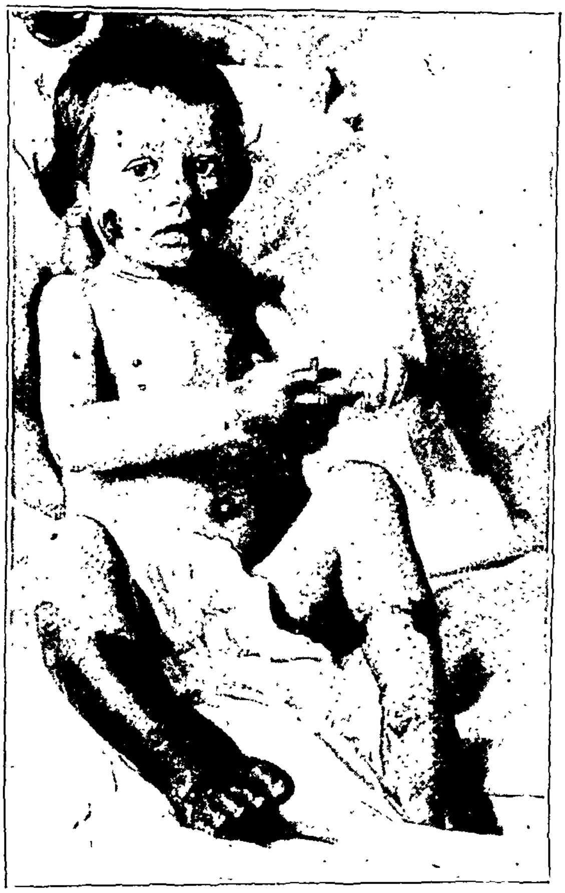
2. Riggs, C. E.: Reference Handbook of Medical Sciences, New Ed., New York, William Wood & Co., 1900, vi, 844.

In a review of the literature here, we find a variety of conditions reported as Raynaud's disease. Some authors[3] cite as cases conditions which appear to be due solely to certain occupations, while others[4] describe asymmetrical Raynaud's disease in which trophic ulcers, diabetes and other pathologic changes are clearly set forth. Numerous instances can be given in which the diagnosis is at least clouded in doubt. Not only is gangrene usually lacking but in many "cases" there is even failure to establish the existence of Raynaud's phenomena.

In looking over the clinical records of the Cook County Hospital, an institution which treats about 30,000 patients annually, as far back as the records are available (1911), I found but three cases with a diagnosis of Raynaud's disease. This is of interest in that: (1) it indicates how rare the condition really must be and (2) it illustrates how a diagnosis of Raynaud's disease may be made though the clinical evidence does not seem to entirely warrant it. All three of the cases just referred to were in adult males. One patient was in the hospital for eight days; ankles and knees were both swollen, while his chief complaint seems to have been pain in the rectum. Weiss has described the latter symptom in a case. In Case 2 the patient had rheumatic pains in ankles and shoulders. He was in the hospital twenty days and the history states that he had "rheumatism six times before." The third patient applied for admission to the hospital at 11:40 a. m. and left at 12:30 p. m. the same day. He was in the hospital forty minutes; he refused to allow a physical examination and left. The diagnosis on his clinical record is Raynaud's disease.

Osler[5] says that in a period of twenty years at the Johns Hopkins Hospital there were but nineteen cases among about 20,000 patients admitted. Of thirty-two cases reported as Raynaud's disease in the United States, previous to 1900, twelve, or about 37 per cent., had symmetrical gangrene, and of the twelve, there appears to have been only one[6] in which all four extremities were involved simultaneously. Hyde[7] reported three cases of "hand and foot disease" in which all four extremities were involved, but there was no true gangrene, the chief characteristic, apparently, having been an onychauxis.



Symmetrical gangrene, fourth day. Remains of old varicella lesions are also shown.

Of ninety-seven cases in the literature, gangrene occurred in forty-nine, but in only thirty-three of these cases was it symmetrical and in many of these latter instances it was extremely superficial. In twenty-one of the thirty-three symmetrical cases, the lower extremities were involved, in nine the upper, in two,[6, 8] both upper and lower and in one,[9] one upper and both lower extremities showed gangrenous changes while the tip of the nose and a portion of one ear was discolored.

ETIOLOGY

Very little is known concerning the etiology. Cases are more frequent in the cold months following exposure. Nevertheless, changes of temperature within doors, which are almost imperceptible, may be sufficient to bring on an attack.

Monro states that heredity is a factor in 8 per cent. of the cases. Nationality also appears to play a part. Of the reports reviewed by me, among which seventeen patients were reported as of foreign birth, more than 50 per cent. were Russians, and in my own case the child was of Polish parentage. Apparently the most severe cases are among foreigners. The disease may occur at any age[10] from infancy up. Of eighty-nine cases in which the age was given, approximately 11 per cent. were under 20 years, 17 per cent. over 50 years and 72 per cent. between the ages of 20 years and 50 years. It is quite generally stated that females are much more frequent sufferers than males. In a review of ninety-five cases, however, I found conditions diametrically opposite, the males being in the majority with 56 per cent., while the cases in females totaled but 44 per cent. It is not necessarily the weak and debilitated who are the victims of this disease.

Some of the predisposing factors are thought to be fright, epilepsy and various neurotic conditions. Anemia, syphilis, tuberculosis and malaria are also frequently mentioned and the invasion of pathogenic bacteria, as in the common infectious diseases of childhood, resulting in a lowered vital resistance, deserves careful consideration. The condition has been preceded by injury and hemorrhages, though under such circumstances there is likely to be some doubt in the diagnosis.

SYMPTOMS

Symptoms have previously been touched on. Pain and an absence of fever at the onset are characteristic.

Tips of fingers and toes are most commonly affected; more rarely ears and tip of nose. Contrary to the assertions of most authors, it appears that in the majority of cases reported, the lower extremities were involved. Hyperesthesia to touch is common, and in the first stage or local syncope there is no pitting on pressure.

Loss of sensation in the part affected usually follows when gangrene occurs. While gangrene in Raynaud's disease is presumed to be of the dry variety, some authors state that it may be moist and such was the condition in Macfarland's[6] case. It is not infrequently stated in connection with the symmetrical gangrene of Raynaud's disease that, when tissue death occurs, blebs filled with serum appear on the surface. There was nothing of that character in my case though most reports confirm the assertion. A line of demarcation is usually well developed within a week and the part involved assumes a black, dried, leather-like appearance.

PATHOLOGY

The anatomic cause for true Raynaud's disease is still to be discovered. In 1832, M. Victor Francois[11] of Mons expressed our present knowledge of this condition very aptly when he said "Everything concerning spontaneous gangrene is in a state of distressing uncertainty."

Raynaud believed the condition was caused by a spasm of the arterioles due to some derangement of the central nervous system; that the symmetrical gangrene was due to some error in the innervation of the capillary vessels. Weiss, however, thinks it is not so much the arteries which are contracted as corresponding veins. He also regards the gangrene as trophic, that the vascular spasm is not the cause. Pitres and Vallard[12] found structural nerve changes in cases of symmetrical gangrene. Lustgarten[13] appears to believe that a syphilitic origin is always to be suspected. No pathologic changes, however, should be found in the intima of the vessels in Raynaud's disease. And yet, in spite of this fact, the opinion has been advanced that the condition is due to a proliferation of the endothelial cells. Morgan[8] states there should be no proliferation. It has been suggested by Koga of Japan that an increased viscosity of the blood is responsible for symmetrical gangrene, but such a view is hardly tenable. The theory has also been advanced that the disease is due to some sudden bacterial invasion.

That the central nervous system is partially at fault there can be no doubt. In my case, regardless of what the complete mechanism was, it would seem as though the numerous acute infectious diseases produced a toxemia which impaired the central nervous system either primarily or else secondarily through nutritional changes in the blood.

Granting then that the central nervous system is at fault, it would seem that the origin of many if not all such cases may lie in a depleted blood supply. In other words, the nervous system lacks the proper nourishment necessary to maintain its equilibrium and thus control over the vasomotor system is lost. All reports of symmetrical gangrene seen by me which gave the blood findings showed a marked anemia.

DIFFERENTIAL DIAGNOSIS

If any assignable cause can be given for the affection, it is likely that it is not a case of Raynaud's disease. The following diseases and conditions should be carefully considered and excluded before a diagnosis of Raynaud's disease in any of its forms is made: (1) frost bite, (2) rheumatism, (3) occupational disorders,[3] (4) cardiac defects, (5) embolism, thrombosis, phlebitis, (6) arteriosclerosis, (7) trophic disturbances due to disease of the central nervous system, (8) albuminuria, (9) chronic ergotism or plumbism, (10) diabetes, (11) senile gangrene, (12) traumatism, (13) Morvan's disease, (14) syphilitic endarteritis, (15) sclerodactylia,[14] (16) bilateral ainhum, (17) leprosy, (18) infections including typhoid, malaria, etc., (19) endarteritis obliterans, (20) erythromelalgia, (21) peripheral neuritis, (22) purpura, (23) angioneurotic edema.

Without discussing each of the foregoing, I believe the history in my case will demonstrate that they are all easily excluded. Endarteritis obliterans or thrombo-angiitis as Buerger[15] terms it, might be considered but this condition is progressive and would hardly develop with such rapidity. Collins[16] has written a valuable paper on the classification of circulatory and trophic disturbances.

PROGNOSIS

The disease usually exists for a number of years and acute fatal cases are extremely rare. Even in cases with severe symmetrical gangrene, the outcome is as a rule favorable despite the fact that one or more limbs may be eventually lost. Nevertheless, Fischer[17] states that while records of cures exist, the diagnosis may always be questioned.

TREATMENT

Practically everything has been tried in the way of treatment, including nerve stretching,[18] the Roentgen rays, galvanism and Bier's[19] hyperemia; atropin, nitroglycerin, thyroid extract, salvarsan, injection of normal salt and Ringer's solution. All have had their advocates. Peyton[20] believes that drugs are of no value.

Symptomatic treatment is all that can be advised. The parts should be kept warm and dry and when gangrene develops the case must be considered from a surgical point of view. The illustration, from a photograph taken June 17, the fourth day of the affection, is of particular interest in showing the distribution of the parts involved.

REPORT OF CASE

S. U., a fairly nourished, light complexioned boy 5 years of age, was admitted to my service at the Cook County Contagious Disease Hospital, May 4, 1915, suffering from scarlet fever of three days' duration. He had been an inmate of an orphanage. No other history was obtainable at that time.

Subsequently the following history was secured. Father and mother, of Polish nationality, were both living and well. Two other children, aged 8 and 6 years, were living and well. The first child died of some "head sickness" in the second year of its life. The mother had never had any miscarriages and was six months pregnant.

The patient had never been ill before; neither coldness nor blueness of the extremities nor hemorrhages of any character had been either complained of or observed. When minor injuries occurred, the blood always clotted readily.

Physical Examination.—The patient presented a typical rash of scarlet fever and did not appear to be extremely ill.

The tonsils were large and inflamed but there was no membrane. Throat and nasal cultures were negative for diphtheria. There was a moderate cervical adenopathy but all other findings were negative.

When admitted to hospital, patient's temperature was 103 F., pulse 126, respiration 32.

The temperature showed a gradual decline until on the fifth day after entrance it began to rise. This elevation of temperature continued for four days when the eruption of measles appeared on the eighth day after admission to hospital. The patient, then, was in the hospital but four days before the onset of measles and consequently contracted this disease outside.

On the fifteenth day after entrance, it was noted on the clinical record that the extremities were cold. On the seventeenth day after entrance, about twelve days following the measles onset or twenty-one days after the onset of scarlet fever, a double otitis media was evidenced by discharge from the ears. The temperature had been normal since the eighth day following the measles onset and there was no elevation of temperature accompanying the involvement of the ears. The child's condition was such that he was allowed to be up and about the ward on the twentieth day after entrance.

Six days later, or twenty-six days after admission, some swelling in the region of the right parotid gland was observed and it was believed the patient had contracted mumps. There were no cases of mumps in the hospital at this time but there had been one case in the same ward several weeks previously. There was no fever at this period nor was the region of the left parotid swollen at any time.

From May 30 till June 6, the temperature continued normal, but on the latter date, an eruption of varicella appeared. The lesions were profuse and the temperature rose to 104. The child had a good vaccination scar. On June 6, the patient coughed a good deal and on the following day a whoop was noticed. In the meantime the varicella lesions continued to appear in fresh crops daily until June 11. During this period the temperature remained high for the greater part of the time but on June 11 it had again reached normal. At this time the patient was somewhat anemic but otherwise his condition was fair. The whooping cough was not of a severe type, the paroxysms being comparatively few in number.

About 8 a. m., June 14, the forty-sixth day after the onset of scarlet fever, the thirtieth day after the onset of measles, the ninth day after the onset of varicella and the seventh day after the beginning of whooping cough, large patches of a bluish black hue appeared on the dorsum of the feet near the base of the toes. Smaller patches on the back of the right wrist were also evident and a small area of discoloration on right cheek. These areas were at first thought to be purpuric in character. The following examinations on this morning with their results follow: heart absolutely negative. Blood count showed 54,000 white cells (due to pertussis), with a differential count of 82 per cent. small lymphocytes, 6 per cent. large lymphocytes and 12 per cent. polymorphonuclear neutrophils. The coagulation time of the blood was about seven minutes. The urine showed a slight amount of albumin with hyaline and granular casts. There was no sugar, no hemoglobinuria. Blood was not present in either the urine or feces.

By evening of June 14, the areas had enlarged. The entire right lower extremity was involved from about one half the distance from the knee down, slightly more posteriorly than anteriorly, the greater part of the calf being affected. The left lower extremity was less affected, the big toe and second toe not being included in the process which did not extend up beyond the ankle except for a separate patch situated posteriorly about the middle third of the calf. During this first day an area, identical in appearance with the others, had developed on the left cheek. This was about the size of a quarter while the patch on the opposite cheek was as large as a silver dollar. All areas described were rather sharply defined and extremely painful. Proximally for some distance above the cyanotic areas on all four extremities the skin had a swollen, tense, waxy appearance. It looked edematous but was rather hard, did not pit on pressure and was very painful. All the affected parts were icy cold from the first. The temperature on this day did not go above 99, pulse 106, respiration 24.

Second day, June 15: Both ears were now discolored over the upper half and became black and cold. The lower extremities began to look gangrenous but there was no extension of the process. In the upper extremities, the left two ulnar and the right three ulnar fingers were black and cold. No blebs containing bloody serum as frequently noted in these cases were observed on any of the areas involved.

At the beginning of the process it was thought to be of a purpuric nature and horse serum was given intramuscularly in 10 c.c. doses every six hours until the end of the second day. On the second day the temperature rose to 101.8 in the evening. The urine showed a faint trace of albumin and there were some hyaline casts.

Third day, June 16: The only change in the lesions was a deepening of the black color, the parts affected remaining ice cold. An examination of the chest disclosed a bronchopneumonia; temperature 103, urine negative. Patient looked very anemic and a blood count showed red cells, 1,840,000; hemoglobin, 35 per cent. (Sahli); white cells, 41,550. Differential: small lymphocytes, 49 per cent.; large lymphocytes, 10 per cent.; polymorphonuclear neutrophils, 37 per cent.; eosinophils, 2 per cent. and transitionals, 2 per cent. On this day the left thumb and thenar eminence appeared very pale and waxlike. Lines of demarcation were being established. The areas on the cheeks appeared improved but the right forefinger had become cyanotic as far as the first phalangeal joint. The patient's general condition appeared greatly improved on this day in spite of his bronchopneumonia. The temperature was 102.2 F., pulse 148, respiration 48. The pain was greatly decreased. He had a good appetite and was much interested in everything about him.

June 18, the fifth day, the boy managed to get the dressings loose and chewed off the tip of the third right digit. There was no bleeding, the finger end resembling a piece of old leather. The gangrenous areas had an offensive odor at the lines of demarcation. The urine continued negative. The pulmonary condition was less favorable. Temperature rose to 103, pulse 144, respiration 58.

June 19, the sixth day, suppuration at the lines of demarcation was evident but all of the original areas were in a state of dry gangrene. The patient had involuntaries. Temperature 102 to 104 F.

June 20, the seventh day, the patient was irrational. The gangrenous portions showed no extension and were assuming the dried leather boot appearance. The skin of the affected parts was an ebony black. All parts were dressed with magnesium carbonate and powdered boric and the open-air treatment adopted.

June 21, the eighth day, the gangrenous portions were drying and beginning to separate. There was little change in the general condition.

June 22, the ninth day, the gangrenous portion of the right ear fell off, leaving a clean border. Temperature fell to 98.6, pulse 148, respiration 36.

June 23, the tenth day, the gangrenous portion of the left ear dropped off leaving a clean margin as in the case of the other ear. The uninvolved parts of the left hand looked very pale, swollen and waxlike. The boy was restless and irrational. Temperature 99 to 101.

June 24, the eleventh day, all the gangrenous areas were becoming loose from their adjoining tissue. On the extremities at the lines of demarcation the slough appeared to extend only to the deep fascia.

June 25, the twelfth day, the bronchopneumonia seemed slightly improved. Temperature 99.2. Dr. Joseph M. Patton kindly made an examination of the patient's heart on this day and reported the findings negative.

June 26, the thirteenth day, the gangrenous patch on the right cheek dropped out without much tissue destruction. Blood for a Wassermann was taken which was later reported negative.

June 27, the fourteenth day, the gangrenous patch on the left cheek extended to a slightly greater depth than on the opposite side and the resulting scar was consequently more extensive. The general condition of the patient was considered fair under the circumstances, though the pulse and respiration were rapid and bronchopneumonia was still present. The child, however, seemed to be losing in strength. He was toxic, had involuntaries, but apparently suffered little pain. The involved regions were dry except at the demarcation borders, and were shriveling up and separating. On the evening of this day, the child died as a direct result of the pneumonia, but a general toxemia was of course a strong contributing factor.

Had it not been for the pneumonia, it is possible the patient would have eventually recovered. Nevertheless amputation of both lower extremities, one at the upper third and one at the middle third of the leg, would have been inevitable. It would also have been necessary to adopt a similar procedure with respect to the greater part if not all of both hands.

The blood examination on the last day was as follows: Red cells, 1,650,000; hemoglobin, 27 per cent. (Sahli); white cells, 36,000. Differential, 200 counted, small lymphocytes, 41 per cent; large lymphocytes, 4 per cent.; polymorphonuclear neutrophils, 51 per cent.; eosinophils, 1 per cent.; transitionals, 3 per cent.

NECROPSY

In 1901, Greiwe[21] stated that the number of cases of Raynaud's disease examined postmortem could be summed up on the fingers of one hand. Consequently it is to be regretted that space does not permit the presentation of the complete necropsy findings.

Among the chief points demonstrated by Dr. H. Gideon Wells, who performed the necropsy, are the following:

On cut section, the gangrenous areas over the legs were found to be markedly edematous and to involve all the soft tissues down to the bone, which also showed erosion. The thymus was smaller than normal. The thyroid seemed somewhat enlarged and succulent; no gross changes were noted.

The heart was normal in size. No changes were seen in the aorta. The valves were normal.

The lower lobes and lower half of the upper lobes of the lungs were consolidated.

The kidneys were very pale, somewhat firmer than normal. Cross-section showed them markedly pale but otherwise normal. The adrenals were enlarged.

The large vessels of the lower extremities showed no evidence of thrombosis or embolism. The right femoral vein showed a large antemortem clot.

ANATOMIC DIAGNOSIS

1. Acute symmetrical dry gangrene of both lower extremities, both upper extremities and cheeks, with beginning sequestration.
2. Thrombosis of right femoral vein. Dr. Wells believed this to be of recent formation and secondary to the gangrenous process.
3. Bilateral confluent pneumonia of both lower lobes. Discrete bronchopneumonia of both upper lobes.
4. Acute hyperplasia of peribronchial lymph glands.
5. Perilobular infiltration of liver.
6. Fatty degeneration of the kidneys.
7. General lymphadenoid hyperplasia including glands, spleen and Peyer's patches, the latter of which were pigmented.

Later Dr. Wells reported that the histologic examination gave no definite findings which could throw light on the etiology of the gangrene.

Dr. George Mather, of the Memorial Institute for Infectious Diseases, conducted a bacteriologic examination. He made cultures from the thrombus of the right femoral vein and isolated a green streptococcus and a hemolytic streptococcus. Injected into rabbits, these caused a malignant endocarditis.

25 East Washington Street.

AN UNUSUAL CASE OF SALVARSAN POISONING

Karl C. Eberly, M.D., Fort Wayne, Ind.

Mr. B., aged 36, consulted a physician for lightning pains in the calves of his legs, occurring chiefly at night. Family history was negative. His past history gave no definite evidence of syphilis, although, twelve years ago, he had gonorrhea and thought possibly that he had contracted syphilis at the same time. The Wassermann on the blood was strongly positive. Physical examination was negative. Neural examination showed no other signs than absent knee-jerks. No examination of the spinal fluid was made.

An early tabes was diagnosed and neosalvarsan was chosen for treatment. Through an error 0.6 gm. of salvarsan was mixed in 10 c.c. of freshly distilled water, only a part of it dissolving. This unneutralized solution of salvarsan was injected into the cephalic vein of the right arm. Almost instantly the patient complained of a choking sensation and constriction of the pharyngeal muscles. He became extremely pale, pulse was small, weak and rapid. Respiration was dyspneic. At once the needle was removed, about 5 c.c. having been injected. Within an hour he was markedly prostrated, coughed and vomited and complained of general weakness and pain in the region of the left kidney. Nitroglycerin 1/100 grain was administered orally every twenty minutes until the pulse improved. Then it was repeated every two hours.

For the next twenty-four hours his general condition remained the same. He voided no urine. A catheterized specimen of 3 ounces showed a trace of albumin but no casts. On the second day the pain in the region of the left kidney and suppression of urine continued. The patient complained of weakness, chilling and a general myalgia. A phlebitis started in his cephalic vein, extending from the point of injection to the shoulder. The arm was swollen, reddened and painful. The vein appeared to be completely obliterated. His temperature and pulse were 100.

On the third day I was consulted over the long distance telephone. Fischer's solution, hot packs, saline cathartic, potassium acetate ,and digitalis were suggested to increase the elimination and local applications for the phlebitis. Fischers' solution, 6 to 8 ounces, was given every four hours by rectum and 1 dram of sodium bicarbonate every two hours by mouth. The other drugs were administered in the customary dosage. During the next twenty-four hours he excreted 15 ounces of urine, and the pain in the region of his left kidney was much improved. His prostration diminished but the severity of the phlebitis increased. His arm became much more painful and swollen. His temperature was 101, pulse, 105. On the seventh day I first saw the patient. He was a strong, powerfully built man, well nourished but now appeared thoroughly exhausted. He complained of weakness and pain in the right arm. This arm was twice its normal size and severely inflamed. The cephalic vein was palpated as a rigid tube. Physical examination of the heart and lungs was negative. The pulse was rapid—100—but of good volume and tension. Temperature was 102.4. Since the third day the amount of urine had gradually increased to normal. The urine showed a trace of albumin without casts.

---

[21] Greiwe: Philadelphia Med. Jour., 1901, viii, 236.

The leukocytes numbered 12,500. The differential gave 80 per cent. polymorphonuclears. The diet had been liquid.

After six weeks the phlebitis subsided, the urine became free from albumin and apparently he has not suffered any permanent lesion from this mistake.

Whether the marked toxic symptoms were due to the acidity of the solution or the salvarsan would be difficult to say. It is of interest, however, to note that the alkaline therapy relieved the anuria and toxic symptoms almost immediately.

Gauntt Building.

TUMOR OF THE HAND CAUSED BY FOREIGN BODY

F. P. Hammond, M.D., Chicago

R. S. S., an American, aged 30, complained of a tumor mass the size of a hazelnut which had been deeply seated in the thenar eminence of the left hand as long as he could remember. Only occasionally did the mass produce any discomfort yet a constant worry possessed him lest some day it should turn into a cancer. About six weeks ago it began to enlarge toward the surface, became slightly reddened and tender and seemed to grow gradually and slowly worse, which alarmed him sufficiently to cause him to seek treatment.

His family history was negative. His past history was negative, except that about two months ago he remembered giving the "lump" an accidental bump while swimming, a fact he had almost forgotten because it caused him so little pain.

For the last six years the patient had been a university student, previous to which time he worked on his father's farm. He denied venereal history.

A general examination was negative in result; there were no other enlargements. Temperature and pulse were normal.

Local examination revealed the tumor to be hard and elastic, movable, with a cone-shaped projection toward the surface, slightly tender and reddened but with no demonstrable fluctuation and apparently no connection with the bone.

The Wassermann test was negative. The Roentgen ray revealed nothing.

Diagnosis of a chronic attenuated infection probably due to a foreign body was made and under local anesthesia the mass was incised. About 1 cm. from the surface the slightest bit of pus exuded. Deep in the center of the mass a locust thorn 8 millimeters in length was discovered and removed.

On seeing the thorn he exclaimed, "Well, let me see, I was about 11 or 12 years old when I got that sliver." It is needless to say an uneventful recovery followed.

30 North Michigan Boulevard.

Removal of Swallowed Foreign Bodies.—The following may be of interest to some on account of the simplicity of the treatment. I claim no originality for it: Mr. C. B., aged 29, came to my office, October 7, complaining of a pricking sensation in the left hypochondrium, annoying him, but felt only occasionally. Twenty-four hours previously, while eating some pudding, he bit on a hard object, which proved to be a piece of glass. He did not think he swallowed any glass, but in view of the history, I concluded that he had. I gave him about 2 or 3 drams of absorbent cotton, with instructions to pick it into small shreds, put them into a glass of milk and drink the mixture. In addition, I gave him half an ounce of magnesium sulphate crystals, with instructions to dissolve in a half glass of water, and take one hour after the milk and cotton. The motions were passed in a vessel, and on examination, a wedge-shaped piece of glass about three-eighths inch long, very sharp, was found entirely covered with cotton. The pricking sensation disappeared. Tacks, pins and other pointed or rough foreign bodies may be easily removed by this means in many instances.

R. Penn Smith, M.D., Pittsburgh.

Therapeutics

TOXICOLOGY OF EMETIN

Dr. F. B. Sigworth, Albuquerque, N. M., writes:

Will you please give me the toxicology of emetin hydrochlorid used in hemorrhage? I wish to test it for its effect in tuberculosis; also to try it out experimentally on guinea-pigs.

Comparatively little has been added to our knowledge of the systemic actions of emetin in mammals during the past few years, and the descriptions in recent text books of toxicology are much like those given by Lewin in 1888.

The following statement is based largely on the statements of Kunkel[1] and von Jaksch.[2]

Emetin is an active local irritant, causing inflammation, and even ulceration of the tissues with which it comes into contact in sufficient concentration. When powdered ipecac is handled, it may give rise to irritation of the eyes and even ulceration of the cornea, and cause burning in the mouth and throat. The inhalation of the powder causes a sense of oppression in the chest and difficulty in respiration (so-called emetin asthma).

The application of an ointment containing emetin or ipecac to the skin causes irritation, progressing to pustulation with the continued application of strong preparations.

The subcutaneous injection of emetin causes pain, swelling and even ulceration.

Emesis following the oral administration is generally attributed to the local irritant action on the gastric mucous membrane; if emesis fails to occur and emetin passes into the intestine, it gives rise to diarrhea, and this may be bloody, the latter effect being augmented by the extreme dilation of the intestinal vessels. If absorption occurs, systemic effects follow.

The systemic effects observed after the entrance of emetin into the blood stream include general depression with failure of respiration, due to paralysis of the center, and cardiac failure due to the direct action of the emetin on the heart and circulation. There is a profound fall of blood pressure because of the cardiac and vascular effects.

The central nervous system undergoes rapid depression and paralysis even in the frog, which is not immediately killed by removal of the heart. Emetin stops the mammalian heart in diastole.

Alterations in the blood have been described; these are attributed to the accumulation of acid products of metabolism, but they are not responsible for the effects just described.

Kunkel describes the effects of toxic doses of from 50 to 100 mg. per kilogram of body weight in the cat and dog, but the results of experiments performed in the laboratory of the writer (unpublished) show that as little as 2 mg. of emetin per kilogram administered intravenously may cause some depression at times, while doses of from 8 to 12 mg. per kilogram cause general depression with weakened and accelerated heart and lowered blood pressure. There is an apparent improvement after a short time, but usually these doses are fatal within forty-eight hours. The effects of the oral administration of emetin in solution are about like those seen after intravenous injection, but death may occur with general paralysis and cardiac failure within three minutes after the intravenous injection of a large dose (15 mg. per kilogram).

---

[1] Kunkel: Handbuch der Toxicologie, 1901, p. 841.

[2] Von Jaksch: Die Vergiftungen, Ed. 2, 1910, p. 493.

It is generally stated that emetin causes emesis only through its action on the gastric mucous membrane, but it also causes emesis after the intravenous injection into a dog from which the gastro-intestinal tract has been removed; hence it is also capable of acting on the vomiting center directly.

One observer reported that vomiting, colic, abdominal cramp and collapse occurred, followed by death within an hour and a half after a patient had taken a large amount of wine of ipecac. Hyperemia of the tomach and duodenum were found at necropsy.

Several authors state that the toxicology of emetin s not very important, and von Jaksch states that the prognosis in case of poisoning by it is good. The diagnosis is made by finding the alkaloid in the vomitus.

Emetin is absorbed from the gastro-intestinal tract when given in solution more readily than when adminstered in the form of a preparation of ipecac. Tannin, n the form of krameria, is recommended as the antidote in such cases.

The following observation of Kunkel's is interesting n view of the date of his writing it and the use of emetin in hemoptysis at present. He says (1901) that it was formerly believed that emetin induced a specific anemia of the lungs from which circumstance it was used in hemoptysis. He states that the belief probably arose from the observation that the pulmonary vessels of animals that had been killed with emetin were empty, which he explains as being due to the maximal dilation of the vessels of the splanchnic area, with the consequent drainage of the pulmonary vessels.

This observation of Kunkel's is at least worthy of attention at this time, in view of the fact that even small doses of emetin are capable of causing depression.

THE SO-CALLED CONCENTRATED SOLUTION OF SILVER IODID

John K. Thum, Ph.G., pharmacist at the German Hospital, Philadelphia, writes:

> There is on the market, at the present time, a so-called soluble preparation of silver iodid. That is to say, the silver iodid is in concentration in the form of a solution, and the addition of this solution to a designated volume of water makes a 5 per cent. suspension of silver iodid. Whether this method of dispensing silver iodid possesses any advantages over the usual method is questionable. In my opinion it would be far safer for a patient to receive a freshly prepared precipitate of this chemical, well washed, and held in suspension with the aid of a solution of gelatin, Irish moss, or some other appropriate gummy substance.
>
> This solution of silver iodid is made by taking advantage of the fact that silver iodid is soluble in an excess of potassium iodid. One of the claims made for this preparation is that "it is also less expensive" than preparations of the same salt sufficiently diluted for immediate use. When one considers that the solution of this salt requires *a considerable excess* of potassium iodid (the preparation on the market showing on analysis at least 60 per cent. of free potassium iodid), and then considers the price of potassium iodid even in normal times, one is averse to agreeing with this statement.
>
> It is also well to remember that potassium iodid as found on the market is usually quite alkaline, and while it may be true that such a preparation is painless when introduced into the urethra, this does not prove that it is harmless. It is also well to remember that suspensions of silver iodid are frequently used in eye infections, and for that purpose should be very carefully prepared, the silver iodid first being carefully and thoroughly washed with sterile distilled water. If this technic is not followed, the application of the preparation to an eye condition will result in much irritation, pain and an inflammatory condition which it is difficult to control.
>
> My investigation of this preparation revealed that it can be prepared readily according to the following formula:

	gm. or c.c.
Silver nitrate................	3|70
Potassium iodid.............	17|00
Distilled water............ad	25|00

> This volume of 25 c.c. solution, when added to 75 c.c. of distilled water, makes a 5 per cent. suspension of silver iodid.

New and Nonofficial Remedies

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED BY THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION. THEIR ACCEPTANCE HAS BEEN BASED LARGELY ON EVIDENCE SUPPLIED BY THE MANUFACTURER OR HIS AGENT AND IN PART ON INVESTIGATION MADE BY OR UNDER THE DIRECTION OF THE COUNCIL. CRITICISMS AND CORRECTIONS ARE ASKED FOR TO AID IN THE REVISION OF THE MATTER BEFORE PUBLICATION IN THE BOOK "NEW AND NONOFFICIAL REMEDIES."

THE COUNCIL DESIRES PHYSICIANS TO UNDERSTAND THAT THE ACCEPTANCE OF AN ARTICLE DOES NOT NECESSARILY MEAN A RECOMMENDATION, BUT THAT, SO FAR AS KNOWN, IT COMPLIES WITH THE RULES ADOPTED BY THE COUNCIL.

W. A. PUCKNER, SECRETARY.

BISMUTH TRIBROMPHENATE.—**Bismuthi Tribromphenas.**—Bismuth Tribromphenol.—$Bi(C_6H_2Br_3O)_2OH.Bi_2O_3$.—Basic bismuth tribromphenate.

Actions and Uses.—Bismuth tribromphenate is claimed to be a nonirritant and nontoxic antiseptic. It is said to be useful as an odorless and efficient substitute for iodoform; as valuable in ulcus cruris and all weeping eczemas; internally, in gastro-intestinal catarrh, proctitis, dysentery, bacillary and choleraic diarrhea, cholera infantum, etc.

Dosage.—From 1 to 3 gm. (15 to 45 grains) per day to adults; from 0.12 to 0.3 Gm. (2 to 5 grains) at a dose to children. Externally, as a dusting powder, in bandages, etc., like iodoform.

Nonproprietary Preparation:

Bismuth Tribromphenate, Merck, Merck and Co., New York.

It is a fine yellow, nearly odorless and tasteless powder, neutral in reaction, and unaffected by light. It is only slightly soluble in water, alcohol, chloroform, liquid petrolatum and vegetable oils, but soluble in 2 per cent. hydrochloric acid. By alkalies it is decomposed with the formation of bromide; it is not decomposed by heat at temperatures below 120 C., and therefore may be sterilized.

It should yield not less than 49.5 per cent. of bismuth oxide. If 1 Gm. is boiled with sodium hydroxide T. S. and filtered, the filtrate rendered acid with sulphuric acid and the white, curdy precipitate washed and dried, it should melt at 95 C. (tribromphenol).

It is incompatible with alkaline mediums and should not be heated above 120 C.

BUTYL-CHLORAL HYDRATE (See N. N. R., 1915, p. 77).—The following non-proprietary preparation has been accepted:

Butylchloral Hydrate Merck.—Manufactured by E. Merck, Darmstadt, Germany (Merck and Co., New York).

SUGAR IN NORMAL URINE

With the increasing number of tests for the presence of sugar in the urine has come an attempt at greater delicacy in the reaction involved. Just as Fehling's test far exceeded in sensitiveness some of the older methods for the detection of sugar, so the newer tests recommended from time to time have as a rule been characterized by the property of revealing smaller and smaller amounts of the carbohydrate. With the exception of the fermentation test, most of the reactions are really indirect in indicating the presence of sugar. Most of them are reduction tests involving the use of salts of copper or other metals.

Inasmuch as other urinary components besides sugar may reduce the cupric solutions, it is sometimes difficult to decide whether traces of observed reaction are due to sugar or to other constituents such as creatinin. From this point of view a reagent may sometimes be unduly sensitive and give a false answer in respect to the occurrence of sugar. On the other hand, certain urinary compounds also interfere with the delicacy of the tests by preventing the separation of small amounts of red cuprous oxid on the familiar appearance of which the clinical observer so often depends.

Folin[1] has lately devised a reagent which combines extreme sensitiveness to sugar with the property of removing creatinin and other interfering substances from the urine. In the course of nearly a hundred tests made with this new reagent on the urines of as many different normal persons (students), Folin obtained a positive reduction in every case. This corresponds with the statement occasionally made that traces of sugar are present in practically every urine. Various investigators have succeeded in demonstrating the probability of this by concentrating larger amounts of urine and making tests on suitably prepared fractions thereof.

It would, after all, be strange if an organ like the kidney which responds so readily to very small changes in the usual concentration of blood sugar should retain an absolutely complete impermeability to a sugar level only very slightly lower than that which leads to easily detected glucosuria. It is theoretically easier to conceive of the "impermeability" as being relatively rather than absolutely perfect; or, if one is committed to a different explanation of the sugar-free character of normal urine, a comparable contrast applies with equal force. The demonstration given by Folin's new test therefore need not surprise us. As he says, the amount of sugar present in normal human urine is probably greater than is indicated by the negative findings recorded on the basis of the clinical qualitative tests for sugar in current use. Those who, like life insurance examiners, change their analytical methods from time to time in order to secure greater sensitiveness and detect smaller contents of sugar in urine, must be prepared to reach a point at which they encounter normal rather than pathologic sugar excretion. This is only an added instance of the vague borderline between the normal and the abnormal.

---

THE LOCALIZATION OF STREPTOCOCCI

The relation to infection of the affinity of bacteria for certain tissues was discussed recently in these columns.[1] It was pointed out that many of the pathogenic bacteria in their localization manifest a special affinity for some particular tissue or tissues. This elective localization may be conceived to be due to the circumstance that the conditions for growth are more favorable in some tissues than in others. On account of differences in metabolism and chemical composition, there is no doubt that different tissues and places in the body present radically different conditions for bacterial growth and activity. It was pointed out, further, that the work of Forssner and especially the more recent work of Rosenow have established that among the streptococci, which have the power to invade many tissues and to cause a variety of infections, strains may appear which, when introduced into the blood, are found to localize by preference in certain tissues. In his article in this issue of The Journal, Rosenow[2] presents a summary of the results of his experiments of elective localization of streptococci obtained from a wide range of human infections and injected intravenously into dogs and rabbits. The animals were killed soon after the injection, and the facts as to localization of the streptococci determined by systematic, careful examination of the whole body. Obviously this method gives a much better idea of early localization than can be obtained if only the animals that die are examined.

Stated in the simplest way, the results obtained by Rosenow with his method show (1) that streptococci isolated from active lesions in different human organs and tissues, in many instances, have a pronounced affinity for the corresponding organs and tissues in rabbits and dogs, and (2) that streptococci isolated from the tonsils and pyorrheal pockets in persons with active streptococcal infection in the interior of the body may have the same sort of affinities as the streptococci from the internal lesions. In the light of these results, many of which are striking indeed, as may be seen at a glance from the table in Rosenow's article, human streptococcus infections acquire new interest because a road now opens to a better understanding of their genesis and of the difficulties of curing them by the specific means now in use. Obviously a chief danger from chronic foci in which streptococci are present, of which those in the tonsils and about the teeth appear to be the most important because the most common, seems to depend on the fact that in such foci, even when quiescent, streptococci may get into biochemical conditions which fit them for invasion of the blood, to be followed by localization in some tissues rather than in others. Persons going about with chronic, more or less latent foci of this character, consequently, are not only dangerous to themselves in that what one may call internal streptococcal metastasis may occur at any time, but they are also undoubtedly dangerous to others because they scatter about them streptococci of specialized pathogenic possibilities. Hence the efforts now made to detect and then to obliterate all forms of focal infection in the mouth and throat as well as elsewhere in the body, for preventive as well as curative purposes, besides being in accord with sound reasoning from general principles, here receive the support also of strong experimental evidence. When we consider the wide range of action of pathogenic streptococci, the great variety of disease due to their localizations in different tissues according to what Rosenow's work indicates are states of special "elective affinities," no effort should be spared that in any way will tend to reduce the supply of such streptococci and lessen the chance of infection.

---

[1] The Relation of Selective Tissue Affinity to Infection, editorial, The Journal A. M. A., Sept. 26, 1915, p. 1114.

[2] Rosenow, E. C.: Elective Localization of Streptococci, The Journal A. M. A., this issue, p. 1687.

At this point it may be well to recall that we owe it especially to Rosenow's work that we now understand more clearly than before the part played by streptococci in causing gastric and duodenal ulcer, cholecystitis, appendicitis, herpes zoster and erythema nodosum, as well as the joint and other infections long accepted as streptococcal in nature. In showing that streptococci cause gastric and duodenal ulcer, herpes zoster and erythema nodosum, Rosenow has broken new ground, and if future work confirms his results, particularly as to gastric and duodenal ulcer, great progress indeed will have been made. To this already formidable list of streptococcal diseases Rosenow now adds still another, namely, mumps, being careful to note, however, that the organism he finds does not seem to differ essentially from that described by Laveran, Herb and others as the cause of this disease. This raises the question whether all the organisms classed by Rosenow as streptococci will be accepted by bacteriologists as entitled to classification as streptococci. It would seem possible that some of these organisms, as, for instance, the one in mumps, may be found to be independent forms with rather constant affinities, such as illustrated by the meningococcus, for example. The fact that the organism isolated by Rosenow from mumps did not localize in the testicles is contrary to expectation, being another point that will require further investigation. Still another question, and one of fundamental importance, remains to be answered, and that is the question as to the antigenic properties of streptococcal strains of different affinities as postulated by Rosenow. Is a streptococcus that has special affinity for articular structures capable of causing the production of the same antibodies and subject to the action of the same antibodies as a streptococcus that has special affinity for the gallbladder? Or are streptococci distinguishable into a number of groups by means of immunologic reactions in the same general way as pneumococci? This question must be answered before any real advance can be made either in serum treatment or in vaccine treatment of streptococcus infections.

It is quite self-evident, so far as vaccine treatment is concerned, that for the present the free use of stock streptococcus vaccines, as advocated with unwarranted assurance by manufacturers, is not justified. The only vaccine to be used in the infections under consideration, if any, is the autogenous, that is, one made from cultures of the organism isolated from the lesion of the patient whom the physician wishes to treat with vaccine. Only by so doing will the right thing be done, because the autogenous vaccine will represent most closely in all its reactions the particular bacterial strain that is to be attacked.

WHY NOSTRUM MAKERS FAVOR SECRECY

Physicians know what the *National Druggist* stands for. For years it has championed the "patent medicine" business and for years, too, it has blackguarded the medical profession generally and the American Medical Association specifically. It is published by Henry R. Strong of St. Louis, who also publishes the *Medical Brief*. Physicians will remember at least some of the pamphlets issued by the *National Druggist* in its attempt to discredit the medical profession: "The Menace of the Dispensing Doctor," "The Machinations of the American Medical Association," "Confiscatory Legislation" and "A Conspiracy to Establish a Physicians' Trust." These were some of the tirades that emanated from this source in the nation-wide attempt to indict the medical profession.

It is not surprising, therefore, to find the *National Druggist* urging "patent medicine" makers to refuse to obey the law that is to go into effect in New York City on the last day of this year. As our readers will remember, the revised health code of New York City requires that on and after December 31, 1915, patent or proprietary medicines must either bear on their labels the names of the active ingredients, or the names of these ingredients must be deposited, in confidence, with the Department of Health. The *Weekly Bulletin* of the New York Department of Health for October 30 reprints a communication "which the publisher of the *National Druggist* is sending to druggists throughout the country." It is an interesting communication. It assumes that "the Health Board wants these formulas to be used as evidence in prosecutions under the Food and Drug laws, not only of the state and city of New York, but of the federal government as well." Being thus convinced that the ordinance is a deep plot, the communication continues:

> "The medical plotters have not yet obtained a conviction in a single case under the Sherley Amendment in which the defendant has put up a fight, for *it is practically impossible to prove that the therapeutic claims made for a preparation whose composition is not known* are 'false and fraudulent.' And since they cannot obtain this information by analysis, they are seeking to inveigle the manufacturers into furnishing it themselves. Once, however, they are given the formulas, they can get as many doctors as is necessary to testify that the preparations made according thereto are not good for the diseases for which they are recommended; and suits may be brought against all who may ship their products to New York City, regardless as to where they live, and manufacturers may have to go to that city to defend themselves." [Italics ours.—Ed.]

Put in other language, the thought conveyed by the foregoing paragraph could be expressed thus: We know that most "patent medicines" are swindles and that the therapeutic claims made for them are false and fraudulent, but so long as we can keep up the element of secrecy regarding composition, the courts will have difficulty in convicting the business! The most avowed enemy of the fraudulent "patent medicine" business has never brought so strong an indictment against the trade as this one, delivered by its friend, the *National Druggist*. The communication closes with the declaration that if the New York ordinance is upheld, other cities and states will be likely to adopt similar measures with the result:

> ". . . manufacturers . . . will have *to give up the trade secrets* upon which the prosperity of their business depends; and more serious still, *they will be supplying evidence which may result in their own undoing.*" [Italics again ours.—Ed.]

All of which means that just so soon as the element of secrecy is removed from fraudulent "patent medicines" the manufacturers will no longer be able to keep out of jail. No wonder the nostrum interests fight the disclosure of formula. No wonder the *National Druggist* fears for its clientele.

THE LECITHINS OF MILK

The nitrogenous and phosphorized fatlike compounds described as lecithins, and more recently designated phosphatids in scientific literature, have been popularly endowed with a variety of potent virtues. In medical advertising, in particular, effects on growth and a number of tonic properties have been ascribed to these "lipoids." There is no doubt that phosphatids are widely distributed in both animal and plant tissues, and in view of this they doubtless play significant parts in various biologic phenomena. Their abundance in nervous tissue, their involvement in the structure of the blood corpuscles, their presence in large amounts in the yolk of the egg — the early nutrient of the young of certain species — point clearly to the importance of phosphatids in the functions of animals.

The question of the existence of phosphatids in milk has been answered in different ways by successive investigators. Presumably competent biochemists have affirmed, others have denied the fact of such occurrence. Even a critical, trained reader would find it difficult to form a judgment on the subject. The reason is largely centered in the methods employed. The detection of the lecithins has ordinarily been indirect in character. Extracts of milk, made with organic solvents, have been tested for phosphorus and nitrogen; and if these elements were detected in so-called "lipoidal" fractions, the presence of a phosphatid was postulated. It happens, however, that such solvents as ether do not always extract true phosphatids from animal tissues and fluids, because these compounds seem frequently to be chemically combined with other substances, such as proteins, from which they need to be liberated before they become "lipoid-soluble." Egg-yolk, for example, yields far more lecithins to the solvent ether if the material has first been treated with alcohol. The nature of these native combinations of phosphatids with proteins is as yet not understood; in any event, they are easily disrupted by so mild a treatment as boiling with alcohol. The facts may be expressed by saying that the lecithoproteins are not soluble in ether; the lecithins are soluble. It will thus be understood that the usual mode of extraction with organic solvents may or may not yield phosphatids, the outcome depending on the preliminary treatment. Hence the discrepant statements of the older literature. In plants, the phosphatids are even combined with carbohydrates in some cases. Thus the chemical problems of these lipoid compounds have become even more complex and uncertain with the progress of knowledge.

The evidence of at least two phosphatids in cow's milk has at length been definitely settled by the excellent investigation of Osborne and Wakeman[1] under the auspices of the Carnegie Institution of Washington. Their unique success has depended on the actual isolation and identification of the compounds made possible by the utilization of hundreds of quarts of milk. One of the phosphatids thus separated contains nitrogen and phosphorus in the 1 : 1 or monamino phosphatid ratio; it yields the nitrogenous base cholin, glycerophosphoric acid and fatty acids, and otherwise resembles the typical lecithin of the textbooks. The other milk phosphatid found contains nitrogen and phosphorus in the 2 : 1 ratio, belongs to the group of diamino phosphatids, and is apparently similar to a compound of this type which has been obtained from egg-yolk, kidneys and other animal organs.

---

[1] Osborne, T. B., and Wakeman, A. J.: Some New Constituents of Milk, First Paper, The Phosphatides of Milk, Jour. Biol. Chem., 1915, xxi, 539.

From the failure to extract phosphorus-containing residues from milk solids by treatment with dry ether, it is evident that the phosphatids are not associated with the common fats or glycerids of milk, which has frequently been assumed. Further evidence of this is furnished by the recently announced fact that butter-fat can be freed from all but extremely minute traces of nitrogen and phosphorus by purely mechanical methods.[2]

PHYSIOLOGIC ASPECTS OF SPINAL ANESTHESIA

The advent of a new and manifestly important technic in the field of clinical medicine or surgery almost presupposes a careful experimental study of its scientific aspects. Modern spinal anesthesia belongs to this category. There is a large literature already available on the clinical aspects of this type of procedure, its successes and limitations, and its advantages and disadvantages. Nevertheless the data on the fundamental responses of the organism to spinal anesthesia and their interpretation under conditions of rigid scientific critique are surprisingly meager. The situation is excellently summarized as follows: "The dangers and discomforts of ether anesthesia have long been recognized. Inevitable nausea, possible pneumonia, difficult respiration, renal injuries, make ether anesthesia impossible in certain cases, dangerous in others, and distressing in all. To meet these difficulties, spinal anesthesia was devised for use in fields where general anesthesia is superfluous, such as operations on the perineum. As a rule beneficent spinal anesthesia is nevertheless by exception open to a grave and sudden danger. In the course of surgical procedures otherwise completely successful, the vasomotor apparatus may suddenly give way. The fall in blood pressure is immediate, sometimes profound, always disquieting. Nor can the surgeon predict in what patient it may appear."[3]

It is obvious that the new method, to be completely successful and satisfactory, must suspend sensations of pain without at the same time paralyzing those regions of the spinal cord which are of importance for functions of the body which cannot well be interrupted. These include preeminently the respiratory and vasomotor responses. Vascular changes which will exsanguinate the "master cells" of the spinal bulb are certain to produce untoward results. A drug may affect the respiratory center either directly, or indirectly by lowering the blood pressure to a point where there is not enough of the circulating fluid to supply the nutritive needs and furnish sufficient oxygen to the bulb. Insufficient blood supply to other regions of the cord may affect other vital functions. It is not sufficiently realized that the vascular area of the abdominal viscera alone is so large as to make splanchnic paralysis very serious. Smith and Porter[3] remind us that the dilatation of the arteries controlled by the splanchnic vasomotor fibers may allow so much blood to enter the corresponding veins that not enough is left in the bulb and cord to support their needs. They state that a rabbit, for example, "may be bled to death into its own portal system, by section of the splanchnic nerves."

The injury to nerve cells caused by low blood pressure and consequent impaired nutrition to them depends on the low level to which the pressure falls rather than on the percental or absolute fall. The duration of the low pressure is an added factor, for nerve cells are notably sensitive to lack of nutrient surroundings. Smith and Porter,[3] at the Harvard Medical School's Laboratory of Comparative Physiology, have just published an elaborate study of the blood-pressure changes in spinal anesthesia with novocain or tropacocain. In their experiments, out of twenty subjects (animals), there was only one case in which a moderate but adequate injection in the lumbar region caused a fall of blood pressure which might have been serious. In the cases suitable for this observation, there was no paralysis of respiration after lumbar injection.

There are, however, marked falls in blood pressure. Recovery from them may take place. Of course, injections can be made so as to reduce the blood pressure very materially and paralyze the vasomotor apparatus as effectually as if the spinal cord had been extirpated. For this result one need only enter the vertebral canal at higher levels, such as the cervical region. These are of only indirect interest in a practical way, because the lower regions alone are ordinarily entered in surgery. It is important to learn that after dorsal or lumbar injection the fall of blood pressure is due to paralysis in the splanchnic area, not to involvement of the bulbar vasomotor center.

It would be almost ideal if a spinal anesthetic were found to paralyze the afferent sensory paths alone in the cord; but a strength of drug sufficient to do this will also paralyze the efferent vasomotor fibers. So far as the diffusion of the drugs used is concerned, on the whole, the bulk of the solution seemed to Smith and

[3] Smith, G. G., and Porter, W. T.: Spinal Anaesthesia in the Cat, Am. Jour. Physiol., 1915, xxxviii, 108.

Porter to be of greater importance than its strength. Dilute solutions usually, but not always, spread farther than concentrated ones. Gravity, too, is of some importance, inasmuch as tilting the animal into a head downward posture increases the diffusion of the drug. A greater fall of blood pressure occurred in the cases in which epinephrin was used in connection with tropacocain or novocain. Measures taken to raise the fallen blood pressure were of little value. It was easy to restore the pressure to normal, but the normal level could be maintained for only a few minutes.

It should be distinctly understood that these findings and conclusions represent the outcome of animal experimentation alone. They must be regarded as furnishing the key to the explanation of the most serious symptom attending spinal anesthesia, namely, the occasional serious fall of arterial pressure. Such information is the indispensable prerequisite to any rational progress in the application of the method in surgical practice. The experiments teach that spinal anesthesia can be successful only when the afferent paths are paralyzed, without at the same time paralyzing enough splanchnic cells or splanchnic root fibers to lower the blood pressure to a degree that may threaten the continued activity of the centers situated in the cervical cord and the spinal bulb.

Current Comment

"MAY WE COUNT ON YOUR ASSISTANCE?"

In the Propaganda Department this week, we print an editorial on advertising copied from the *New York State Journal of Medicine*. The conclusion is couched in strong language — but not a whit too strong:

> "When an exploiter places on the market a nostrum of no intrinsic value (excepting the bottle and cork) for which he claims virtues which it does not possess . . . he robs the purchaser of his money and health, thereby becoming a thief of the most despicable order. Any medical journal printing the fraudulent claims contained in the advertisements of the nostrums condemned by the Council on Pharmacy and Chemistry is an accessory to this act of thievery and the subscriber to such journals voluntarily assumes the position of an accomplice."

An appreciation of the subscriber's responsibility, emphasized in the editorial just quoted, may have prompted a Brooklyn physician to write us, "Cast your eye over the enclosed advertisements [from the *Therapeutic Gazette*] and then wonder at the nerve in asking subscriptions from the profession." Almost the same mail brought us, from another New York physician, a similar protest accompanied by advertisements from the New York *Medical Record*, these differing from those in the *Therapeutic Gazette* in degree but not in kind. Still another New York physician sent a collection of advertisements from the *New York Medical Journal*. Some of the advertisements sent us are of the rankest frauds, neither better nor worse than the fraudulent "patent medicine" advertisements appearing in lay periodicals — in fact, some are of "patent medicines" which many of the better lay magazines will not admit to their advertising pages. We hope that our correspondents have expressed their views on the subject to the publishers of the respective journals; nothing will so speedily bring about reform as determined and practical protest from the profession. One of the advertisements enclosed by a correspondent is pertinent here: "May we count on your assistance?" ingenuously inquires the Berlin Laboratory, Ltd., and with cool effrontery continues: "We are telling the layman about Intesti-Fermin. . . . May we count on your assistance in spreading this message to everyone. . . ?" Now who and what, doctor, may "count on your assistance?" Is it the quack and the nostrum manufacturer? Do you want to be an accomplice in what the *New York State Journal of Medicine* terms an "act of thievery"? Do you wish to assist in the promotion of Bell-Ans, Sal Hepatica, Campho-Phenique, Angier's Emulsion, Bromidia, Tongaline, Sanatogen, Sanmetto, Kutnow's Powder, Phenalgin, Micajah's Wafers, Ammonol, Chionia, Formamint, Anedemin, Neurosine, Pasadyne, etc.? If so — lend your support to the medical journals that advertise them. If, however, it is the public — your own patients — that may "count on your assistance," then your course is equally clear: refuse to accept from the mail, subscribe for, contribute to, or in any way countenance the journals that help to keep alive quackery and fraud — and *let the publishers know why!* The result will soon be evident. Do not, however, stop with this negative measure; it is equally important to sustain those journals which, without the backing of professional organization, have cleaned up their advertising pages and freed themselves from the blighting influence of the nostrum evil. If, through inertia and inattention, you permit your mail box and library table to become littered with the unclean swarm of nostrum-purveying journals, clean house. Then help support as many as you can afford of the unofficial publications that are making a creditable stand for decency in advertising. If the medical profession as a whole will manifest its opinion and desires in an unmistakable and practical way, an uplift in medical journalism will speedily be accomplished. Then and not till then can we consistently appeal to lay magazines and newspapers to stop promoting frauds in their advertising pages.

THE PUBLIC IS WAKING UP

A week or two ago we reprinted an editorial from the New York *Sun* on "The Newspaper Press as an Educator in Medicine." The editorial contains one paragraph which is peculiarly appropriate in connection with the comment given above. Here it is:

> "The *Sun* has endeavored to impress upon its readers the fallacy, if not the danger, of accepting prescriptions from doctors who, too indolent or unscientific to think out their own prescriptions, write for 'Kill or Kurem's' Hydrated Phosphate Compound, or C. D. & X. Company's 'Diostenin' or 'Professor Chadelle's Cresolated Compound,' the composi-

> tion of which they either do not know at all or accept from the manufacturers. The chief aim of the latter naturally is to popularize these preparations by leaving samples at the doctor's office or offering them in generous quantities for the mere cost of a postal card. This injustice and danger to the lay patient will never be removed, because the medical journals with but a very small exception advertise these preparations, the value and uses of which the manufacturers, with the most brazen effrontery, offer to teach the doctor who will listen."

How many times The Journal has said the same thing. It is encouraging to see that the newspapers are helping to reform the medical profession in this regard. When the average layman wakes up to the fact that his doctor is prescribing a "patent medicine" — for the average layman will not be able to distinguish between many of the so-called "ethical proprietaries" and the common, every-day "patent medicine," any more than we are able to do so — he will either go to a doctor who will give him the benefit of scientific training and individual thought, or he will go to the druggist and purchase his own medicine and read for himself what the manufacturer has to say regarding it.

ASEPSIS AND THE DISH TOWEL

Among the low-priced restaurants and lunch rooms which are numbered by hundreds in our large cities, there is one (it is but a type—there are dozens like it) whose exterior of white brick and plate glass is as sparkling and bright as a newly frosted cake. Within, an expanse of white enamel, resplendent metal and spotless linen proclaims a devotion to cleanliness rivaled only by the surgical ward in a hospital. The waitresses are as neat and trim as uniformed nurses. In this stainless temple of alimentation one of the immaculate priestesses has been seen to pick up a glass just used by a departing guest, polish it with the dish towel at her belt, and calmly replace it on the table to be used by the next patron! One might instance even more horrifying infringements on prandial decency in more pretentious establishments; one might expatiate on the possible dangers of infection from such practices. The establishments do not lose custom thereby, probably because the public, while vaguely impressed with the beautiful ideal of asepsis or perfect cleanliness, has a pathetically inadequate idea of what it means. It is therefore encouraging to read the following, under the heading "The Mischievous Wiping Cloth," in the November issue of the *Journal of Home Economics*:

> The dish towel, even the genteel barred variety, called a tea towel, is in bad repute. Ever since men began to look through the microscope and think in terms of the microscope its fate has been sealed. Only when freshly washed and boiled and used in clean hands to wipe the rims of already scalded and drained dishes is it to be admitted into a modern kitchen. Used in dirty hands till grimy, carried on the arm of a waiter and used to polish a plate or wipe up a table, it belongs to the dark ages, hygienically speaking. In dish washing the household should more and more approach the practice of the laboratory where glassware and porcelain are washed, rinsed in boiling water and placed to drain. No cloth, no matter how well known its antecedents, is allowed to touch them, for they are now absolutely clean and must remain clean.

Perhaps, if such ideas as these are becoming current, we may hope for the day when Bridget will invariably sterilize her dish cloth and scorn the dish towel for her aseptic dishes, while "neat-handed Phillis" will always complete her coiffure beyond all revision before coming to serve our food. At any rate, one may always hope.

THE "CHEMICAL" WAR

The present war has been frequently called — not inaptly — a "chemical war" because so many of the destructive energies at work are due to modern advances in chemistry, particularly in our knowledge of the nitrogen compounds.[1] This designation has seemed, perhaps, a slur on the science of chemistry. It has even been hinted that chemistry is more harmful than beneficial, and that its development represents a serious detriment to mankind. In an address presented at the meeting of the American Chemical Society at Seattle, Dr. L. H. Baekeland[2] discusses some of these imputations. This is by no means the first "chemical" war. The art of killing and robbing became chemical the day gunpowder was invented, how long ago we are not quite sure; but it is certainly over 1,000 years ago and perhaps nearer 2,000 years ago. Napoleon, over 100 years ago, was probably the first to recognize that chemistry and the related sciences might be used to great advantage in giving him decided advantages over his enemies. Incidentally he thus helped to lay the foundation for some important branches of chemical industry. It was not very long, however, before his enemies learned the lessons of chemistry, and he is reported to have stated that "the dogs have learned something from us." The perversion of chemistry to military uses has been only a side issue. Some of the most important advances in military methods have originated in some of the most beneficent steps in progress made by chemistry. Dr. Baekeland insists emphatically that it is not fair to reproach chemistry with "the fact that nitrocellulose, of which the first application was to heal wounds and to advance the art of photography, was stolen away from these ultrapacific and highly laudable purposes for making smokeless powder and for loading torpedoes." Nor is it fair to blame the chemist for the fact that phenol, which in Lister's hands revolutionized surgery, was turned from a blessing to humanity into a fearful explosive after it had been discovered that nitration changes it into picric acid. Curiously enough, many of those who have been engaged in diverting or perverting chemical compounds from usefulness in peace to the greatest destructiveness of war have been convinced that this very destructiveness from its awful character would produce an inevitable reaction which would guarantee peace. Alfred Nobel, the founder of the world peace prize, was a manufacturer of dynamite and made a fortune in high explosives. He fondly hoped that these high explosives would make war so destructive as to put an end to it forever. The old Romans had a maxim that from the abuse of a thing no argument was valid against the use of it. Chemistry has been an immense boon to the human race, even though at times its misuse has led to some of the worst calamities of human history.

THE RÔLE OF THE THYROID IN IMMUNITY

A number of observations have been made in order to determine what rôle, if any, the thyroid plays in immunity. Fassin recorded a diminution in the hemolytic and bacteriolytic properties of the blood after thyroidectomy, and Marbé found that the opsonic and phagocytic powers suffer, while Frouin declared that in dogs there was no loss of antitoxin, although the alexin was diminished. Lerda and Diez found that guinea-pigs are about as resistant to tetanus toxin without the thyroid as with it. Fjeldstad did not observe any interference with the formation of typhoid agglutinins after thyroidectomy in guinea-pigs. Most recently Launoy and Levy-Bruhl[1] have studied the problem in question, using an animal that heretofore has not been made the subject of experiments in this particular direction. These investigators were unable to make out that the removal of the thyroid in the chicken had any effect whatever on the course of a spirochetal infection (spirochetosis gallinarum). In view of the part played by the thyroid in maintaining the health of the body, it would not be surprising if disturbances of the function of this gland should be found to favor the development of infection, if not by direct interference with the formation of antibodies, then in some more or less indirect manner, such as disturbances of the functions of the leukocytes. As shown by this review of experimental work, the results obtained are not in agreement—a circumstance which is not so remarkable when we consider the variety of animals and methods employed. Much more work is required before the question as to the exact rôle of the thyroid in the resistance to infection will be settled. Under any circumstances the results obtained so far do not warrant the direct association of the thyroid with the production of antibodies.

---

[1] Launoy and Levy-Bruhl: Ann. de l'Inst. Pasteur, 1915, xxix, 213.

State Control of Sewerage Systems.—The Maryland act of 1914 empowers the State Board of Health to order local authorities to install public systems of water supply, sewerage or refuse disposal in any municipal division of the state whenever the absence or incompleteness of such systems was sufficiently prejudicial to the health or comfort of the community. The local authorities might if they deemed any such order unlawful, unreasonable or unnecessary, bring an action in the courts to set aside the order. In October, 1914, the State Board of Health ordered the county commissioners of Baltimore County to install a sewerage system in a specified area. The commissioners sought in the courts to have the order set aside. They attacked the constitutionality of the law, but did not allege that the order was unreasonable. The supreme court of the state held that the sections of the act attacked were constitutional, but sent the case back to the circuit court to have determined the reasonableness of the order.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest; such as relate to society activities, new hospitals, education, public health, etc.)

DISTRICT OF COLUMBIA

Home from Serbia.—Dr. Louise Taylor Jones, who has been serving in Serbia with the Red Cross, landed in Boston, October 21.

Measures for Health.—The Public Health Committee of the Board of Trade, in its annual report, has made health recommendations as follows: an appropriation to permit the erection of the proposed municipal hospital; the establishment of dental clinics in connection with the work at all local hospitals; improvement of ventilation in street cars; the establishment of an institution for idiotic, imbecile and feebleminded children; legislation for voluntary commitment for the Government Hospital for the Insane; the provision of a medical psychologist for every reformatory in the District; the erection of public baths in the various schools of the city; the establishment of a hospital for inebriates; the appointment of additional inspectors, the provision of increased laboratory facilities in the health department, and the erection of additional underground public comfort stations.

ILLINOIS

Personal.—Dr. Emmett A. Garrett has been appointed health commissioner of Peoria to succeed Dr. Edward Hasson.——Dr. J. W. Allison, Essex, who was operated on October 29 at Rochester, Minn., for the removal of gallstones, is reported to be doing well.——Dr. C. St. Clair Drake, secretary of the State Board of Health, Springfield, has returned from a trip to the Pacific coast.——Dr. Robert C. Bourland, Rockford, is convalescing from an attack of diphtheria.——Dr. Harrison R. Rogers, Rockford, was operated on for appendicitis in the Presbyterian Hospital, Chicago, October 30, and is said to be doing well.——Dr. William G. Bechtold, Breeze, who has been under treatment for tetanus in St. Elizabeth's Hospital, Carlyle, is reported to be improving.——Dr. James A. Kleinsmid, Aledo, who has been seriously ill as the result of an automobile accident, early last month, is now convalescent.——Dr. Barker Althunian, Joliet, has sailed for Europe, November 3, to work with the Russian Red Cross.

Chicago

Correction.—Dr. Oscar Dodd has been elected president of the Illinois Charitable Eye and Ear Infirmary Alumni Association, and not the Illinois Charitable Eye and Ear Infirmary as erroneously stated in the issue of October 30.

Meeting of Gynecologists.—At the thirty-seventh annual meeting and dinner of the Chicago Gynecological Society October 15, the following officers were elected: president, Dr. Channing W. Barrett; vice presidents, Drs. Franklin H. Martin and Mark T. Goldstine; secretary, Dr. N. Sproate Heaney; treasurer, Dr. Charles B. Reed; editor, Dr. W. A. Newman Dorland, and pathologist, Dr. Arthur H. Curtis.

To Prosecute Quacks.—Thomas S. Hogan of Chicago has been appointed special state's attorney in Cook County to handle violations of the medical practice act prosecuted by the state of Illinois. Mr. Hogan held the appointment of official counsel to the State Board of Health until the position was abolished by a decision of the supreme court. The court decision which in effect abolished the position held by Mr. Hogan with the state board, placed in jeopardy all pending prosecutions against quacks. The appointment had the approval of Governor Dunne.

Institute of Medicine Organized.—The Institute of Medicine of Chicago, the purpose of which is stated to be the encouragement of the advancement of medical science, was organized formally at a dinner at the Hotel La Salle, November 5, which was attended by 150 charter members of the organization. The officers elected were as follows: president, Dr. William E. Quine; vice president, Dr. Ludvig Hektoen; secretary, Dr. John G. Wilson; treasurer, Dr. J. A. Clapp; and board of governors, Dr. Frank Billings, chairman, William Allen Pusey, E. Fletcher Ingals, and William

H. Wilder. The objects of the organization are similar to those of the College of Physicians of Philadelphia, the Academy of Medicine of New York City, the Boston Medical Library, etc. It will conflict with no other medical organization. One of the immediate objects will be the securing of a permanent home for the medical profession of Chicago and vicinity.

INDIANA

Pure Food Violators.—A new policy has been adopted by H. E. Barnard, state food and drug commissioner, who declares that any saloon that violates the pure food law of Indiana and refuses to abide by the orders of the pure food bureau will be closed up the same as a restaurant that refuses to obey the law.

Mural Decorations for Hospital.—The mural decorations for the new Burdsal wing of the City Hospital, Indianapolis, have just been completed by William E. Scott, a colored artist. The work has required many months and is regarded as the most successful which the artist has done in this line. The subjects for the women's ward were "The Four Seasons" and "Nations Coming to Light." For the obstetrical ward Mr. Scott chose the subject of the life of Christ. Three hundred figures were used on twenty-two panels, varying in width from five to forty feet.

The Dispensary and University Trouble.—For several years the board of health of Indianapolis has contracted with the School of Medicine, Indiana University, so that there would be but one free dispensary in Indianapolis, in lace of the former City Dispensary and the Bobbs Disensary at the college. The board of health, however, eserved to itself the right to conduct and supervise this oint dispensary and also the power to discharge all mployees and officers. The board of health paid the Medial College $915 a month for its share of the expenses to e dispensary, the college paying the balance, which mounted to nearly $300 per month. Various breaches of e contract recently, although the contract has but two ore months to run, have caused the board of health to disontinue its support to the Medical College and to refuse o admit the medical students to the City Hospital. A new ity dispensary has been opened at the City Hospital and he staff, officers and employees of the previous joint disensary are all taken care of in the new dispensary. At he present time the only clinical facilities open to the tudents of the Medical College are those at the Long Hosital, which has very few patients compared to the City Hospital. A mass meeting of the students was held Novemer 5, to ascertain what the faculty intends to do in regard o furnishing them with clinics. Nothing definite has been done concerning the solution of this problem.

IOWA

Branch Laboratories Established.—Branch laboratories of the State Bacteriologic Laboratory have been established at Davenport and Waterloo. The work of these branches will be superintended by Dr. Henry Albert of the University of Iowa, Iowa City.

Pathological Laboratory Incorporated.—Articles of incorporation of the Davenport Pathological Laboratory were filed with the Scott County recorder, November 2. The organization is not for profit and the officers are as follows: president, Dr. Henry U. Braunlich; secretary, Dr. William A. Stoecks, and treasurer, Dr. Anthony P. Donohoe.

Personal.—Dr. James M. Brooks, Newell, has been made a life member of the Buena Vista County Medical Society. ——Dr. Hobart E. Martin, Clinton, who was operated on for hernia at Mercy Hospital, October 21, is reported to be doing well.——Dr. Edward J. Van Metre, Tipton, was seriously injured by the overturning of the automobile in which he was riding, near Tipton, October 9. His collar bone and three ribs were fractured.

MARYLAND

Medical Societies Merge.—The medical societies of the University of Maryland School of Medicine and the College of Physicians and Surgeons were merged at a special meeting of a committee appointed by the combined faculties, recently. Since the combination of the two schools of medicine has become permanent, it was decided that a single medical society representing both schools would bring about the best results. Dr. Albert H. Carroll was elected chairman of the new society, Dr. Elmer B. Freeman, vice chairman, and Dr. Alexius McGlannan, secretary.

Personal.—Dr. Karl H. Van Norman, first assistant superintendent of Johns Hopkins Hospital, has resigned to accept a captaincy in a Canadian regiment, which is soon expected to be assigned to active duty.——Dr. William B. Hunter, Baltimore, superintendent of Kernan's Hospital and Industrial School for Crippled Children, has resigned, to take up private practice in Wilmington, N. C.——Dr. John D. Fiske, Baltimore, who is employed by the Atlantic Transport Company, while climbing a ladder up the side of a ship, slipped and fell 20 feet, breaking his shoulder.——Dr. Leonard G. Rowntree, assistant head of the department of medicine of Johns Hopkins University, has been appointed professor of medicine and chief of the department in the University of Minnesota, succeeding Dr. Charles Lyman Greene, St. Paul, resigned.——Dr. C. Hampson Jones assumed his duties as chief of the bureau of communicable diseases of the State Department of Health, November 4.——Dr. William Travis Howard, Jr., became assistant commissioner of health of Baltimore, November 4.——Drs. Lewis C. Spencer and Martillus H. Todd of the staff of American surgeons at the Pau Base Hospital, France, returned to Baltimore, October 26. ——Dr. Marshall B. West, Catonsville, is reported to be ill with septicemia.

MINNESOTA

New Bi-County Sanatorium.—On October 18, work was commenced on the Clay-Becker County Tuberculosis Sanatorium at Sand Beach Lake. The cost of the construction of the sanatorium will be about $45,000 and it is to be completed about July 1, 1916. The building will be of brick and reenforced concrete, three stories in height and will accommodate about twenty-five patients.

Personal.—Dr. James F. Hammond, St. Paul, who has been in service on the Gallipoli Peninsula, returned to London in charge of wounded soldiers, September 23, and after a short stay, returned to the Mediterranean.——Dr. William J. Mayo and party ended their cruise on Dr. Mayo's steamer *Oronoco*, at Louisville, October 23, and returned to Rochester by rail. The trip included the Mississippi River from Winona, Minn., to Cairo, Ill., the Ohio and Cumberland rivers as far as Rome, Tenn., and then the Ohio River to Louisville, Ky., where the cruise ended.——Dr. William J. Mayo, Rochester, has been elected president of the Good Roads Organization for Olmstead County which was organized recently.——Dr. Delbert F. Dumas, Cass Lake, has sold the Cass Lake Hospital to Dr. Samuel R. Fraker, Chelsea, Iowa.——Dr. James A. Rippert, Chisholm, lectured before the senior class of the University of Minnesota Medical School, October 27, on "Medical Supervision in Public Schools."

Whole-Time Men in Health Service.—A report of the public health committee of the Minnesota Public Health Association contained the following comment on the reorganization of the health service in Minneapolis, St. Paul and Duluth: Minneapolis is talking of employing several whole-time men and having a complete reorganization of the department, to be effective about Jan. 1, 1916. It is hoped that the talk will materialize into something definite. Outside of their visiting nurse service, and in Duluth the milk inspecting service, the health departments of the three large cities of the state have nothing worth commenting upon. A rating of efficiency of organization by the federal department would be disgraceful to the state of Minnesota. In spite of a lack of organization, poor facilities and inadequate pay, the men in charge of the departments in the three cities are doing excellent work. In all three, Minneapolis, St. Paul and Duluth there should be a complete reorganization with the employment of whole-time men trained in public health work.

MISSISSIPPI

State Board of Health Wants Sanatorium.—The State Board of Health has appointed a committee composed of Drs. Waller S. Leathers, University; L. Wade Glass, Lyon; Harvey F. Garrison, Seminary; James J. Haralson, Forest, and Daniel J. Williams, Gulfport, to draft a bill to be presented to the next legislature, asking for the creation of a state sanatorium for tuberculosis.

Health Day.—Pursuant to a proclamation by Governor Brewer, dated September 14, October 29 was set apart as Health Day at the request of the state educational department. Programs were carried out on that day in the public schools and a six-months' campaign of education prepared by the State Board of Health and the department of education was inaugurated.

MONTANA

Medical Inspection.—The school board at Bozeman has accepted the proposition of the Gallatin County Medical Society to establish medical inspection in one school in Bozeman. The society by resolution agreed to furnish medical inspection for one of the smaller schools of the city and to give detailed report of such inspection to the board of trustees without making any charges. The Hawthorne School has been selected. Bozeman has not heretofore had medical inspection of schoolchildren.

Personal.—Dr. John W. Frizzell, Great Falls, fractured his leg while cranking his automobile, October 18, and also received internal injuries when the car started, crushing him between the car and the garage wall. He is reported to be in a critical condition at the Deaconess Hospital, Great Falls.——Dr. Charles F. Jump, Bozeman, has returned after postgraduate work in Chicago.——Dr. Willoughby G. Dye, Deer Lodge, has gone to Boston for postgraduate work in Harvard Medical School.——Dr. William L. Renick and Dr. Thomas C. Witherspoon of Butte have recently purchased the ranch of the late Dr. Robert P. R. Gordon, Great Falls, on the Swan River, in the vicinity of Swan Lake. The ranch will be used as a summer residence.——Dr. Herbert H. Judd of Bozeman addressed the Woman's Club at Livingston, November 3, on medical inspection of schoolchildren.

Medical Attention Under Compensation Act.—The attorney-general has given the following opinion to the State Accident Industrial Board regarding medical attention under the provisions of the workmen's compensation act:

> "Whenever an accident occurs and no loss of time results to the injured employe, and the nature of the resulting injury is such as to make it reasonably necessary to secure medical service, attention or medicines, or to give care, attention or treatment to the injured employe, the employer, insurer or industrial accident fund, as the case may be, depending upon the plan adopted by the employer, is liable for the reasonable and necessary expenses incurred for such medical services, attention or medicines, not exceeding in any one case the sum of $50, and not extending over a period of more than two weeks immediately following the accident."

NEBRASKA

Personal.—Dr. John A. Waggener, Humboldt, has been appointed physician to the Soldiers' and Sailors' Home, Grand Island.——Dr. Volney D. Douglas, Crab Orchard, was severely injured by an axe wound of the knee, October 10.——Dr. Adrian F. Burkard, Omaha, has moved to Soquel, Calif.——Dr. William R. Peters, Stanton, while returning from a professional call, recently, was seriously injured by the overturning of his automobile.

Contagious Disease Hospital for Lincoln.—Following a visit to the Isolation Hospital of Lincoln by a special committee from the Lancaster County Medical Society, the committee has recommended that another hospital for the treatment of contagious diseases be built. Under the present system there is no provision for the care of patients suffering with diphtheria and scarlet fever and the isolation hospital is used chiefly for smallpox. The plan of the committee is to erect a small cottage some distance from the isolation hospital, for the treatment of other communicable diseases.

NEW YORK

Vassar Alumnae Ask Health Work.—Twelve young women, members of the Buffalo Chapter of the Vassar College Alumnae Association, have requested the deputy health commissioner to assign them to work in connection with the extension of the health center movement.

Health Centers for Buffalo.—Health Commissioner Fronczak announces that he intends to designate Dr. Nelson G. Russell as chief consulting physician for Buffalo. He has also decided to inaugurate three additional health centers, one at 1067 Grant Street, one at 591 William Street and a third on the grounds of the Municipal Hospital at 770 E. Ferry Street. The entire scheme is merely a rearrangement and readjustment of the territory now covered by the staff of the health department. The following physicians have been appointed by Dr. Russell to take charge of the tuberculosis work: Dr. James H. Donnelly, chief examiner; Dr. David Cohn, examiner at the Municipal Hospital health center; Dr. George J. Eckel, examiner at the East Buffalo center, and Dr. Harry Mead, examiner at the Black Rock center.

New York City

Home for Cancer Patients.—The new House of Calvary on Macomb's Road in the Bronx, erected at a cost of $120,000, has been formally opened by Cardinal Farley. This home for the cancerous poor was founded many years ago in Perry Street by Adrian Iselin, and was later moved to upper Seventh Avenue.

Personal.—Dr. and Mrs. W. Seaman Bainbridge and Dr. John Van der Poel have returned from Europe.——Dr. Clarence A. McWilliams sailed for France, November 3, to take charge of the French Military Hospital at Passy.——Dr. W. J. Maloney, who was wounded by shrapnel while serving with the Red Cross at the Dardanelles, reached New York on the *St. Louis*, October 31.

Violations of the Drug Law.—A report just made by District Attorney Wilmot shows that since the first of the year there have been 700 convictions in the court of special sessions of persons selling and possessing drugs. This number, however, does not include the many thousand addicts who have been committed by magistrates to hospitals for treatment. Among those convicted there have been fifty druggists and a number of physicians. The report states that the sale of habit-forming drugs has been greatly decreased because of the crusade of the district attorney's office.

Health Department Again Warns Traction Companies.—Dr. Haven Emerson, who has just succeeded Dr. Sigismund Goldwater as health commissioner of New York City, has declared his intention of carrying out Dr. Goldwater's policies. One of his first steps along this line has been to send a notice to the car companies that the order issued by Dr. Goldwater last March calling attention to that section of the city charter which forbids overcrowding is still in effect and that inspectors will begin to ride on the cars shortly and count passengers.

NORTH CAROLINA

Hospital News.—Mrs. Edith Vanderbilt, widow, and W. K. Vanderbilt, executor, of the late George W. Vanderbilt, have executed a deed to the Clarence Barker Memorial Hospital on the site now occupied by the Biltmore Hospital and Dispensary. The deed proposes that the hospital be used continuously for hospital and dispensary purposes for thirty years and that otherwise it shall revert to the estate of the late George W. Vanderbilt.——St. Luke's Hospital, New Bern, has been completed and was formally opened November 1 for public inspection. On the next day the hospital was ready to receive patients.

Personal.—Dr. Herbert H. Purinton, Durham, has been appointed by the British government, health officer to the Leeward Islands, British West Indies, and has left for his new post of duty.——Dr. C. Banks McNairy, superintendent of the State School for Feebleminded, Kinston, was severely injured in an encounter with an enraged bull on the farm attached to the school.——Drs. Watson S. Rankin, Raleigh, secretary of the State Board of Health, and Thomas M. Jordan, Raleigh, have returned after a tour of school inspection systems in eastern cities. Dr. Jordan started on the school inspection work for the State Board of Health, November 1.——Dr. R. H. Crawford, Rock Hill, has returned from service with the American Red Cross in Germany and Austria.

OHIO

Tuberculosis Hospital Donated.—Peter Kuntz, Dayton, has purchased a site for the proposed tuberculosis hospital which he will erect for the use of the people of Dayton at a cost of $500,000. The site selected is on the highlands west of the city.

Western Reserve News.—President Charles F. Thwing of Western Reserve University in his annual report renews a recommendation that a fund be established to take the name of the late Dr. Hunter H. Powell, a distinguished member of the faculty of the school of medicine. To the $40,000 which is expected will be set aside for this fund, President Thwing said that $10,000 may fittingly be added.——He also asks that a special fund be set aside from the $1,000,000 donation to the school of medicine under the name of Dr. Dudley P. Allen, the income of this fund to be used in research in surgery.——The delay in rebuilding the Western Reserve School of Medicine and Lakeside Hospital is contributed to by the "commercial and industrial depressions and uncertainties caused by the European War."

Personal.—Dr. Charles L. Files, Van Wert, who has succeeded Dr. John R. Johnson as superintendent of the District Tuberculosis Hospital, Lima, assumed the duties of his new position, November 1.——At the quarterly meeting of the council of the State Medical Association held in Columbus, October 25, Mr. George V. Sheridan was unanimously elected executive secretary of the organization.——Dr. Joseph G. Fudge, Spring Valley, was seriously burned by the explosion of an acetylene tank, October 23.——Dr. James G. Cullen, Toledo, is reported to be critically ill.——Dr. John N. Calhoun, Lisbon, is reported to be ill with nephritis in Lakeside Hospital, Cleveland.——Dr. Edwin A. Hamilton, Columbus, has returned after four months' Red Cross service in Gleitwitz, Germany.——Dr. Philip D. Wilson, Columbus, has returned after military hospital service in France.——Dr. Charles H. Ross, Alliance, was knocked down by a motorcycle, October 11, fracturing his right leg below the knee.——Dr. Cassius M. Shepard, Columbus, who was operated on for appendicitis, October 2, has made a satisfactory recovery.——Dr. Howard W. H. Nelles has been elected chief of staff and Dr. Joseph J. Sweeney, secretary of the Lucas County Hospital, Toledo.——Dr. Charles G. Souder, has been appointed superintendent of the Lucas County Tuberculosis Hospital, Toledo.

PENNSYLVANIA

Cornerstone Laid.—The cornerstone of the new Children's Building of the Tuberculosis League Hospital, Pittsburgh, was laid by Dr. Samuel G. Dixon, commissioner of health of Pennsylvania, October 29.

State Hospital Officials Meet.—At a meeting held in Philadelphia the week of October 29 of the trustees and superintendents of state and incorporated hospitals for the insane and feebleminded of Pennsylvania, the following officers were elected: president, William M. Donaldson, Harrisburg; vice president, Dr. Harry W. Mitchell, Warren; and secretary, Dr. Henry I. Klopp, Rittersville.

Personal.—Dr. Benjamin Frye, Sharpsville, who has been seriously ill with diphtheria, is reported to be much improved.——Dr. J. Burket Howe, Erie, underwent an operation October 18 and is reported to be doing well.——Dr. Clinton T. Saylor, Rockwood, who was operated on for appendicitis at a hospital in Johnstown recently, is convalescent and will soon resume practice.——Dr. Fremont W. Frankhouser, Reading, who has been incapacitated for some time on account of an automobile accident and then by reason of an operation on the eyes, has recovered and resumed practice.——Dr. Michael George Dewey, Girardville, was seriously injured in an automobile accident, October 12.——Dr. Theresa G. Breene Baum, Oil City, is reported to be critically ill.——Dr. Francis E. DeLong, Bayers, was seriously injured, October 2, by being thrown from his buggy in a runaway accident.

Philadelphia

Personal.—Dr. Frank R. Starkey has returned from a five months' tour of North America and has resumed practice.——Dr. Ray Parker of the Philadelphia Hospital for the Insane has resigned to accept an appointment as first assistant at the State Hospital for the Chronic Insane, Wernersville, where she will succeed Dr. Robert M. Alexander, resigned to enter private practice in Reading, Pa.——Dr. Horatio Connell Jones underwent an operation in the Samaritan Hospital, October 29.——Dr. Bertha Whaland and Dr. Ann T. Gibson have been appointed assistant medical school inspectors by Director Ziegler.

Hospital Wins Suit.—Judge Gummey in the Orphans Court, November 3, awarded to the Episcopal Hospital a bequest of James J. Hope for the establishment of a ward in a hospital devoted to the treatment of contagious diseases. The bequest was frequently referred to as a fifty-thousand dollar legacy, but, according to the adjudication, it amounts to $18,924.90. In January the legacy was awarded to the Philadelphia Hospital for the treatment of contagious diseases and was later set aside and all hospitals invited to submit evidence. Upon the testimony of trustees of the Episcopal Hospital that they intended to alter their buildings for the purpose of treating contagious diseases, the new award was made.

VIRGINIA

Hospital Notes.—The contract between the Abingdon Hospital and the Board of Supervisors of Washington County has been renewed for one year.——The William A. Crowder Memorial Hospital, Petersburg, was formally opened the first week in October.

Washington County Physicians Organize.—Physicians of Washington County met at Bristol, October 22 and organized a medical society with an initial membership of fourteen and the following officers were elected: president, Dr. Andrew F. Horne, Glade Spring; vice presidents, Drs. D. L. Kingsoliver, Green Springs; William L. Gannaway, Abingdon, and W. H. Teeter, Barytes; and secretary, Dr. Paul Kernan, Bristol.

Tri-County Medical Society Organized.—Physicians of King George, Stafford and Spotsylvania counties and the city of Fredericksburg met October 19 at Fredericksburg and organized the Tri-County Medical Society, electing the following officers: president, Dr. William A. Harris, Spotsylvania; vice presidents, Drs. Joseph N. Barney, Jr., Fredericksburg, and Henry W. Patton, Hemp, and secretary-treasurer, Dr. C. Mason Smith, Fredericksburg.

New State Society Officers.—At the forty-sixth annual meeting of the Medical Society of Virginia, in Richmond, October 26 to 29, the following officers were elected: president, Dr. Joseph A. White, Richmond; vice presidents, Drs. Marshall J. Payne, Staunton; Edward E. Feild, Norfolk, and Robert M. Wiley, Salem; treasurer, Dr. Mark W. Peyser, Richmond (reelected); secretary, Dr. Paulus A. Irving, Farmville (reelected); delegates to the American Medical Association, Drs. Southgate Leigh, Norfolk, and William E. Anderson, Farmville; Dr. Edwin L. Kendig, Victoria, councilor from the Fourth District; and Dr. John Staige Davis, University, councilor at large. Norfolk was selected as the next place of meeting.

Antituberculosis Work.—The executive secretary of the Virginia Antituberculosis Association in her annual report states that during the year sixty-five lectures were given in sixteen counties of the state. That in six counties, county societies have been formed and that at present sixteen active leagues or committees are at work in the state. Danville has opened a fresh-air school. The association received from the sale of Christmas seals, $3,886.——The Tuberculosis Sanatorium on Reservoir Hill, which is being erected by the Danville Antituberculosis Society and the city of Danville, is practically ready for occupation. At present there are two tuberculosis patients in the camp who have been occupying tents for several months and are showing great improvement.

CANADA

Personals.—Dr. Harold C. Sutton, Cooksville, Ont., has joined the Canadian Army Medical Corps.——Dr. R. W. Bruce Smith, Toronto, inspector of the provincial hospitals for the insane for Ontario, who has been ill since last spring, is now reported to be recovering rapidly.——Dr. J. Arthur Sutherland, who since his graduation from Trinity University in 1896, has been practicing in British Columbia and Fairbanks, Alaska, was in Toronto in October on his way to go into service with the French Army Medical Corps.——Lieut.-Col. Walter T. Connell, Kingston, Ont., on duty with Queen's Stationary Hospital in Egypt, has sailed for Canada.——Dr. Alfred W. Nixon, M. P. P., Georgetown, Ont., has volunteered for active service and has been accepted. He will leave shortly for England to join the R. A. M. C.——Dr. Vernon Lamb, St. Andrews, N. B., is at present attached to the Canadian Cavalry depot at Shorncliffe, England, having 1,500 men in his charge.——Dr. Thomas G. Brodie, University of Toronto, recently returned from England, after a summer with the University of Toronto Base Hospital.——Dr. Darius A. Coon, Elgin, Ont., has resigned as superintendent of the Kingston General Hospital and will enter private practice in that city. He has been succeeded by Dr. M. F. Coglan.——At Woodstock, Ont., November 5, the members of the medical profession of that city gathered at the residence of Dr. A. Beverley Welford to do honor to five of their confrères who had entered the army medical service. All were presented with wrist watches. Capts. Franklin S. Ruttan and Samuel M. McLay are at the front; Capts. David J. McKay, J. McKenzie Cochrane and Jim B. Jupp are in training.——Six doctors have been selected in Toronto to reinforce the Canadian Army Medical Corps. They are: Dr. G. A. Wallace, Bellevue Hospital, New York; Dr. Karl H. Van Norman, Baltimore; Dr. Roy H. Thomas, Toronto; Dr. Albert J. Fisher, New Liskeard; Dr. John Hunt, Sault Ste. Marie, Ont.; Dr. Reginald A. Mathews, Toronto.——Major Frederick Guest, R. A. M. C., St. Thomas, Ont., is home on short leave of absence necessitated by an accident. He will return to the Dardanelles in two months. There are no Canadian troops where he was stationed, at West Mudros on Lemnos, Greece.

GENERAL

Hospital Ship for Fishing Banks.—The Coast Guard Cutter *Androscoggin* has left the Charlestown Navy Yard for Gloucester, Mass., preparatory to a cruise to the Banks of Newfoundland and the coast of Nova Scotia where it will act as hospital ship for the fishing fleet.

Surgeons' Congress at Boston.—At the annual meeting of the Clinical Congress of Surgeons in Boston, the following officers were elected: president, Dr. Fred B. Lund, Boston; vice presidents, Drs. Jasper Halpenny, Winnipeg, Man., and Samuel M. D. Clark, New Orleans; general secretary, Dr. Franklin H. Martin, Chicago (reelected); and treasurer, Dr. Allen B. Kanavel, Chicago (reelected). Philadelphia was selected as the next place of meeting.

Vaccination Regulation Rescinded.—It is reported that Secretary of Commerce William C. Redfield has ruled that the provisions of the new seaman's act relative to vaccination within a period of five years before a certificate of competency will be issued to a seaman, need not be enforced. The seaman's law went into effect November 4, and the designated stations for physical examination of applicants have been crowded with seamen applying for certificates. The physical examination required by the law is a rigid one. The reason for Secretary Redfield's ruling has not been disclosed, so far as known.

Cancer Cultures.—To provide against contingencies that might be brought about by the Zeppelin raids on London, Dr. James A. Murray, director of the Imperial Cancer Research Fund, several weeks ago sent to the Columbia University laboratory in New York duplicates of all the cultures and specimens that have been developed in London through thirteen years of patient work by the fund. A recent Zeppelin raid narrowly missed causing the destruction of the laboratories in London. The specimens sent to New York were placed in charge of Dr. Francis Carter Wood, director of the Crocker Cancer Research Fund of Columbia University, and will remain there indefinitely unless those in London should be destroyed. The Crocker Fund and the Imperial Research Fund are in close communication and have exchanged scientists on occasion.

Seize Substitute Specifics.—Several shipments of worthless imitation drug products have been seized by the officials in charge of the enforcement of the Food and Drugs Act. A preparation put up in imitation of neosalvarsan is being distributed to drug stores in this manner. A sample labeled "Neosalvarsan," which was recently examined by the department, was found to be nothing more than salt colored with a coal tar dye, none of the genuine neosalvarsan whatever being present. The label on this product was an exact reproduction of the genuine imported neosalvarsan, or it was an original container refilled with the imitation articles. Other preparations peddled to druggists and purporting to be acetylsalicylic acid, or aspirin, have been seized by officials in charge of the enforcement of the Food and Drugs Act, because an analysis showed that the products were worthless imitations.

Metabolism Investigation Assistant Wanted.—The United States Civil Service Commission announces an open competitive examination for assistant in metabolism investigations, for men only, on December 8, at the usual places in the United States at which such examinations are held. From the eligible list certification will be made to fill the vacancies in this position at the United States Public Health Service for field duty at a salary of $1,500 a year. The prerequisites are, graduation after a four years' course at a university, college or medical school of recognized standing; at least six months' practical experience in work with the respiratory apparatus and the calorimeter; verification of statements as to education and experience, and age, below 45 on the day of examination. Application for those who take this examination is to be made to the United States Civil Service Commission, Washington, D. C., or the secretary of the local board.

Bequests and Donations.—The following bequests and donations have recently been announced:

Johns Hopkins University, $37,500, to be invested under the name of the Beal Memorial Fund, the income to be used at the discretion of the Board of Trustees; Eudowood Sanatorium, Towson, Md., $10,000, by the will of James M. Beal.

Kansas University School of Medicine, Lawrence, $30,000, by the will of Dr. Joseph L. Porter, Paola, Kan.

Columbia University for the Sloane Hospital for Women, New York, $50,000, by the will of William D. Sloane.

Columbia University, the residuary estate estimated at several million dollars, by the will of Emil F. Eno.

Germantown, Philadelphia, Hospital, $5,000, to endow a free bed in memory of George Wilson Harmer and Harry G. Hale Harmer; Children's Hospital, Pittsburgh, $2,500, to endow a free bed in memory of Elizabeth Hale Phillips and Hale Phillips; Allegany Hospital, Pittsburgh, $5,000, to endow a free bed in memory of Henry G. and Elizabeth Hale, these bequests to become operative upon the death of her two brothers, by the will of Mrs. Jane H. Harmer.

Presbyterian Hospital, Philadelphia, 10 per cent. of the residue of his estate by the will of Dr. DeBenneville J. Ludwig.

FOREIGN

Leprosy in Manila.—Twenty-three former inmates of the Culion Leper Colony were brought to Manila sometime ago to undergo a period of observation and thorough examination to determine whether the chaulmoogra oil treatment as administered at the colony had been effective in curing the leprosy with which they were affected. The three physicians under whose inspection they were placed, Drs. Johnston, Mercado and Ordonez, all agreed that there were no longer any indications of the disease present. The patients were allowed to go to their homes, but will be required to report every two or three weeks to their district health officers for the next two or three years. If there are any indications of a return of the disease, the patients will be returned to the leper colony.

Peking Hospital Opened.—Dr. Wallace Butterick, director of the China Medical Board, Dr. Simon Flexner of the Rockefeller Institute for Medical Research, New York, and Dr. William H. Welch, professor of pathology at Johns Hopkins University, Baltimore, were the guests of honor at the dedication of the new Sleeper-Davis Memorial Hospital, Peking, China. The new building is a five-story structure erected by the Methodist-Episcopal Church at a cost of $180,000 and has accommodation for 150 patients. The building is heated by steam, lighted by electricity, equipped with modern plumbing and provided with a diet kitchen. The patients are treated by American physicians who have Chinese assistants and are cared for by Chinese nurses, the head nurse being an American.

The Death of Sir Charles Tupper.—The Right Honorable Sir Charles Tupper, M.D., K.C.M.G., G.C.M.G., aged 94; Canadian physician and statesman; died in Bexley Hall, Kent, England, October 30. He was born at Aylesford, Nova Scotia, July 2, 1821, and obtained his doctorate degree in medicine from the University of Edinburgh in 1843. For twelve years Dr. Tupper practiced in Nova Scotia. He was then appointed as member from Cumberland County to the Nova Scotia Assembly, and in 1867 became prime minister of that province. In 1864 he did memorable work at the Quebec Conference for Confederation and also at the final Colonial Conference in London two years later. He declined a seat in the Canadian Cabinet in 1867 and also the chairmanship of the Intercolonial Railway Board in 1868. Two years later he was made a member of the Privy Council of the Dominion of Canada, and served as its president from 1870 to 1872, when he was appointed minister of inland revenue. In 1873 he became minister of customs, from 1878 to 1879 served as minister of public works and from 1879 to 1884 was minister of railways and canals. In 1884 he was made high commissioner for Canada in Great Britain and served for three years, and then after a lapse of a year in which he was minister of finance of the Dominion, he again returned to England as high commissioner and served until 1896. During this term of office he was one of her majesty's plenipotentiaries on the Fishery Commission at Washington in 1887-1888, and was also a plenipotentiary to negotiate the treaty between Canada and France in 1893. On Jan. 15, 1896, Sir Charles entered the Bowell Ministry as secretary of state and leader of the House of Commons, and from May 1 to July 8 of that year was prime minister of Canada, but with the overthrow of the ministry became leader of opposition in the House of Commons for four years. Honors were deservedly showered on Sir Charles Tupper. For fourteen consecutive terms he was a member of parliament for Cumberland County, N. S., and represented the county for thirty-one years. At one time he was president of the Canadian Medical Association. As minister of public works he created the department of railways and canals, and carried out the policy of the government in the enlargement of the Welland Canal, deepening of the St. Lawrence River, improvement of the Intercolonial Railway and the construction by a private company of the Canadian Pacific Railway. He was made a Commander of the Bath in 1867; K.C.M.G. in 1879, G.C.M.G. in 1886, a baronet in 1888 and an imperial privy councilor in 1908. Sir Charles Tupper was one of the notable figures in Canadian history and played a prominent part in the development of the Dominion from its establishment until his retirement from active life. He shared with the late Lord Strathcona the title of "Canada's Grand Old Man." While he will always be remembered as a political leader and a pioneer in the building of railroads and development of the Dominion, the medical profession of Canada esteemed him as one of the most prominent and able physicians the Dominion has produced.

LONDON LETTER

LONDON, Oct. 22, 1915.

The War

THE CARE OF THE WOUNDED

As pointed out before, the arrangements for the care of the wounded have been very well organized and probably have never been equaled in any previous war, unless by the Japanese. But there is the great difficulty that the wounded have often to lie for hours unaided because any attempt to help them at once draws the enemy's fire and they can be succored only when night gives protection from this danger. They are picked up as rapidly as the operations permit, carried to regimental aid posts by stretcher bearers, then through the field ambulance advance dressing stations, and then by motor ambulances to the casualty clearing stations. Here they remain until fit to proceed further or until operations of urgency are performed. They are then transferred by the hospital trains to the hospital bases. The work is performed with such celerity that as many as 450 patients have been transferred from ambulances to beds in the train in fifty-eight minutes. Whenever possible, patients are classified at the field ambulance headquarters, the most serious cases sent to the nearest casualty clearing station, and the less serious to the more distant. Use is also made of barge ambulances, which the canal system of France and Belgium has made available. Experiments with this novel method of transporting the wounded have proved so satisfactory that the tendency is to increase the number of barges. They offer the great advantage over motor cars or trains that there is absolutely no jolting. A new feature in the present war is the extent to which specialists of all kinds are employed in heir own work. Like all classes in the profession, they have joined the army in large numbers. Thus at several of the asualty clearing stations there are specialists in abdominal work, and as many as possible of soldiers with abdominal gunshot wounds are sent to these stations. Moreover, they do not reach the station in the usual indirect manner, but are ent straight in by a field ambulance when picked up. It has been proposed that men wounded in the abdomen should undergo operation practically where they fall, in mobile operating theaters. But this is rendered impossible by the fact that enemy aeroplane observers direct fire on every place where they see men collected.

THE AMERICAN RED CROSS IN ENGLAND

At Paignton in Devonshire a large Red Cross hospital was established by the American women in England and staffed by an American unit which came over in September, 1914, with a staff of six surgeons and twenty-four nurses to which were added an equal number of British and Australian nurses. Later Dr. Crumley of the Mayo Clinic joined as pathologist and bacteriologist. The hospital has been in charge of Dr. Howard Beal of the Medical Service of the United States Army. He has just returned to America, and before leaving was entertained at a farewell luncheon by Sir William Osler, who is consulting physician to the hospital. In proposing a toast, Sir William said that the American women in England had achieved a fine piece of organizing work. Sir Alfred Keogh, director general of the Army Medical Corps, bore testimony to the excellent work done by the American Red Cross at Paignton, and by the Harvard and other units in France. In the name of our Army Medical Corps he thanked Dr. Beal and the American women in England. Dr. Beal said that the hospital now possessed 250 beds, with twenty others in an isolation block. During the year they had treated 1,900 patients with only five deaths. Americans who, like himself, were of English ancestry, felt the call of the blood, and he was confident that if the British War Office wanted to widen the scope of its medical service, he could get a corps of Americans with British blood who would be delighted to come.

EXHIBITION OF FRACTURE APPARATUS AT THE ROYAL SOCIETY OF MEDICINE

Experience is considerably modifying our views of the treatment of wounds and other injuries. A large number of splints and other apparatus for the treatment of fractures have already been devised under the exigencies of active service. Under the auspices of the army medical authorities, an exhibition of apparatus was held at the Royal Society of Medicine, and was largely attended by physicians, most of whom were in khaki. In opening the exhibition, Sir Alfred Keogh, director general of the Army Medical Department, said that it was a step toward making scientific information common property. The surgeons on active service had made great progress. Nevertheless much difference of opinion as to the best methods of treatment of injuries and of the complications of wounds still existed; for instance, there was as yet no agreement as to how best to treat tetanus, as to whether antitoxin, if it were used, should be injected intravenously, subcutaneously or intrathecally, and as to the value of phenol (carbolic acid) and other methods of treatment. Whether the apparatus in the exhibition would be applicable to civil conditions was not the immediate question, but he felt confident that for military surgery a system of splinting fractures had been worked out which marked a permanent advance. The objects had been to allow the patients to make those spontaneous movements which would not be detrimental to the fracture, to insure freedom from pain during transport, and to provide ready access to the wounds, especially for irrigation, which was the rule of the day in France. Many most ingenious apparatus were exhibited.

PARIS LETTER

PARIS, Oct. 14, 1915.

The War

TREATMENT OF ABDOMINAL WOUNDS

Last June Dr. Quénu, professor at the surgical clinic of the Faculté de médecine de Paris, read before the Société de chirurgie de Paris a paper which I mentioned in a previous letter (THE JOURNAL, July 24, 1915, p. 348). At a recent session of the same society Quénu reported 153 observations by Drs. Petit, Charrier, Bichat, Pascalis, Pellot, Bouvier and Caudrelier of abdominal wounds, of which 110 were operated on, 6 by the Murphy operation and 104 by laparotomy.

Summing up these observations, one obtains a total of 96 penetrating wounds (60 of which were intestinal) with a mortality of 55 per cent. This percentage indicates the advantage of operation over nonoperative treatment, which gives a mortality of at least 67 per cent. It may be said, moreover, that laparotomy has won the day with respect to abdominal wounds of war. Every penetrating wound should be operated on. The diagnosis of penetration is sometimes difficult; it is based largely on a calculation of the course followed by the projectile, figures from the position of the orifices of entry and exit, or, in the case of a single orifice, of the position of the projectile as indicated by roentgenograms. Practically, however, this last resource is not always available, and every wound of the abdominal wall (or even of the adjacent regions) with but a single orifice may be held under suspicion. In cases of doubt, if circumstances permit, it is well to make an exploratory laparotomy.

What are the conditions which call for operation? One should not waver and hesitate on the pretext of shock. Shock is by no means a constant phenomenon; it is often absent in the first hours and it seems to result principally from hemorrhage. Delay can only favor loss of blood and peritoneal infection. It is therefore necessary to decide definitely at the outset on operation or abstention. Promptness of operation is one of the principal elements of success. To attain this promptness greater rapidity in the removal and transportation of the wounded is needed, or indeed the operative equipment might be brought to the patient, that is, an operating station might be installed as near as possible to the firing line.

As for postoperative treatment, it appears from the observations of Pascalis, Bouvier and Caudrelier that it is preferable to remove the patients a short distance within two or three days after operation rather than to await the critical period.

ORTHOPEDIC APPLIANCES FOR CRIPPLES

M. Gratien Candace, a deputy, has found that some manufacturers of orthopedic apparatus sell at from 125 to 150 francs (about $25 to $30) the same types of apparatus which others sell at 200 francs (about $40). He has therefore demanded that the government exercise control over orthopedic manufacturing establishments. The question is under discussion in the Chamber of Deputies. It appears that the chaotic conditions in the manufacture of apparatus are due to the lack of agreement as to types of apparatus. This lack necessitates a multiplicity of models and produces a variability in price. The undersecretary for the medical service called the head physicians of the orthopedic centers of Paris, Lyons, Montpellier and Bordeaux into conference Aug. 10, 1915, to consider means of improving the situation by hastening the production and controlling the manufacture of apparatus. It was agreed that it would be wise to seek a standard type of prothetic appliance for each kind of mutilation of the limbs; this would make it possible to establish a scale of prices that would apply uniformly to the products of all manufacturers. As a long period of inactivity is harmful from all points of view, the undersecretary decided that, without waiting for the final choice, each cripple would receive a temporary appliance, which would later be replaced by the standard type. Every cripple should in any case have two sets, in order that his activity and work may not be imperiled by the breaking of some part of a crutch or artificial limb.

It has also been asked if the government ought not to organize factories for orthopedic appliances in which the cripples themselves should be utilized. The undersecretary consulted surgeons and manufacturers on this point. These were unanimous in saying that the most ingenious prothetic appliances were invented, not by surgeons and manufacturers, with all their knowledge and experience, but by the cripples themselves. He therefore has sought for workmen crippled in the lower limbs, who before their incapacity, were woodworkers, mechanics and shoemakers, for employment in the manufacture of prothetic apparatus. At the Saint-Maurice asylum, near Paris, a workshop is being constructed, and also at Lyons, in connection with the Ecole des mutilés.

TREATMENT OF THE SEQUELAE OF WOUNDS BY PNEUMATIC MASSAGE

Dr. J. Bergonié, professor of biologic physics and of the clinic of medical electricity at the Faculté de médecine de Bordeaux, has reported to the Académie des sciences a method of treatment of the sequelae of wounds, which consists in applying to the affected members or regions a mechanical and pneumatic massage, by rhythmic variations of pressure transmitted to the parts through capsules or drums, one of the walls of which is alternately inflated and deflated. These various receptors or massage instruments may be adapted, in size and in form, to the most varied cases. They transmit pressures of a kilogram per square centimeter and more, and likewise the slightest degree of pressure, scarcely brushing the skin. The pressure may be regulated by a stopcock. The variations of pressure or pulsations are furnished by a piston pump without valves, giving 120 alternations of pressure and aspiration per minute. The apparatus already installed, with 25 mechanical masseurs, can give 300 pneumatic massage treatments in a six-hour day. Excellent results have been obtained in cases of paralysis due to fractures of the hand, stiffness of the fingers, vicious adherent or deep cicatrices, myositis due to retraction of cicatrices, edemas and trophic troubles, tendinous and muscular adhesions, etc.

This new method cannot take the place of manual massage administered by a trained and experienced physician, but it does permit a great number of wounded to benefit by massage.

TREATMENT OF WOUNDS BY MAGNESIUM CHLORID

Dr. Rosenblith of Paris has reported to the Académie de médecine the results which he has obtained by dressing wounds with a 1.2 per cent. solution of magnesium chlorid. Cicatrization is much more rapid in wounds so dressed than in the case of wounds dressed with the usual antiseptics. Prolonged suppuration and cytolysis are avoided.

BERLIN LETTER

BERLIN, Oct. 13, 1915.

Personal

Professor Oberländer, the urologist, died in Dresden, October 2, at the age of 66 years. He was the associate of Nitze, the inventor of the cystoscope, and as such contributed much to the development of the instrument and its use in urethroscopy. He was also associated with Professor Zülzer in the publication of the "Clinical Handbook of Genito-Urinary and Sexual Organs." He has published many monographs and textbooks bearing on the pathology and treatment of gonorrhea. He was the editor of the *Zeitschrift* and *Zentralblatt für Urologie.*

Health of Prussia and Germany

Two comprehensive publications which appeared recently contribute information as to health matters in Prussia and Germany. One book entitled "Health Matters in Prussia during 1913" was published by the medical division of the ministry of the interior; the other book was the eighteenth volume of medical statistics of the imperial health department. It was entitled "Vital Statistics of the German Empire during 1912." The one essential point brought out by these publications is the fact that health conditions have improved very much. The total mortality for 1913 in Prussia was 14.9 per thousand population, as against 15.49 in 1912 and 17.21 in 1911. The natural increase in population was 3,021 greater than in the preceding year, but because of the continued decrease in the birth rate, this increase did not equal that of previous years. The birth rate per thousand population was 28.17, as against 28.88. The decrease in the birth rate was 0.71 greater than the decrease in mortality, which was 0.59 lower than the next lowest rate. In 1912 the number of births was greater by 12,783 than in 1913; in 1906 it was 99,527 greater. In the cities 513,135 children were born, and in the country 696,520. Of the former, 16,354 were born dead; of the latter, 19,615. The provinces of West Prussia and Westphalia led in the number of children born living, whereas Brandenburg and the suburbs of Berlin had the lowest number of children born living. Exclusive of those infants born dead, 175,989 infants died during the first year of life; 71,880 of these died in the cities. The remaining 104,109 died in the rural districts. A lowering in mortality was particularly noticeable in cases in which the cause of death is given as congenital malnutrition and developmental defects, nervous diseases, cerebral apoplexy, old age, and diseases of the respiratory and circulatory organs. The mortality was higher where the cause of death was diseases of the digestive organs, suicide, murder or accidents.

There is no appreciable decrease in the mortality from diphtheria, tuberculosis and scarlet fever. On the other hand, the mortality from whooping cough has been lowered, whereas that of measles, smallpox and venereal diseases is higher. During this time there were 76,631 cases of diphtheria, as against 77,420 in 1912; 171 cases of cerebrospinal meningitis as against 178 cases; 5,220 cases of puerperal fever as against 4,888; 38,318 cases of pulmonary and laryngeal tuberculosis as against 39,820; 70,396 cases of scarlet fever as against 66,070; 9,443 cases of typhoid as against 11,353 cases, and 58 cases of smallpox as against 165 cases during the preceding year. Twenty of the smallpox patients were foreigners. Most of the native or domestic cases occurred among persons who were infected by the foreigners. Forty-one of these patients had been given a timely vaccination, as against thirty-two similar cases in 1912. In each case this was the first vaccination, but vaccination could not be held responsible for the subsequent fatal illness.

In 1913 there were 2,344 general hospitals, exclusive of private hospitals with ten beds or less. The number of available beds was 1,177,184. These hospitals took care of 1,534,209 patients, with a total of 42,715,475 bed days.

These statistics also show that, based on the census of 1910 and 1900, the number of living persons between the ages of 30 and 60 has increased by 9.6 during this decade over all other age classes. Between the ages of 1 and 60, this increase was 3.3 per cent., although the deaths among the nurslings diminished by 3.4 per cent. The death rate as well as the birth rate of 1912 was the lowest recorded, although the figures of Prussia for 1913 are still lower. A consideration of the mortality by ages shows a considerable diminution in infant mortality as against 1911, noted for the extreme heat. The death rate between 1 and 15 years is also lower, but has not decreased among those dying after 15 years. The mortality from gastro-intestinal diseases is considerably lower, whereas the mortality is higher for diseases of the circulatory organs, the appendix, malignant disease and puerperal fever than it was during the half decade of 1905-1910. During the same period, the death rate from pulmonary tuberculosis was 15.2, as against 13.1 in 1913. The total death rate per 10,000 of the middle class fell from 175.2 to 155.4 per cent.

Transportation of the Wounded by Aerial Tramway

One of the Bavarian divisions in the south Vosges mountains has built several electric aerial tramways (*Drahtseilbahn*) for the purpose of transporting ammunition, food and building material for the army. Several hundred soldiers under the direction of engineering officers constitute the personnel of this railway. After a battle, or at any other time that the wounded need to be transported, special baskets are attached to this tramway in which the wounded can be transported comfortably through the mountain territory to the nearest railway station in the valleys.

Deaths

Brigadier-General George Miller Sternberg, Surgeon-General, U. S. Army, from 1893 to 1902; died at his home in Washington, D. C., November 3, aged 77. Dr. Sternberg was born at Hartwick Seminary, Otsego County, N. Y., June 8, 1838; received his preliminary education in that institution and commenced the study of medicine at Cooperstown, N. Y., under the preceptorship of Dr. Horace Lathrop and then attended lectures in the College of Physicians and Surgeons in the City of New York from which he was graduated in 1860. He entered the Army as assistant surgeon in 1861, was promoted to captain in 1866, to major in 1875, to lieutenant-colonel in 1891 and two years later was appointed Surgeon-General of the Army; he was retired June 8, 1902. During his more than forty years of active service in the Army, General Sternberg was repeatedly on duty against Indians, in epidemics of yellow fever and cholera in addition to the ordinary duties which pertain to medical officers; he was a member and secretary of the Havana Yellow Fever Commission of the National Board of Health in 1879; a delegate from the United States to the International Sanitary Conference at Rome, in 1885; was detailed to make investigations in Brazil, Mexico and Cuba relating to the etiology and prevention of yellow fever, from 1887 to 1889, and was consulting bacteriologist to the health officer of the port of New York in 1892 when the cholera ships came to that port. He was president of the American Medical Association in 1896; president of the Association of Military Surgeons of the United States in 1894; once president of the American Public Health Association; president of the section on Military Medicine and Surgery of the Pan-American Congress; vice president of the American Microscopical Society and a member of many other learned societies at home and abroad. General Sternberg was best known as a bacteriologist; his work on "Bacteria" published in 1884 and his "Manual of Bacteriology" which appeared in 1892 are standard works. He was a pioneer in this line of research work and was a prolific writer on the etiology of diseases, comparative value of methods of disinfection, and the like. Since his retirement from the Army, General Sternberg has resided in Washington, D. C. On his seventieth birthday, June 8, 1908, he was given a complimentary banquet by residents of Washington, both military and civilian, who paid tribute to the service to humanity rendered by General Sternberg, and after a number of laudatory addresses, presented him with a silver loving cup. While General Sternberg made an enviable record as a military sanitarian, having been repeatedly commended in orders, he was a scientist of world-wide fame, and a genial gentleman beloved by all with whom he came in contact.

Brigadier-General George Miller Sternberg, 1838-1915.

Nathaniel D. Cox, M.D. Medical College of Indiana, Indianapolis, 1884; aged 73; formerly a Fellow of the American Medical Association; a member of the Indiana State Medical Association and a charter member of the Owen County Medical Society; a veteran of the Civil War; died at his home in Spencer, Ind., October 27, from heart disease.

Edward Porter Colby, M.D. Long Island College Hospital, Brooklyn, 1861; aged 76; acting assistant surgeon, United States Navy, for three years during the Civil War; professor of nervous diseases in the Boston University School of Medicine; consulting neurologist to the Massachusetts Homeopathic Hospital and the Westborough Insane Hospital; died at his home in Boston, November 1.

Edward S. Crill, M.D. Eclectic Medical Institute, Cincinnati, 1865; aged 72; state senator in the Florida Legislature from 1880 to 1885 and from 1897 to 1901; state treasurer from 1885 to 1889; and from 1889 until the time of his death president of the East Florida State and Trust Company, Palatka; once mayor of that city; died at his home October 23, from uremia.

Isaac L. Firebaugh, M.D. Miami Medical College, Cincinnati, 1875; aged 68; of Robinson, Ill.; a Fellow of the American Medical Association; for many years a member and once president of the Aesculapian Society of the Wabash Valley; for forty years a practitioner of Robinson; died in the Presbyterian Hospital, Chicago, October 25, from cirrhosis of the liver.

Julius Augustus Post, M.D. Bellevue Hospital Medical College, 1866; aged 68; a member of the Michigan State Medical Society; a medical cadet during the Civil War; for more than forty years a practitioner of Lansing, Mich.; once assistant superintendent of the Lansing City Hospital; died suddenly on the street in Lansing, October 28, from heart disease.

Horace Greeley Norton, M.D. University of Pennsylvania, Philadelphia, 1880; aged 57; a member of the Medical Society of New Jersey and secretary of the State Board of Medical Examiners; for two terms president of the Mercer and Monmouth County medical societies; died in St. Francis' Hospital, Trenton, October 27, from cerebral hemorrhage.

John White Stevenson, M.D. Medical College of Ohio, Cincinnati, 1883; aged 56; a Fellow of the American Medical Association; acting assistant surgeon, U. S. P. H. S., since 1893 and in charge of the office in Cincinnati; for thirty years a practitioner in that city; died at his home in Walnut Hill, Cincinnati, October 24, from heart disease.

Ira Morton Martin, M.D. Kentucky School of Medicine, Louisville, 1891; aged 49; formerly a member of the State Medical Society of Wisconsin; a specialist on diseases of the eye, ear, nose and throat; for the last nine years a practitioner of Green Bay, Wis.; died suddenly on the Oneida Reservation, from heart disease.

Hugh Clayton Blair, M.D. Vanderbilt University, Nashville, Tenn., 1908; aged 29; a Fellow of the American Medical Association and local surgeon of the Sante Fe System at Rincon, N. M., while on his way to Albuquerque, N. M., to seek hospital care for appendicitis; died on the train, October 27.

William M. Johnson, M.D. American Eclectic Medical College, Cincinnati, 1857; aged 86; a member of the Illinois State Medical Society and president of the Wayne County Medical Society in 1910; for sixty years a resident of Johnsonville, Ill.; died at his home, August 13, from carcinoma.

Josias Louis Duval, M.D. McGill University, Montreal, 1898; aged 39; of St. John West, N. B.; major in the Canadian Army Medical Corps and on duty with the First Canadian Field Ambulance in Flanders; is reported on the casualty list of September 1, as having died in Flanders.

John Ditmars VanNuys, M.D. Jefferson Medical College, 1870; aged 69; formerly a Fellow of the American Medical

Association; for twenty years physician at the Osawatamie State Hospital, Osawatamie, Kan.; died at the home of his son in New Castle, Ind., November 1, from myocarditis.

Ira D. Knotts, M.D. University of Pennsylvania, Philadelphia, 1887; aged 58; formerly a Fellow of the American Medical Association; and president of the Greene County (Pa.) Medical Society; of Davistown, Pa.; died in a hospital in Pittsburgh, October 22, from cerebral hemorrhage.

Timothy Jerome Regan, M.D. College of Physicians and Surgeons in the City of New York, 1884; aged 54; for many years a member of the staff of the New York Polyclinic Hospital and of the Brooklyn Board of Health; died at his home in Brooklyn, October 27, from nervous breakdown.

Herbert Eugene Knowlton, M.D. Harvard Medical School, 1891; aged 49; formerly a member of the Massachusetts Medical Society and a practitioner of Cambridge, Mass., and Belfast, Me.; died at his winter home in National City, Calif., October 24, from septicemia.

George D. Johnston, M.D. Washington University, St. Louis, 1858; aged 79; for many years president of the St. Louis Car Shops, but for the last thirty-five years a ranchman and real estate dealer of San Antonio, Texas; died at his home in that city, October 28.

Joseph Robert Rosson, M.D. University of Alabama, Mobile, 1888; aged 46; formerly a druggist, auditor of the Southern Express Company and a postoffice inspector; editor of the *Cullman Democrat;* died at his home in Cullman, Ala., July 29, from nephritis.

John J. Kennedy, M.D. Starling Medical College, Columbus, Ohio, 1897; aged 47; of Mill Creek, W. Va.; was murdered October 31. The motive is supposed to have been robbery. Dr. Kennedy's body was found on a lonely road near Mill Creek.

Victor Gus Becska, M.D. Detroit College of Medicine and Surgery, 1907; aged 34; a member of the Medical Society of New Jersey; and a member of the Passaic (N. J.) Board of Health for two years; died at his home in that city, October 25.

Edwin D. Schaeffer, M.D. Baltimore Medical College, 1893; aged 48; a Fellow of the American Medical Association; for many years a member of the school board of Reading, Pa.; died at his home in that city, October 23, from septicemia.

Alan Butler Murray, M.D. College of Physicians and Surgeons in the City of New York, 1890; aged 50; for many years a practitioner of Montana, but recently a resident of Clinton, Ind.; died in a hotel in Terre Haute, Ind., October 27.

George Frank Harris (license, Illinois), aged 96; a practitioner for seventy-five years; an honorary member of the Morgan County (Ill.) Medical Society; died at his summer home near Jacksonville, Ill., August 9, from lobar pneumonia.

James McGeoch, M.D. Saginaw Valley Medical College, Saginaw, Mich., 1900; aged 56; a Fellow of the American Medical Association and a well-known practitioner of Bay City, Mich.; died at his home October 28, from pneumonia.

James Gerald Cullen, M.D. University of Pennsylvania, Philadelphia, 1905; aged 38; a member of the Ohio State Medical Association and city physician of Toledo for three years; died at his home in Toledo, October 26.

E. R. Young, M.D. Medical College of Georgia, Augusta, 1859; aged 83; one of the oldest practitioners of Thomas County, Ga.; and for thirty years postmaster of Metcalfe; died at his home, August 6, from heart disease.

Joseph Leslie (license, years of practice, Illinois, 1877), aged 77; a practitioner of Macon County, Ill., for forty-eight years; and until five years ago a practitioner of Elwin, Ill.; died at his home in Decatur, Ill., October 26.

Horace K. Braisted, M.D. University of Michigan, Homeopathic College, Ann Arbor, 1880; aged 59; a physician and druggist of Delta, Colo.; died at his home, July 23, from cerebral concussion due to accidental injury.

Nicholas F. Schwartz, M.D. University of Wooster, Cleveland, 1872; aged 67; for many years a practitioner of Cuyahoga County, Ohio, and recently a resident of Chagrin Falls; died in Auburn, Ohio, October 27.

Lockhart Brooks Farrar, M.D. Berkshire Medical College, Pittsfield, Mass., 1848; aged 93; for more than half a century a resident of Ford County, Ill.; died at his home in Paxton, October 30, from senile debility.

John N. Sigler (license, Indiana, 1897), aged 66; died at his farm near Sedalia, Ind., October 15.

Marriages

P. A. Surg. Julian Mason Gillespie, U. S. P. H. S., Ellis Island, N. Y., to Miss Verna Duplantis of New Orleans, in New York City, October 20.

Benjamin Franklin Montgomery, M.D., Stevens City, Va., to Miss Lucy Deahl of Barryville, Va., at Washington, D. C., October 27.

Daniel James Ellison, M.D., Lowell, Mass., to Miss Anna Gale Newhall of Lynn, Mass., at Swam Scott, Mass., November 3.

John Samuel Hick Leard, M.D., Forest Hills, Boston, to Miss Isabelle H. Earnshaw of West Roxbury, Boston, October 26.

James Louis Quesenberry, M.D., Worthington, Ky., to Mrs. Ada Freeman Bauer of St. Matthews, Ky., October 28.

Hubert Benbury Haywood, M.D., Raleigh, N. C., to Miss Margaret E. Manor of Harrisonburg, Va., October 19.

Milton Augustus Broemser, M.D., Holly, Colo., to Miss Berenice Edwords of Kansas City, Mo., October 26.

Abraham Hyman, M.D., New York City, to Miss Belle Davis of Erie, Pa., in New York City, October 28.

Edgar Paul McNamee, M.D., Cleveland, Ohio, to Miss Ethel Marian Petrie of Oneida, N. Y., October 30.

Lawrence E. Kelley, M.D., Des Moines, Iowa, to Miss Sue Gunn of Kellogg, Iowa, at Des Moines, October 2.

Leon Wolf, M.D., Portland, Ore., to Miss Rose L. Hochberg of New York City, in Portland, October 21.

Thomas Francis Hennessey, M.D., Lynn, Mass., to Miss Gertrude Miller of Allston, Boston, October 27.

Albert David Kaiser, M.D., Rochester, N. Y., to Miss Margaret Dickinson of Brooklyn, November 4.

Matt Blakely Weir, M.D., to Miss Pearl Parker, both of Grant, Iowa, at Red Oak, Iowa, September 14.

Russell Comber Doolittle, M.D., Des Moines, Iowa, to Miss Myrtle Cordner of Chicago, October 2.

Henry W. Greist, M.D., Casper, Wyo., to Mrs. Mollie Ward Butler of Monticello, Ind., October 18.

Roscoe E. Cook, M.D., to Miss Floy D. Sloan, both of Des Moines, Iowa, at Boone, Ia., September 16.

Warren E. Bradbury, M.D., Clinton, Ill., to Miss Ida Brulle of Neillsville, Wis., October 26.

Lawrence Leslie Irwin, M.D., to Miss Zona M. McDowell, both of Bloomington, Ill., October 10.

Frank Kaiser Bartlett, M.D., Ogden, Utah, to Miss Mary Paxton of Aurora, Ill., recently.

Samuel D. Rosenthal, M.D., to Miss Tubie Greenspohn, both of Chicago, November 7.

Association News

THE DETROIT SESSION

Officers of Local Committee on Arrangements and Chairmen of Subcommittees

The following constitute the officers of the local committee for the Detroit session of the American Medical Association:

Chairman: Louis J. Hirschman.
Secretary: Ernest K. Cullen.
Treasurer: Thaddeus H. Walker.

The following physicians are chairmen of the various subcommittees of the Committee on Arrangements:

Finance: E. W. Haass.
Entertainment: A. D. Holmes.
Hotel: Roland Parmeter.
Halls and Meeting Places: F. B. Tibbals.
Registration: F. B. Walker.
Scientific Exhibit: J. W. Vaughan.
Commercial Exhibit: John N. Bell.
Printing and Publication: *J. H. Dempster.*
Automobiles: Angus McLean.

The local committee on arrangements has established an office at the Wayne County Medical Society Building, 33 High Street E., Detroit, Mich. All communications should be mailed to this address.

The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

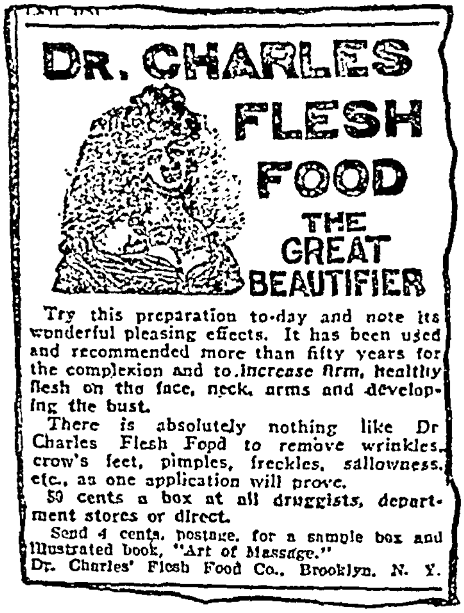
DR. CHARLES FLESH FOOD

In Brooklyn there is a concern styled Dr. Charles Flesh Food Company that sells "toilet specialties." In addition to rouge and face powders of various tints as well as soaps and toilet creams, the concern puts out such preparations as "Foot Relief" for "sore, tired, aching feet" and "Revivo" claimed to be a "Remedy for Dandruff and All Scalp Diseases." The "Dr. Charles Co. Tonic Tablets" are put forward by the company as "the very best preparation for restoring health to the debilitated; rich blood to the anemic; relief to women from their specific ills, strength to those tottering along life's pathway with a burden of liver and kidney troubles, nervous prostration, dyspepsia and many wasting diseases that lead to consumption." The product on which, apparently, they lay more emphasis than any other is "Dr. Charles Flesh Food" an ointment sold under such claims as:

> "Applied to the skin nourishes by absorption."
>
> "*It builds firm, healthy flesh.*"
>
> "Acts quickly and surely on a skin that is seamed and wrinkled either by exposure or age, smoothing away furrows of the forehead and lines about the eyes and mouth."
>
> "Undeveloped busts and those shrunken through sickness or nursing may be materially increased in size; made full, firm, plump and rounded out into a beautiful contour by the use of this wonderful flesh developer. IT ACTS ALIKE ON THE GROWING GIRL AND MATURED WOMAN."

In an advertising booklet the company declares that Dr. Charles Flesh Food has the endorsement of physicians and to prove it declares:

> "The *Therapeutic Record*, a leading Medical Journal tells in its August, 1908, number of two lady patients who used it [Dr. Charles Flesh Food] under the advice of their physician, Dr. M. P. Creel."



DR. CHARLES
FLESH
FOOD
THE
GREAT
BEAUTIFIER

Try this preparation to-day and note its wonderful pleasing effects. It has been used and recommended more than fifty years for the complexion and to increase firm, healthy flesh on the face, neck, arms and developing the bust.

There is absolutely nothing like Dr Charles Flesh Food to remove wrinkles, crow's feet, pimples, freckles, sallowness, etc., as one application will prove.

50 cents a box at all druggists, department stores or direct.

Send 4 cents, postage, for a sample box and illustrated book, "Art of Massage."

Dr. Charles' Flesh Food Co., Brooklyn, N. Y.

An appeal from the Chicago Daily News.

The *Therapeutic Record* is one of those medical journals (Heaven save the mark!) that are supported by the nostrum interests. From editorial endorsements of a fraudulent "rupture cure" (Stuart's Plas-Tr-Pads) to advertisements of such frauds as fake ear drums, Duffy's Malt Whiskey and Antikamnia, it is not a far call to the equally fraudulent "Flesh Food." Neither is one surprised to find in the advertising pages of the *Therapeutic Record* advertisements of Stuart's Plas-Tr-Pads and Dr. Charles Flesh Food. The *quid pro quo* is thus established.

Whatever Dr. Charles Flesh Food may lack in therapeutic efficiency it makes up in color and odor. The preparation is an appealing pink, highly perfumed ointment. A box of the stuff was submitted to the Chemical Laboratory of the American Medical Association and in due time one of the chemists gave the results of his investigation. The findings may be summed up as follows:

Starch	38.5 per cent.
Petrolatum (vaseline)	51.0 per cent.
Zinc oxid	2.0 per cent.
Impure stearic acid	1.5 per cent.
Perfume, coloring matter.	

From the report it is apparent that the alleged "flesh food" is no better than, if as good as, an ointment made by mixing five parts of vaseline with four parts of starch and adding a dab of zinc oxid. Dr. Charles Flesh Food is a fraud and if articles of this nature come under the purview of the federal Food and Drugs Act the concern should be prosecuted for misbranding. The stuff is not, in any sense of the word, a "flesh food"; it does not "build firm healthy flesh," it will not develop the bust and it does not "nourish by absorption."

"WHAT IS THE CHARACTER OF THE MEDICAL JOURNALS YOU READ?"

"At the session of the House of Delegates held in San Francisco, the Board of Trustees presented a special report on the work of the Council on Pharmacy and Chemistry in which it condemned in unqualified terms the advertising in medical journals of proprietary nostrums.

"We do not believe that the sincerity of the philanthropic desires of the American Medical Association in its efforts to destroy the manufacture and sale of nostrums, proprietary or otherwise, is questioned by any one except the financially interested purveyors of these fraudulent remedial concoctions. We do not believe that any one, not excepting the foregoing mentioned purveyors, questions the honesty of the reports of the Council on Pharmacy and Chemistry. It must furthermore appear patent to every one that financial gain is the one and only aim of these conscienceless individuals who dupe the public, that there is no more philanthropy in their reptilious souls than there is sympathy for any living thing in the brain of the venomous adder. No one with a modicum of reason believes that the ordinary business man invests his capital in exploiting any form of merchandise for your, rather than his material benefit. His is a crusade for profit. The American Medical Association is in need of money to carry on its beneficent projects, but is its crusade against nostrums tinged with the hue of expected profit or is it a truly altruistic crusade? The query requires no answer. It is self evident.

"Referring to the subject of the man with purely business instincts: in placing an article on the market he estimates the cost of production, its greatest obtainable profits, and the ways and means to create a demand for his ware. If its intrinsic value is approximately recognizable he must attune his profits to that general knowledge. The purchaser of his wares cannot be fooled or swindled to any great extent. If they be, their loss is a material one and can be recovered from. But when an exploiter places on the market a nostrum of no intrinsic value (excepting the bottle and cork) for which he claims virtues which it does not possess and which the wise and the unwise cannot dispute until victimized; when he envelops it in an air of mystery, appealing to superstition, ever present in the human mind, he robs the purchaser of his money and health, thereby becoming a thief of the most despicable order. Any medical journal printing the fraudulent claims contained in the advertisements of the nostrums condemned by the Council on Pharmacy and Chemistry is an accessory to this act of thievery and the subscriber to such journals voluntarily assumes the position of an accomplice."—*New York State Jour. Med.*, October, 1915.

Laboratory Research and Type of Individual.—The laboratory worker who conducts his investigations without regard to type leaves them open to criticism. Thus metabolism experiments must be conducted on individuals of the same type or the subjects will react differently to a given diet. Doubtless in this fact lies a possible suggestion for the solution of certain discrepancies reported by various laboratories working on a given problem.—John Bryant, M.D., *Boston Medical and Surgical Journal*, Sept. 9, 1915.

Correspondence

An Accurate Microchemical Method of Estimating Sugar in the Blood

To the Editor:—The microchemical method of estimating blood sugar, I described in The Journal, Nov. 7, 1914, p. 1667, is very reliable. Numerous examinations of blood, with and without the addition of known quantities of sugar, yield remarkably concordant and exact results. The maximum error encountered does not exceed ± 3 per cent.

I wish, however, to call attention to the fact that the apparatus (styled the Epstein microsaccharimeter) sold on the market has until lately included standard tubes containing solutions of improper color intensity. Estimations of blood sugar made with such standard tubes are necessarily faulty.

I have attempted to reach all those using this apparatus by personal communication, to apprise them of the error. Standard tubes are now on sale by Eimer and Amend, and also by E. Leitz of New York. These have been prepared under my supervision and contain the proper solutions.

Albert A. Epstein, M.D., New York.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

MAASE-ZONDEK TEST FOR URIC ACID IN BLOOD

To the Editor:—Please describe in your columns the method of Maase and Zondek for testing uric acid in the blood.

H. C. Rucker, M.D., Richmond, Va.

Answer.—This colorimetric method was described by Maase and Zondek in the *Münchener medizinische Wochenschrift*, 1915, lxii, 1110. The following is their description of the method: From the fasting patient 6 or 7 c.c. of blood are drawn into an Erlenmeyer flask containing a little sodium fluorid. Then exactly 5 c.c. of the blood is taken into a pipet and transferred to 25 c.c. hundredth-normal acetic acid and stirred vigorously while it is being heated until coagulation is complete. It is then filtered while hot into a porcelain dish. The filtrate is limpid, but a slight yellowish tint does no harm. The residue and dish are then rinsed at once with about 60 or 70 c.c. of boiling water, to which—to avoid colloid solutions—about 0.5 gm. sodium acetate has been added. This brings the total filtrate to about 100 c.c. Then 2.5 c.c. of 50 per cent. acetic acid are added and the whole is evaporated on the water bath down to exactly 5 c.c., which usually takes about an hour. There is no precipitation as a rule with this technic, but even if there is, this is immaterial. After neutralizing with a saturated solution of sodium carbonate, added a drop at a time, the contents of the dish are transferred to a 25-c.c. measuring flask and the dish is rinsed with cold water. Then 2.5 c.c. of saturated solution of sodium carbonate and 1 c.c. of the phosphotungstic acid reagent are added, and the total amount of fluid brought up to 25 c.c. by addition of distilled water. Then the mixture is allowed to stand for ten minutes to allow the blue tint to reach its greatest intensity.

Generally the fluid is limpid. It is then compared in the Autenrieth-Königsberger colorimeter with the scale for uric acid. If the tint does not correspond exactly, the fluid should be filtered once or twice. The tint is examined by good daylight, and by diffuse light. In very hot weather the fluids had better be kept cool.

They give a table of values for minute gradations, ranging from 7.7 mg. uric acid at the 20 mark to 0.8 mg. at the 85 mark. The phosphotungstic acid reagent is made exactly according to Autenrieth's directions (*München. med. Wchnschr.*, 1914, lxi, 457). They have tested all the other substances in the blood that might interfere with the reaction, but found that none reduce phosphotungstic acid except in a concentration such as could scarcely ever occur in the blood, even under extreme conditions. At the same time, to avoid possible error from this source, they deduct always 0.5 mg. as the standard figure, determined by various tests described.

The blood to be tested must have been drawn within twenty-four hours at longest, as otherwise products of albumin disintegration might interfere with the reaction. Another point they emphasize is that the evaporation must be carried to the exact point mentioned, namely, down to 5 c.c. Certain volatile substances in the mixture are driven off by this, which otherwise might disturb the reaction. The dish they use has two blue rings under the glaze, marking off the 10-c.c. and the 5-c.c. capacity. They always take whole blood for the test, as Zondek has demonstrated that the blood clot may contain more or less uric acid.

Maase and Zondek are assistants at the first University Medical Clinic at Berlin, of which His is director. Their technic requires only 5 c.c. of blood and not more than an hour and a half of time. It scarcely ever fails, they say, and is simple enough to be applied by even those unskilled in chemical research. The amounts of uric acid added to the blood are recovered with the loss of, at most, a few tenths of a milligram. The findings, especially the averages, harmonize with the figures obtained by other authors with far more complicated methods. Precipitation of the uric acid is avoided, and with it the losses inseparable from this. The average in thirty healthy persons, mostly soldiers, after three days of a purin-free diet, was 2.5 mg. uric acid in 100 c.c. of whole blood. (Steinitz' average, with the Folin-Denis method, was 2.7 mg.) In five cases of gout, the figures were 5, 4.8, 4.9, 4.5 and 5.5 mg. uric acid after three days of purin-free diet. On prolonged abstention from purins, the findings in true gout indicated a decline, the figure dropping from 5 to 4 mg. and even to 1.8 mg. in one case.

Autenrieth prepares the phosphotungstic acid reagent by boiling 100 gm. of sodium tungstate with 80 c.c. of 85 per cent. phosphoric acid and 750 c.c. of water for three or four hours, under a reflux condenser, and then diluting, after cooling, with water to 1 liter. The 85 per cent. phosphoric acid is made by gradually stirring 65 gm. of commercial phosphoric acid anhydrid into 30 c.c. water. The red sediment is separated out over an asbestos filter.

ARTICLES ON DETECTION OF TYPHOID CARRIERS

To the Editor:—I should appreciate references to recent publications bearing on the methods and reliability of the methods of examination of supposed typhoid carriers.

W. S. Rankin, M.D., Raleigh, N. C.

NO ANTINARCOTIC LAW IN CANADA

To the Editor:—Will you be good enough to inform me whether there is in Canada anything corresponding to the Harrison Narcotic Law? The question has come up concerning an individual who has recently been treated for the opium habit and is thinking of going to Canada.

W. G. Richards, M.D., Billings, Mont.

Answer.—Canada has no such law as the Harrison Narcotic Law, nor is there any law serving the same purpose.

COMING EXAMINATIONS

California: Los Angeles, December 14. Sec., Dr. Charles B. Pinkham, Room 527 Forum Bldg., Sacramento.

Delaware: Dover and Wilmington, December 14. Sec., Dr. H. W. Briggs, 1026 Jackson St., Wilmington.

Florida: Jacksonville, December 7-8. Sec., Dr. E. W. Warren, 102 Front St., Palatka.

Kentucky: Louisville, December 7-9. Sec., Dr. A. T. McCormack, Bowling Green.

Louisiana: New Orleans, December 2-4. Sec., Dr. E. L. Leckert, 716 Macheca Bldg., New Orleans.

Maryland: Regular, Baltimore, December 14. Sec., Dr. J. McP. Scott, Hagerstown. Homeopathic, Baltimore, December 15-16. Sec., Dr. O. N. Duvall, 1817 N. Fulton Ave., Baltimore.

Missouri: St. Louis, December 13-15. Sec., Dr. J. A. B. Adcock, State House, Jefferson City.

Ohio: Columbus, December 7-9. Sec., Dr. George H. Matson, Columbus.

Virginia: Richmond, December 14-17. Sec., Dr. J. N. Barney, Fredericksburg.

Illinois May Report

Dr. C. St. Clair Drake, secretary of the Illinois State Board of Health, reports the written examination held at Chicago, May 13-15, 1915. The total number of subjects examined in was 10; total number of questions asked, 100; percentage required to pass, 75. The total number of candidates examined was 165, of whom 135 passed and 30 failed. The following colleges were represented:

College	Year Grad.	Total No. Licensed
PASSED

Book Notices

Habits That Handicap. The Menace of Opium, Alcohol and Tobacco and the Remedy. By Charles B. Towns. Cloth. Price, $1.20 net. Pp. 289. New York: The Century Company, 1915.

After perusing this little volume, one is at a loss to know the real object of the author in writing it. Did he intend it to be read by physicians or by the laity, or both? He surely could not imagine that physicians would readily subscribe to his wholesale arraignment of the medical profession by the purchase of his cleverly gotten up journalistic production. The book contains much that is true, much that is valuable; but the man without a medical training who attempts to preach on medical subjects to medical men must necessarily make blunders. The author makes the statement that 15 per cent. of physicians are addicted to the use of opium. Who is there in the profession who will not stigmatize this statement as extravagant? It must be admitted that the author, who is at the same time the proprietor of a sanatorium for the treatment of drug addictions, cannot be entirely disinterested when he makes the dogmatic statement, "The average sanatorium is merely a small colony of drug-users." A mere glance at the book's cover reveals, as the first line, "A revelation, a warning, a way out." This, of course, prepares the reader for some sensational reading. And the author has not disappointed us. After having censured the medical profession for their extreme ignorance and having called the sanatoriums mere money-making institutions and drug-colonies, the author has a slight premonition that some one might suspect, and he hastens to say: "Of course the general reader may think this book merely a clever advertisement. In it I state that it is wrong to stop the use of morphin and alcohol unless the victims can be treated for the habit, and next I condemn doctors and sanatoriums for their useless methods of treatment, while lauding my own. Naturally, my reader may assume that my only motive is the selfish one of money." Certainly, the assumption might be justified. Those of us who have had the opportunity to try it are convinced that the Lambert method of treating opium addiction is one of the best of the so-called rapid cures, but Mr. Charles B. Towns has not yet informed us who communicated to *him* the formula which he claims as his own.

T. B. Playing the Lone Game Consumption. By Thomas Crawford Galbreath. Paper. Price, 25 cents. Pp. 80, with 4 illustrations. New York: Journal of the Outdoor Life Publishing Company, 1915.

One of the difficult problems connected with the treatment of tuberculosis is to so inculcate in the mind of the patient the importance of strict adherence to the rules of the modern open air hygienic, dietetic treatment, etc., that the patient will single-mindedly, without deviation, carry out the essentials of the prescribed regimen and thus place himself on the road to recovery. An absolute conviction of the soundness of the regimen and the necessary self control on the part of the patient are important prerequisites of successful direction of each individual case. The tuberculous patient is particularly responsive to the lessons learned by others afflicted with the same disease. Mr. Galbreath tells of his twelve years' experience as a tuberculous patient, "chasing the cure" in Colorado. It is a heart-to-heart talk with the tuberculous patient, placing great emphasis on the importance of early diagnosis and strict observance of the necessary regimen if an arrest of the disease is to be accomplished. The author protests against the too common practice of shipping West patients without sufficient means to carry out a regimen in which the factors of time and financial means are very important. The details of the open air regimen are given in very simple language, and the factors of rest and self control are thoroughly emphasized. Climate is given a subordinate place to hygiene, diet and close medical supervision, and treatment in a sanatorium is recommended to all who cannot "discipline themselves." The practice of sending West patients without adequate means is condemned in the following pointed sentences: "The community may consider it cheaper to pay one way fares to Colorado than to run a sanatorium for its own unfortunate consumptives. . . . It is inordinate selfishness, a kind of civic thievery, and downright cruelty to the ignorant and unsuspecting invalid." The author pleads for the elimination of the too prevalent phthisiophobia, which should have no place in the relationship with a careful tuberculous patient. This volume is an important addition to popular antituberculosis literature. Placed in the hands of every tuberculous patient, it will prove itself a great aid to physicians in the efficient control of individual cases. The cost of the book is very moderate and its circulation should be widespread.

TWELVE LECTURES ON THE MODERN TREATMENT OF GONORRHEA IN THE MALE. By P. Asch, M.D. Translated and Annotated by Faxton E. Gardner, M.D., Assisting Visiting Genito-Urinary Surgeon, New York Polyclinic. Cloth. Price, $1. Pp. 104, with illustrations. New York: Rebman Company, 1915.

The German edition of this book was reviewed in this department, Dec. 5, 1914. At that time attention was called to the fact that Asch's treatment is that of the French and German schools, and that American opinion differs on several phases, for instance, especially as to the injection method—more favored in America—as against irrigations, which are the choice abroad. This translation has been annotated by the translator with a thoroughness which makes the book more valuable. Practically every page contains footnotes calling attention to the different points in which the foreign method differs from the American procedures in treating this disease. This makes the book more valuable than the original.

Medicolegal

Implied Promise to Pay for Medical Services

(Bigelow vs. Hill (Minn.), 152 N. W. R. 763)

The Supreme Court of Minnesota affirms a judgment in favor of the plaintiff, a physician, for services rendered in the treatment of the defendant's niece, aged 14. It appeared that the girl's parents had been divorced, and that she had come to live with the defendant and his wife, on their farm. Not long afterward, the girl being very ill, the defendant's wife, with his consent, drove with her to the plaintiff's office, in a village 3 miles away. Mrs. Hill stated to the plaintiff that "her girl" was sick, and that she wanted him to see her. He diagnosed the case as one of blood poisoning, gave her a treatment then, and was given directions by Mrs. Hill how to reach the defendant's farm. She told the plaintiff to do everything necessary to the girl's recovery. She did not tell him that the girl was not her daughter, and he assumed that she was until his second visit to the farm, when he was told that she was the daughter of the defendant's brother. The plaintiff continued to attend and treat the case, and after the girl's recovery rendered to the defendant a bill for his services, which the defendant refused to pay, claiming that the debt was that of the girl's father. The defendant testified that the girl was employed as a servant in his family, but the trial court found that she was a member of his household. The defendant paid a bill for drugs and one for the services of a nurse.

It is true, the supreme court says, that the rule that, when one requests the performance of services by another there is an implied promise to pay for the services rendered, does not apply where a person requests a physician to perform services for a patient, unless the relation of that person to the patient is such as raises a legal obligation on his part to call a physician and pay for the services, or the circumstances are such as to show an intention on his part to pay for the services, it being so understood by him and the physician. It is also the law that a master is not ordinarily, in the absence of a contract obligation, liable for medical services furnished his servant, though furnished at the request of the master. And it is doubtless correct that the father would be liable for necessary medical attendance furnished his daughter, though the services are requested in his absence by another. But these rules do not necessarily control the decision of this case.

The defendant knew that his wife was taking the girl to see the plaintiff, and consented. There appeared to have been no thought then, or until the bill was presented, that the defendant would not pay the physician, just as he had paid the druggist and the nurse. It would have been easy to have informed the plaintiff that he would have to look to his patient's father for his pay, but he was allowed to render his services under the assumption that the girl was the defendant's daughter, or at least a member of his household whom he was supporting. Under these circumstances the trial court was justified in finding an implied promise by the defendant to pay for the services rendered.

Choice of Persons for Taking Roentgenograms

(International & G. N. Ry. Co. vs. Bartek (Tex.), 177 S. W. R. 137)

The Court of Civil Appeals of Texas, in affirming a judgment for $2,000 damages in favor of plaintiff Bartek for personal injuries sustained in a wreck, says that one of the assignments of error was based on a refusal of the trial court to compel the plaintiff to submit to having roentgenograms taken of his back, to be exhibited to the jury. But this court does not think that the trial court abused its discretion in this matter. The facts of the case did not bring it within the rule that, while a party has the right, in the first instance, to refuse to submit his person to an examination, yet by doing so, and being so examined by his own physician in the presence of the jury, he waives his privilege in this regard, and the opposite party is entitled to have a like examination made by his physician. In this case the plaintiff exhibited his back to the jury, and his physician pointed out thereon the evidence of the injury as he claimed it to be. A like examination was made, without objection, by the physician of the defendant, who denied that profert of the plaintiff's back furnished conclusive proof that one of his vertebrae had been fractured as was claimed by the plaintiff's physician. The evidence further showed that the defendant had been afforded an opportunity to have roentgenograms of the plaintiff's back taken by an alleged expert of Houston, who presumably was impartial in the matter, inasmuch as he was not personally known to the plaintiff or either of his counsel. The plaintiff's counsel at this time objected to having such pictures taken by a party in Waco, on the ground that they doubted his competency. This was some time before the trial. The Waco party referred to was the same party whom the defendant requested should be permitted to take such pictures during the trial. The plaintiff's counsel agreed that if the roentgenogram was taken by the Houston physician he would make no objection to its introduction in evidence. The introduction of a roentgenogram taken by an incompetent person might have proved prejudicial to the plaintiff. The Waco party may have been competent, but the plaintiff's counsel did not think so, and the court was justified in not compelling the plaintiff to have a roentgenogram taken by a party who was objectionable to him, when he offered to have such picture taken by a party whose competency and disinterestedness were not called in question.

MINNESOTA STATE MEDICAL ASSOCIATION

Forty-Seventh Annual Meeting, held at Rochester, September 30 and October 1, 1915

(Concluded from page 1675)

Clinical Observations on Syphilitic Disease of the Heart and Aorta

Dr. R. D. Mussey, Rochester: In 1,379 cases of syphilis, clear-cut syphilitic disease of the heart or aorta occurred in fifty-nine. Syphilis of the heart does not present a typical syndrome other than that of myocardial change, dyspnea being the chief complaint, and the signs of myocardial insufficiency with dilatation and hypertrophy the chief findings. Syphilis affects the aorta more frequently than the heart. In the aortitis group pain and dyspnea are the chief complaints with the signs of insufficiency of the valves. In the aneurysmal group, pain is predominant with the usual aneurysmal signs. Blood pressure is of value in the prognosis and an aid to diagnosis, especially in the aortitis group in patients with aortic insufficiency. Syphilis of the heart and mediastinum responds more readily to treatment than syphilis of the aorta. The use of potassium iodid and mercury seems to be of value, even when the patient is showing evidence of broken compensation; these may be followed by salvarsan and more especially by neosalvarsan with marked benefit in symptoms. Vigorous and persistent treatment will apparently arrest progress in certain aneurysmal cases.

DISCUSSION

Dr. S. Marx White, Minneapolis: The importance of the aortitis and aneurysmal group is very great, and we commonly learn to look on every case of aortic lesion with considerable suspicion, a suspicion justified in the majority of instances by the discovery of the evidences of syphilis. We have lesions in the aortic valves from rheumatic infections, but they are almost without exception accompanied by lesions in the other valves. We are learning to use the Wassermann reaction early, and the Roentgen ray to recognize early cases of aortitis. In connection with aneurysm, the medical profession ought to pay very much closer attention to the question of a thorough and painstaking and complete systematic examination of the patient.

Dr. E. L. Tuohy, Duluth: There were twelve cases classed as cardiovascular. In three there was a diagnosis made of mesaortitis luetica. There were three cases of myocarditis, six of aortic aneurysm, and three cases that had syphilis had also valvular lesions due to that disease.

Open Air Treatment in Surgery

Dr. J. W. Markoe, New York: I selected 110 cases of sepsis and considered them under two main groups, namely, those that are treated in the open air and those treated indoors. In one group, the main therapeutic measure was the open air. In all but five of these cases, blood cultures taken by the usual technic under proper precautions and with appropriate mediums, demonstrated the presence of bacteria. The following organisms were recovered from the blood: hemolytic streptococcus in 94 cases; *Streptococcus viridans* in 1 case; pneumococcus in 2 cases; *Staphylococcus aureus* in 7 cases, and *Bacillus aerogenes capsulatus* in 1 case. In no case was more than one organism recovered from the blood. There were 16 cases of postabortive sepsis; 89 cases of postpartum sepsis, 67 of which were admitted from three to ten days or more after delivery, and 22 were admitted with labor in progress; also 5 cases of antepartum sepsis.

This last group of five cases is of interest, for in them even before the onset of labor, the sepsis was fully developed. Of these five cases, in one a sinus thrombosis was present; in two the sepsis followed operative interference; one incision of an abscess of the throat, and the other the removal of an appendix. In a fourth case the patient, on admission, had already a streptococcus meningitis, while a fifth case showed the presence of a general peritonitis for which no cause was found. Of these 110 cases, 42 were in the hospital less than five days with a mortality of 100 per cent.; 68 were in the hospital more than five days with a mortality of 66 per cent. Of the 110 patients, 53 were treated in the open air in addition to the other measures and 57 were indoor patients, of whom 55 died and 2 left against advice. Of the 53 cases treated on the roof, 17 were there less than five days and all died; 13 died that were there more than five days; 1 left against advice, and 22, or 42 per cent., recovered.

In these 22 cases, the following bacteria were present in the circulation: hemolytic streptococcus in 17 cases; pneumococcus in 1 case, and in 4 cases no organism was recovered. Of the cases on the roof more than five days there were 16 of the 21 without complications that recovered, whereas but 6 of the 14 showing the various manifestations of pyemia survived. Thus it seems that when no complications were present, the percentage of recovery was greater. Of the indoor patients, there was 100 per cent. mortality in the 21 cases that were in the hospital more than five days, while, on the other hand, there were 22 recoveries of the 35 treated on the roof more than five days.

In addition to these 110 cases we have treated innumerable cases in the open air where the infection was localized in the pelvis. Among these may be mentioned such cases as pyometritis, parametritis and the large inflammatory exudates commonly observed in the broad ligaments following labor. These patients seem to withstand high temperatures more readily, and they enjoy and assimilate their food better. Their facial expression changes after being on the roof for a few days, from one of despair to that of hope and assurance. The blood picture soon shows an increase in hemoglobin and red cells, which, however, coincides to a certain extent with the reduction of the temperature.

Local Anesthesia

Dr. L. E. Daugherty, St. Paul: By carefully questioning patients who have been operated on during the past year, to whom ether anesthesia has been administered, we have elicited the fact that what they most dreaded was not the operation itself, but rather the loss of consciousness and the resulting nausea and distress caused by the ether. Some on whom secondary operations were necessary have consented to return to the operating room only on the condition that local anesthesia be used.

DISCUSSION

Dr. C. R. Ball, St. Paul: There is benefit in having the consciousness and aid of the patient. Having injected a great many cases of tic douloureux with alcohol, I am conscious of the great aid the patient is able to give in these operations.

Dr. Harry P. Ritchie, St. Paul: I recall one case in which a suprapubic cystotomy was done on a diabetic under local anesthesia. This man was admitted with acidosis and acetonuria, and was practically comatose, yet I drained him suprapubically, after which he received medical treatment, and today he is a well man.

Dr. R. E. Farr, Minneapolis: In foreign countries laminectomy has been done many times under local anesthesia. There they have found that the dura is extremely sensitive in contradistinction to the condition found in the skull. In one case which I had a few months ago, the patient, an intelligent man, talked with me all the way through the operation. In this case I turned up a wagnerian flap as large as my hand. It was impossible to put a needle through that flap of dura without the most intense pain referred to the eyes. I followed Lenander's work for a number of years, and I do not always agree with him. In a case of resection of the intestine, for instance, the patient had a sharp pain every time I put the needle through his intestinal wall, although no traction was made on the mesentery. Again, in some cases patients coming in with a fair-sized ovarian cyst speak of pain on the right side, and give a history of chronic appendicitis. In these cases, by taking hold of the cyst, compressing its pedicle, and compressing the nesentery in various places, we have been able to deliver each of these organs without causing the pain for which the patients sought relief.

Varicose Veins

Dr. D. C. Balfour, Rochester: The veins which are most commonly the site of varicosities are the hemorrhoidal, the spermatic and the long saphenous. It is usually a disease of middle life, although in our series several patients were under 25 years of age, and the ratio of male and female was 3:2. The etiologic factors most apparent were: (1) the occupation which necessitated the prolonged erect posture, and (2) the anatomic and physiologic factors present in veins in the lower extremities, which are important in that they afford opportunity for exciting causes to produce the condition. In 40 per cent. of this series there were chronic ulcers on one or both legs. The chronic congestion of the skin and subcutaneous tissue is a strong predisposing factor to the formation of the ulcer, and a very slight injury may be sufficient to produce a lesion resistant to healthy healing. If these ulcers are not treated, or the causative condition relieved, they increase steadily until they reach an enormous size; they are also subject to malignant degeneration. Preoperative treatment is occasionally advisable, particularly if there is ulceration, or in cases of recent phlebitis in which redness and pain, marking local thrombosis, still exist along the course of the vein. The most satisfactory method, in my experience, for the subcutaneous extirpation of a long saphenous, is that of C. H. Mayo. Of 256 patients, 161 were heard from. Of these, 68 were complicated with ulcer, 93 were without ulcer, and 39 (57.3 per cent.) of the 68 were cured, that is, the ulcer healed, the veins disappeared, and there was no swelling of the feet. Sixteen (23.4 per cent.) were greatly improved, the ulcer healed in the majority, with some of the patients complaining of swollen feet or aching of the legs after a long day's work. Eighty per cent. were either cured or improved, 13 (19 per cent.) were definitely unsatisfactory as regards results. Of the 93 cases without ulcer, 67 (73 per cent.) were cured, 16 (17 per cent.) improved, and 10 (10.5 per cent.) were unsatisfactory. In practically 90 per cent. of this group, good results were obtained. In no case had less than one and one-half years elapsed since operation.

The Prone Position and Its Uses

Dr. M. M. Ghent, St. Paul: Pneumonia patients who are beginning to show signs of exhaustion, such as shortness of breath and cyanosis, are benefited by being placed on the stomach. This is especially true of children with bronchopneumonia. In this position the cyanosis is much less marked during the paroxysms of coughing, and the patient sleeps much better, because the breathing is easier. All of this convinces me that patients under conditions such as I have named above breathe poorly when they lie on their backs. This is especially true in babies because of their helplessness. It is also true of some patients who are unconscious from any cause. This has led me to believe that we keep our patients lying on their back too much; especially is this true after operations. My plan now is to let patients lie in any position in which they are most comfortable. Patients coming out from under an anesthetic are given pillows enough to make them comfortable.

Perforating Gastric Ulcer Following Gastro-Enterostomy

Dr. Arthur N. Collins, Duluth: Gastro-enterostomy is not a curative procedure for all ulcers of the stomach. Simple gastro-enterostomy will not suffice where excision should be done. It does not revolutionize the patient's healing power per se. Postoperative medical care should be established in all cases until cumulative experience tells us where to leave it off. From the standpoint of the patient, simple gastro-enterostomy does not accomplish all that should be really expected of a fairly major surgical operation.

DISCUSSION

Dr. William J. Mayo, Rochester: It is true, gastro-enterostomy does not furnish the complete and satisfactory results in ulcer of the stomach that it does in ulcer of the duodenum. It is extremely fortunate that ulcer of the duodenum is so much more frequent than ulcer of the stomach. About 75 per cent. of all peptic ulcers are in the duodenum, and as long as the stomach itself is normal and the gastro-enterostomy is done on the functionating organ, a cure or at least very great improvement may be expected in as high as 90 per cent. of the cases. I know of no operation in surgery that gives more satisfactory results than gastro-enterostomy or an equivalent operation in ulcer of the duodenum. The failures of gastro-enterostomy that are due in the main to the operation are because the condition in the stomach may not be suitable for the operation; that is, the ulcer may be proximal to the gastro-enterostomy, and in such cases we cannot expect the gastro-enterostomy to cure the patient. In the second place, a gastro-enterostomy is done in many cases in which ulcer does not exist, based on the symptoms of the patient. No surgeon should do gastro-enterostomy for ulcer which cannot be demonstrated accurately at the time of the operation.

Dr. A. C. Strachauer, Minneapolis: Gastro-enterostomy is no longer performed except when ulcer can actually be demonstrated. The ulcer is eradicated either by excision or by the actual cautery. The majority of men with experience in gastric surgery feel very much concerned as to the possibility of malignancy developing on an ulcer, and feel much easier in mind when the ulcer is eradicated either by excision or by the cautery.

AMERICAN ROENTGEN RAY SOCIETY

Sixteenth Annual Meeting, held in Atlantic City, N. J., Sept. 22-25, 1915

(Concluded from page 1670)

New Roentgen Evidence in Early Diagnosis of Gastric Carcinoma

Dr. A. W. George, Boston: Chronic ulcer alone near the pylorus will not show a deformity or defect other than th classical Roentgen sign of ulcer. When the ulcer begins undergo degeneration, the changes due to beginning malignancy can be demonstrated. It is what we have termed th annular deformity. This is ringlike in character, increasin the long diameter of the pyloric sphincter toward the antrum and it is constant in all positions. This is a positive earl sign of gastric cancer.

Roentgenologic Diagnosis of Duodenal Ulcer

Dr. Russell D. Carman, Rochester, Minn.: Though would not place exclusive reliance on cap distortion fo diagnosis, I consider this sign one of the best and well wort searching for in those cases in which more simple method of examination fail to establish or exclude the presence o duodenal ulcer. Irregularities of the duodenal outline ar not pathognomonic of ulcer. Some ulcers do not produc an organic distortion which may be demonstrated roentgenographically, while irregularities of the duodenal contour may sometimes be produced by pericholecystitis and other adhesion-producing lesions, or by spasm reflected from distant sources. Deformity due to such causes is much less common than deformity resulting from duodenal ulcer. Deformity of the bulb and spasm arising from distant sources is more often lacking in persistence and permanency of situation. Deformity, when present as a result of ulcer, is more likely to be constant. While some duodenal ulcers produce a scar, distortion of the duodenal lumen, which can readily be seen on the roentgenogram in other organic deformity, is so slight that it cannot appreciably distort the barium shadow. This is especially true of small mucous or slit ulcers. If bulbar distortion is the result of the intrinsic spasm, the administration of an antispasmodic, such as belladonna, may relax the spasm and cause the deformity to disappear. This is still under investigation. Since using the serial method, our diagnosis of duodenal ulcer has been confirmed at operation with fewer exceptions than before, and fewer ulcers have escaped diagnosis. We have not limited ourselves to this method, but have added it in certain cases of suspected ulcer to our routine screen and plate examinations, because it is not always necessary to make multiple plates. Hypertonus, hypermotility and hyperperistalsis are most valuable indications of duodenal ulcer. These phenomena are seen in various combinations, and often all together. Hypertonus is seen in the majority of duodenal ulcers, perhaps more frequently in this than in any other condition. Gastric hyperperistalsis is notable in a large proportion of the cases, perhaps 60,000 or more. Hypermotility is the logical result of hypertonus and hyperperistalsis. More than one quarter of these ulcers are certainly obstructive and produce a six-hour retention. In testing motility, our modification of Haudek's double meal method is an indispensable part of our routine. A six-hour retention in the stomach, with an unbroken contour, ought, first of all, to suggest duodenal obstruction, and the most common cause of this is duodenal ulcer. If there is typical gastric hyperperistalsis, the presence of duodenal ulcer is well-nigh certain.

DISCUSSION OF PAPERS BY DRS. GEORGE AND CARMAN

Dr. Lewis G. Cole, New York: Dr. Carman referred to duodenal ulcer, gallbladder adhesions and spasm as being causes of the wave defect in the cap. That is true, but the first two cause permanent organic filling defects and the latter does not. In the case of duodenal ulcer and gallbladder adhesions, the indications for surgical treatment are the same. Some cases of spasm cannot be diagnosticated. I have made a diagnosis of ulcer when it was a case of spasm. In the past year I have seen two cases of adhesive membrane involving the cap that caused a filling defect, which might lead one to diagnose duodenal ulcer. There may be a great deal of deformity with very few symptoms. We should not make the diagnosis too positively. When we find an induration, we should say so, and advise surgical intervention.

Dr. George E. Pfahler, Philadelphia: We should make as nearly a definite diagnosis as possible. If we believe it is carcinoma, we should say so, because otherwise the patient will not be operated on. We leave the surgeon in doubt. On the other hand, we must not state anything definitely that is not there. Dr. Carman presented as nearly the truth on the question of duodenal ulcer as we are able to state it today.

Dr. Frederick H. Baetjer, Baltimore: Spasm is more or less transitory. Two cases came under my observation that are worth mentioning. A girl of 18, with indefinite stomach symptoms, had a filling defect of the greater curvature. The same defect was present on the following day. At the end of a week and at the end of two weeks it was still present, and, finally, it was decided to operate on her. The stomach was normal. Absolutely nothing was found to account for the deformity. Even an examination of the inside of the stomach was negative. A second patient came in with a definite roentgenologic diagnosis of carcinoma, made by a competent roentgenologist. The patient was operated on, but nothing was found. The roentgenograms were reviewed and still the diagnosis of carcinoma of the stomach was made. Six months later another examination was made, with the identical results. We gave the patient atropin for two or three days, and the next examination showed a normal stomach outline. We now employ atropin as a routine, giving from 1/100 to 1/120 grain two or three times a day until the patient begins to feel dry. In one or two obscure cases it has helped me out very much.

Dr. W. F. Manges, Philadelphia: As we now have apparatus that can be used safely for fluoroscopic work, we should extend the examination in these cases beyond the stomach and duodenum, including the entire gastro-intestinal tract, in order to discover other lesions that may be present. That is particularly true of the lower small bowel and the appendix region, where lesions may be overlooked by the surgeon when he is operating for gastric or duodenal ulcer.

Dr. George C. Johnston, Pittsburgh: I have never had any trouble in getting surgeons to accept help in diagnosis. I remember a case of a woman, aged 60, in which the report was early carcinoma of the stomach. The surgeon operated and found the pylorus normal in appearance. He palpated the pyloric region carefully, and did a resection and a posterior gastro-enterostomy. After very careful palpation of the pylorus he had felt an annular ring. There was no erosion of the mucosa—just a little constriction or tightness. The pathologist reported adenocarcinoma. In this case the Roentgen evidence of the disease was responsible for finding the carcinoma. Therefore, I am going to continue to say to the surgeon that, to the best of my knowledge and belief, a careful exploratory operation is justified.

Dr. Wm. H. Stewart, New York: In a case of carcinoma with annular deformity the surgeon hesitated to admit that it was a cancer, and claimed that it was an ulcer. I insisted on a pylorectomy, and on microscopic examination the tumor proved to be a carcinoma of the pylorus. That was the third case of the kind I have had.

CHICAGO MEDICAL SOCIETY

Regular meeting, held Oct. 27, 1915

The President, Dr. Charles F. Whalen, in the Chair

SYMPOSIUM ON LEPROSY

The Fear of Leprosy

Dr. E. L. McEwen: The fear of leprosy arises from erroneous conceptions of the disease; but this fear exists as a definite social factor which is operative to the detriment of occasional victims of the disease in this country. Every physician should take a firm and true stand with regard to leprosy, in order that the lay mind may view the disease more rationally, so that the persecution of lepers when they are discovered shall not occur. This means a campaign of education by every physician with his patients and with his friends in the direction of enlightening the people as to what true leprosy is and the great difficulty of contagion.

Clinical Description of Leprosy

Dr. Oliver S. Ormsby: The clinical picture presented in leprosy depends on whether the integumentary or the nervous system is wholly or chiefly invaded by *Bacillus leprae*. No definite time limit exists between the time of infection and the development of symptoms. It is variously estimated from a period of many weeks to several years. From the time of infection until the eruptive manifestations occur, various prodromes are frequently noted. These differ in no way from those occurring in any other infectious process. The lesions in the eruptive type of the disease may occur on any part of the body. In the anesthetic variety the symptoms exhibited in the part supplied by the affected nerves are those which would naturally follow their irritation, compression or degeneration. The prodromes and macular stage of this variety may be severe or be altogether absent.

Pathology and Bacteriology

Dr. Fred G. Harris: Over seventy attempts have been made to transmit the disease in man by inoculating leprous material from one individual to another, only one, that of Arning, being successful. The bacilli are much more frequently found in the nasal secretion of cases of long standing than in early ones. The bacilli are not often found in the nasal secretions of healthy persons who are in intimate contact with lepers. The most common atrium would seem to be through the skin, for a large majority of the cases give a history of the disease commencing on the extremities. In a series of 275 cases the disease began on the feet in 58 per cent., and on the hands in 11.2 per cent. The infection is disseminated by the blood stream.

Sanitary Aspects of Leprosy in the United States

Dr. William Allen Pusey: Leprosy in North America is limited to a few foci. There has been a focus of leprosy at Tracadie, N. B., for nearly a hundred years. According to Dr. A. C. Smith, leprosy in that district can be definitely traced to one case introduced from Normandy in 1815.

Numerous cases have developed subsequently in that district. The living conditions are hard and the people poor, and there is a lazaretto there containing twenty-six beds. As a result, however, of partial segregation and better living conditions of the people, few of the beds are now occupied, and leprosy is rapidly diminishing in that district. Many cases have been introduced into Minnesota and the other Middle Northwestern States by Scandinavian immigrants. In 1900, according to Bracken, eleven cases of leprosy were known in Minnesota, and in 1903 no new cases had been reported. A few cases of leprosy exist along our Mexican frontier among Mexicans. These have practically been uncontrolled without spread of the disease beyond these people. There has always been a considerable number of lepers in New York, and there are always probably one or more in the Chicago district. These have always been foreigners, and no case has been known to originate in either place. In New York the number is estimated as high as 100, but there has never been any effort to segregate them. They have been admitted freely to the public hospitals. The chief foci of leprosy in the United States are in Louisiana and in Key West. The experience of civilized people in other parts of the world in respect to leprosy corresponds to that of the United States in regard to its slight infectivity. Where leprosy is endemic the situation is different, and public protection requires that practical —not absolute—segregation should be carried out. In districts like Louisiana, where leprosy is active, every effort should be made to segregate lepers as completely as possible.

To that end public asylums of refuge should be provided for them, as has been done in Louisiana. The establishment of a national sanatorium for lepers is advocated by the surgeon-general of the U. S. P. H. S. Federal care and control is undoubtedly the solution of the comparatively simple sanitary problem of leprosy in the United States, and should be insistently advocated by medical organizations, and other organizations within whose purview come matters of public health.

Discussion on Leprosy

Dr. David Lieberthal: According to the historical review of pre-Bible times, there were records of leprosy in the papyri of the Egyptians thousands of years before the Bible, leprosy having prevailed around the region of the Nile from which it spread over Europe. In the middle ages, leprosaria or asylums for lepers increased in great numbers. One could imagine conditions in these asylums under which victims of the disease were huddled together and the manner in which they were taken care of, being subject to reinfection, and yet, with the advent of syphilis, it was noted that leprosy was on the wane. The number of cases was materially decreasing. I believe this decrease was due to the acquirement of a certain immunity. Leprosy is not altogether incurable. The hygienic and dietetic methods of treatment are the same as for any other disease. Lepers suffer from what is known as heat hunger; consequently they ought to be kept warm. They should be given baths. In some countries, as in Japan, lepers are sent to mineral springs and kept there for a long time. If patients cannot be sent to hot springs, plain baths can be given. If there are nodes, Unna suggests they be ablated, cut off flat with a sharp knife or razor until blood begins to flow, and their bases cauterized, and medicinal applications made which consist of remedies of the phenol group, especially pyrogallic acid and resorcin. This is rubbed in and the places covered over with plaster. As a remedy for use internally, I would mention chaulmoogra oil. The leper should be kept under constant observation. It would be a step in advance if the federal government established a colony or home for the lepers of the United States, to which they could go voluntarily and be assured they would be cared for properly.

Dr. O. S. Ormsby: I heartily endorse the recommendation concerning the establishment of a leper home and of placing the victims of this disease under federal control.

Dr. W. A. Pusey: I would recommend that the society express its approval of the establishment of a leper home under the control of the federal government as recommended by Surgeon-General Blue of the U. S. Public Health Service.

6 Intestinal Parasites in Children. G. J. Greil, Montgomery, Ala.
7 Polycystic Disease of Kidney in Infant Three Months Old. J. S. Leopold and M. B. Künstler, New York.

1. **Tetany.**—It was Brown and Fletcher's object to see that if by changing the various food elements, tetany could be produced with a fair degree of certainty, and to note any change in the inorganic salts during the onset, height and curing of the condition and what substances were responsible for the ultimate healing. Their observations were made in thirty cases of definite tetany; and 100 infants thought to be free from tetany were carefully tested, electrically and mechanically, for any evidence of spasmophilia. They found that tetany may be produced by high carbohydrate foods which have been subjected to heat up to or over the boiling point. The monthly incidence of tetany is probably due to a disturbance of the gastro-intestinal tract (constipation), decreased internal combustion and the comparative safety from diarrhea in feeding high carbohydrate foods during the cold months. A diagnosis of tetany is suggestive when there is manifest kidney inactivity in constipated infants fed heated foods of high carbohydrate content. As a result of this improper feeding there is produced a disturbance of the body salts. At the height of the disease there is an almost complete retention of sodium and potassium (the irritating salts) and a great loss of magnesium. As improvement ensues there is an increased flow of urine accompanied by a relief of the constipation, during which the stored up sodium and potassium are rapidly lost. This salt disturbance may be remedied first by purgation, second by diuresis, third by the administration of cod liver oil and phosphorus to build up the calcium content, and fourth by a change of diet. The severe spasms or convulsion may be temporarily relieved by subcutaneous injections of a solution of magnesium sulphate.

2. **Ductless Gland Therapy.**—This contribution has to do with the action of the pars intermedia of the pituitary gland. These particular activities of the gland, from a therapeutic standpoint, have become apparent through a study of an abnormal child carried on for the past two and a half years by Haynes, and previously by several physicians connected with the dispensary of the Babies' Hospital, including Drs. Kerley and Van Ingen. It seems evident in this case, that, assuming a deficiency of thyroid as evidenced by the condition when first coming for treatment, there was also an affection of the pituitary; that this affection of the pituitary partook of the nature of a deficiency of the pars intermedia, and that the exhibition of pars intermedia improved the condition in unexpected ways. It was interesting in following the unfolding of this case to see 1. Symptoms which might rationally have been considered to be due to hypothyroidism clear up with the exhibition of pars intermedia. 2. The remarkable effect which the exhibition of this lobe had on the smoothness, texture, and color of the skin and its warmth. 3. The striking changes in contour of hands, ankles, hips, shoulders, thighs, etc., changes which could be made to come or recede with giving or taking away of the gland.

4. **Tuberculosis.**—There are 166 children out of the 288 examined by Manning and Knott who have been or still are living in intimate contact with active adult cases. In the remaining sixty-two there is no known exposure. These adult contacts, in most instances, one or the other parent, in a few instances both parents, or older brothers or sisters,

are in the stage of lung invasion in varying degrees of activity. There are eighty-four of the 166 children with a definite history of exposure who give a positive von Pirquet test, or about 50.6 per cent. Of this number the largest part, sixty-nine, or 81.2 per cent., show no clinical evidence of tuberculosis. There are fifteen children, representing 17.8 per cent. of those children exposed to tuberculosis, who give a positive reaction and clinical evidence of tuberculosis. They show varying degrees of activity and types of infection, including seven cases of bronchial gland tuberculosis, one active keratitis, two with cervical adenitis, four with distinct lung invasion, and one with tuberculous peritonitis. One inactive, clinically nontuberculous child developed an active tuberculous peritonitis under observation.

Most of those diagnosed as bronchial gland tuberculosis are children with a distinct history of not doing well, with subnormal or slightly elevated temperature, frequently complaining of pain in chest or back, poor appetite, weakness or listlessness, with dilated chest veins, but no physical evidence of tuberculosis except sometimes paravertebral dulness. Roentgenograms showed corresponding shadows about the right hilus. There were eighty-two children with a definite history of exposure who gave a negative von Pirquet. This represents about 49.3 per cent. who give negative reactions out of the total 166 exposed to tuberculosis. One of these children gives distinct clinical evidence of tuberculosis, in which instance, as would be expected, the process has advanced to the third stage. There are eight in whom one of the authors recorded questions of finer shades of harsh breathing. In view of the fact that cutaneous reaction is negative in the presence of measles, it is stated that none of these children had measles at this time or within recent date. Sixty-two children were brought to the clinic because of poor nutrition, or by fear that something of the nature of tuberculosis might be present, rather than because of any known exposure. Fourteen of these sixty-two children, or about 22.5 per cent., give a positive von Pirquet, the remaining forty-eight, or 77.4 per cent., give a negative test.

8. Reappearance of Menstruation After Childbirth.—From the results of Ehrenfest's statistical study of the problem of lactation amenorrhea it seems that clinical experience evidently sustains the following views: A debilitating influence exerted immediately by labor and later by the loss of body fluids during lactation with rare exceptions temporarily arrests ovulation. As soon as the disturbed equilibrium is restored the ovary resumes its function of ovulation, and the first corpus luteum sends its specific hormone to the endometrium. The response of the latter probably to a certain extent is dependent on the anatomic condition of the uterus. If normal, a typical menstrual flow ensues; if subinvoluted or for other reasons hyperemic (retroflexed), the reaction may be unusually strong; on the other hand, if the uterus is in an atrophic condition, it may require the stimulations from more than one ovulation until it becomes anatomically restored to the degree of resuming its function. As a rule, menstruation continues practically regularly during lactation when once reestablished. The debilitating effect of lactation is obviously dependent on the general condition of the woman. Therefore, usually the disturbance in the equilibrium of body fluids ends sooner and menstruation reappears earlier in the strong and healthy woman. For the same reason the amenorrheic state in general will last longer in the sick or weak woman, in the primigravida, whose labor as a rule is longer and more exhausting, and in the woman suckling a large child. But in the majority of women the equilibrium is regained before they have actually ceased to nurse their children, and, therefore, in the majority of instances menstruation reappears before the function of lactation is ended.

13. Tuffier's Ovarian Graft.—Norton recommends this method for diseases of the ovary. He says it should always be done in idiots, defectives and criminals instead of double oophorectomy. It may also be done in those cases which one wishes to sterilize on account of contracted pelves and other conditions which render child-bearing impossible. Except for the fact that it does not allow pregnancy it fulfils all the requirements of an ideal operation. It can be easily and quickly done. The functions of the ovary, both in internal secretion and menstruation are maintained, and at the same time the ovary is placed in a clean healthy bed completely protected from subsequent attacks of gonorrheal infection. With a new and diminished blood supply sclerosis and cystic degeneration are prevented or retarded.

25. Quiet Hip Disease.—Taylor and Frieder have noticed that certain cases of hip disease, beginning usually in the second quinquennium, run a mild course and progress to an excellent recovery with little or no treatment. These occur in children of good constitution, and in good physical condition, which is not impaired by the hip affection. The invasion is usually mild and insidious, beginning with a slight lameness and often without pain, though moderate pain in the hip, knee or groin is common at some stage of the trouble, and night cries occasionally occur. The child is seldom laid up and usually continues fairly active and goes to school. The authors have observed and studied nineteen cases of this disease, thirteen males and six females; the age at invasion ranged from 4 to 16. In twelve the right, in six the left and in one both hips were affected. In two other cases the roentgenogram showed some thickening of the neck of the second hip, but there were no symptoms. In none of the eight cases tested was there a positive Wassermann. Two patients were tested with tuberculin and both were negative. About half the patients were questioned as to indigestion and constipation, which was always denied. Several of the patients were treated at first for rheumatism; later, most of them were treated by the short spica for varying periods of time; a few had braces, or traction in bed; a number had no treatment. Treatment seemed to exert no effect on the symptoms or course of the disease, except that after immobilization of the hip, pain disappeared in several instances. The only cases of marked stiffness encountered were two boys who had worn spicas for a considerable time; in both of them motion returned. Several of the cases were obviously overtreated and it seems that mechanical treatment is often unnecessary and only moderate restriction of activity advisable. Occasionally, if pain and spasm on motion are present, the short spica for a month or two seems beneficial. Operations are to be avoided. The name "quiet hip disease" is proposed for this clinical entity, the origin of which is as yet uncertain but the recognition of which is easy and important.

26. **Osteochondritis Deformans Juvenalis.**—Allison and Moody are inclined to believe that osteochondritis deformans juvenalis is a disturbance of the line of epiphyseal growth, and that it depends for its typical development on changes in circulation which destroy the balance which exists between the metaphysis and epiphysis in growing bones.

29. **Transverse Process of Vertebra.**—Blanchard and Parker cite a case of impingement of the transverse process of the fifth lumbar vertebra on the posterior wing of the ilium, producing pain, numbness and paralysis of the side and leg, so severe as to cause the patient to become bedridden.

30. **Study of Juxta-Articular Sarcoma.**—Roberts urges that a routine examination be made of cases presenting the symptoms of tuberculosis of the vertebrae or of the bones forming the hip and knee joints and that it should include a search for localized tenderness, pain at the site of the lesion, and careful scrutiny of roentgenograms for peculiarities in the picture. Localized pain in the diseased area which in an early case is unrelieved by immobilization is significant of some pathologic process other than tuberculosis. The appearance of unusual shadows in roentgenograms of a clinically tuberculous osteitis is sufficient reason for withholding a positive diagnosis of tuberculosis. Rapid bone changes shown by roentgenogram taken at frequent intervals are suggestive of sarcoma. The disappearance of pain when a part is immobilized, especially when the hip is concerned, does not exclude sarcoma, even though persistent pain in spite of immobilization argues strongly in favor of it. Localized tenderness about the area of disease, especially in spine and hip cases, may be regarded as confirmatory evidence of sarcoma if other factors point in this direction. Age of the patient, a history of local injury and the presence of tuberculosis in the family or in the patient, are features of little significance in arriving at a differential diagnosis between bone sarcoma and tuberculosis. A previous history of malignant disease relieved by operation should immediately suggest malignancy in the case under consideration. The possibility of sarcoma should always be borne in mind in clinically tuberculous joint conditions exhibiting unusual features. A diagnosis of sarcoma should not be made on any one symptom, but on the coexistence of several factors not usually present in tuberculosis.

32. **Case of Typhoid Spine.**—A portion of the bodies of the second, third and fourth lumbar vertebrae on the ventral surface was excised in Rugh's case. The intervertebral disk between the third and fourth lumbar vertebrae was missing and apparently replaced by a bony overgrowth that closely resembled, grossly, the bony tissues of the vertebral bodies. Sections cut from this point for microscopic study show a complete absence of cartilaginous tissue and a marked overgrowth of, or rather a replacement with, dense connective tissue, which has a rather rich blood supply. This connective tissue bridges the space normally occupied by the intervertebral disk and merges into the body tissue of the body of the third lumbar above and the fourth lumbar vertebra below, sufficient to cause a complete ankylosis.

34. **Treatment of Joint Infections.**—Churchman has treated by the method of repeated joint irrigation with salt solution followed by staining of the synovial membranes with gentian violet, a small number of streptococcus and gonorrheal joints. The irrigations are carried out under local anesthesia. The first distention of the joint, before anesthesia can be regarded as established, causes no pain or discomfort whatsoever. The strength of gentian violet used for this purpose has been 1:1,000. Gentian violet in this strength caused no pain or signs of subsequent irritation. In some cases the dye was used in a strength of 1:500. The number of cases treated is small, but, Churchman says, some of them have put the method of lavage and staining to a rather severe test. The results have been sufficiently encouraging to justify a continuance of a study, which is now being carried on in the laboratory of surgery at Yale University and in the wards of the New Haven Hospital. A detailed report is promised later.

40. **Triangle of Petit in Kidney Surgery.**—Crouse's paper deals with a new route for kidney surgery, which, in his experience, has been successful in most pathologic conditions met while dealing with the kidney in a surgical way, and is denominated the triangle of Petit route. By this route the author has removed even a 14-inch kidney, which has been practically destroyed by suppurative degeneration secondary to calculi, and was compelled to cut only slightly the internal and external oblique to gain additional space. On the right side this route can be used for doing appendectomies, and for inspection of the gallbladder and duodenum. The left-sided incision gives access to the tail of the pancreas, the spleen and the splenic flexure of the colon. Crouse has used the triangle of Petit route in over thirty kidney operations in various forms of renal pathology; in several cases the duodenum has been inspected, the upper fourth of which is readily brought to view, when the retroperitoneum is opened and retracted with Payr's broad-bladed retractor or the silver malleable retractor so commonly used for exposing deep cavities. The gallbladder can be drained and even removed, as was done by the author in the case of an old person suffering with a gangrenous condition of the gallbladder. When the lateral position is maintained in bed after operation, this incision gives an ideal line for drainage.

45. **Ventrofixation of Uterus for Relief of Prolapsus.**—The operation described by O'Conor endeavors to restore the cervix to its position by fixing it to the recti muscles in the following manner: The abdomen is opened by the usual low central incision and the uterus exposed, any coexisting adnexal disease or adhesions are dealt with, the uterus is then drawn well up into the wound, and a transverse incision is made through the uterine peritoneum just above and parallel to the uterovesical peritoneal reflection (corresponding to the preliminary uteroperitoneal incision in hysterectomy). The peritoneum, with bladder, is reflected downward and forward until a space about 1 inch square is left denuded on the anterior surface of the cervix. The uterine peritoneum on each side of exposed area is retracted and three strong (eleven day) catgut sutures are passed, about ⅓ inch apart, through the exposed portion of the cervix, and sufficiently deep to obtain a firm grip of the cervical muscular coat. The ends of the sutures are drawn out on each side, respectively, through the recti muscles by a Childe's ligature forceps. Thus the peritoneum is excluded

and the denuded surface of cervix is brought into direct apposition with the recti. In order to avoid subsequent intestinal adhesions at the site of fixation, the parietal wound is closed by tier sutures, the first suture purposely including the uterine peritoneum well above the denuded area.

82. **Fat Formation.**—Underhill and Hendrix found that if warm Ringer's solution is perfused through the kidney of the rabbit for a period of twenty-four hours there may be a percentile or an absolute increase in the amount of fat contained in the cortex of the kidney or of the entire organ. These results confirm those of Gross and Vorpahl. Unlike Gross and Vorpahl, who cite these findings as evidence for the formation of fat from protein, the authors believe that the data may be interpreted merely as an expression of the mechanical difficulty of preventing contamination with fat of that portion of material to be analyzed. Doubt is also expressed concerning the influence of the perfusion with Ringer's solution, for a kidney simply suspended in this medium may yield results entirely comparable with those obtained after perfusion.

83. **Nitrogen in Feedingstuffs.**—The data secured by Hart and Bentley show that the "amid" nitrogen of feedingstuffs is largely composed of free amino-acids and peptid linkings. In most cases the nitrogen in these structures constitutes 50 to 70 per cent. of the water-soluble nitrogen. The acid-amid nitrogen is relatively small, seldom exceeding 20 per cent. of the water-soluble nitrogen, and more often being below 10 per cent. Corn stover is an interesting exception, showing approximately 40 per cent. of the water-soluble nitrogen in acid-amid form. The ammonia nitrogen rarely exceeded 5 per cent. of the total water-soluble nitrogen, and in some instances was wholly absent.

84. **Pituitary Feeding and Egg Production.**—Clark's experiments show that feeding of pituitary gland substance (anterior lobe) increased the egg production of hens whose production curve was on the decline. The dosage was effective on the fourth day after the first dose and lasted for several days after the last dose. The hatchability of eggs from dosed parents was increased.

86. **Carbohydrate Metabolism.**—Underhill and Murlin show that the subcutaneous injection of hydrazin into fasting dogs induced an increased rate of carbohydrate combustion as measured by the respiratory quotient. This increased combustion of carbohydrate probably explains the diminished blood sugar content and the disappearance of glycogen from the liver and muscles observed in previous communications. Subcutaneously introduced dextrose is oxidized more rapidly in dogs that have received hydrazin than in the normal fasting animal. Such injections of sugar to hydrazinized dogs also appear to exert a specific dynamic action. Hydrazin exerts no specific influence of heat production.

88. **Blood Sugar Estimation.**—The method worked out by Pearce is as follows: Two c.c. of blood are added to 19 c.c. of water; 10 c.c. of dialyzed iron and 1 c.c. of saturated sodium sulphate solution are now added and the solution is filtered. Two c.c. of the clear filtrate are taken for estimation by the modified Bang method. This is treated with 10 c.c. of saturated solution of potassium chlorid and 1 c.c. of Bang copper solution, in a 25 c.c. Jena flask, on the neck of which a rubber tube is drawn. The flask is placed in an oil bath heated to 140 C. and left there for exactly five minutes. At the end of this period the rubber tube is clamped off with a hemostat. When cool, CO_2 is introduced to fill the vacuum which has been made by the condensation of the steam, and the solution is titrated in an atmosphere of CO_2 with N/100 iodin solution, starch being used as an indicator. A solution made up with pure water in place of sugar solution will give a reduction equal to 0.2 c.c. of iodin. For this reason, 0.2 c.c. is subtracted from all titration results. The value of the iodin in terms of sugar is obtained before each series of titrations by the method above outlined.

90. **Iodin in Thyroid Gland.**—Marine's experiments emphasize the extraordinary affinity of the thyroid tissue for iodin. When one considers that as high as 18.5 per cent. of a given intake of iodin by mouth may be recovered from a thyroid

whose ratio to the body weight is as 1:687, it stands alone at present among the specific affinities of tissues for inorganic substances. The results further emphasize the fact that maximum thyroid effects are induced by minimum amounts of iodin. The amount of a given intake absorbed depends, for the most part, on the size of gland and the existing degree of hyperplasia or the degree of saturation with iodin at the time of its administration.

92 Exact and Inexact Methods in Neurology and Psychiatry. G. W. Jacoby, New York.
93 *Studies on Localization of Cerebellar Tumors. E. G. Grey, Boston.

93. **Localization of Cerebellar Tumors.**—The purpose of Grey's paper is to discuss the importance of staggering gait, limb ataxia, the Romberg phenomenon, and adiadochokinesis in localizing new growths in the posterior cranial fossa. It is based on an analysis of the records of forty-eight cases of tumor which involved the cerebellum either directly, or indirectly by pressure. The diagnosis and localization of the lesion were confirmed in all of the cases either at operation or on postmortem examination. All records have been excluded which showed that the disease had extended into other parts or which included additional factors likely to confuse the symptom complex. There were nineteen cases in which new growths, gliomata, endotheliomata and tuberculomata occupied one or the other cerebellar hemisphere. On examination all showed some degree of the characteristic tottering or drunken gait. There were nine cases in which the tumors gliomata and tuberculomata occupied a central position in the cerebellum, namely, they involved the vermis and to some extent the neighboring portions of the lateral lobes. In one the gait remained unaffected. Of twelve patients with lesions in one or the other lateral recess, endotheliomata and cysts, one had an apparently normal gait. In the remaining eleven the usual uncertainty was evident. Of three cases of median tumors posterior to the cerebellum, two ependymal gliomata and one angioma, the gait remained unaffected in one.

The Romberg test was used in sixteen patients with unilateral, intracerebellar tumors. Of these, four fell or tended to fall toward the affected side. The swaying or falling was chiefly away from the lesion in five cases. In patients with new growths involving the vermis, three fell, or tended to fall, backward. One was equally unsteady in all directions. The remaining cases, seven in number, swayed more toward one side. Of thirteen patients with cerebellopontine new growths the swaying was directed toward the affected angle in six, and toward the unaffected in two. An unsteadiness equally marked in all directions appeared in three cases. In only one instance was a negative Romberg found. The lesion, an ependymal glioma in one of three cases of median tumors posterior to the cerebellum, rested on the medulla and cord, causing flattening of the latter. The Romberg was negative. The other two cases, an angioma and a second glioma, fell principally in one direction. From the data presented it is evident that in considerably over 50 per cent. of the cases the direction of swaying or falling bore no direct relation to the location of the tumor. Accordingly the author believes that it is fair to conclude that while this test is useful in establishing a diagnosis of subtentorial new growths, a swaying toward one or the other side has no real significance in localizing the tumor.

Limb ataxia was studied in eight patients with tumors involving the vermis. In all, with two exceptions, the amounts of ataxia on the two sides were quite dissimilar. No ataxia was discernible in one case of tumors within one hemisphere. While it was equally marked on either side in five (one had little), in ten it appeared coarser on the homolateral, and in two coarser on the contralateral, side. No ataxia was visible in two cases of tumors in the cerebellopontine angle; in a third it appeared equally marked on the two sides. Of the thirteen members of this group, ten exhibited more incoordination in the limbs of one side. Very little ataxia was evident in median tumors posterior to the cerebellum. In one it was entirely absent; in the remaining two it appeared only in the arms and then to a slight degree. Tumors within one hemisphere: there was normal diadochokinesis in two patients. Adiadochokinesis was present in twelve cases. In three it appeared equally bad on the two sides and in nine more marked on the side containing the new growth. Tumors involving the vermis: two patients exhibited no adiadochokinesis in either limb. In a third it was present, but to an equal extent on the two sides. A unilateral adiadochokinesis was noted in the remaining four cases of the group. In two of these the tumors encroached more on one of the hemispheres than on the other. Tumors in the cerebellopontine angle: of twelve cases with lateral recess tumors four exhibited normal synergic movements. Adiadochokinesis was noted homolateral to the lesion in six.

126 *An Unusual Complication of Acute Appendicitis. M. B. E. Sutton, New York.

126. **Complication of Acute Appendicitis.**—When first called, Sutton found the patient suffering from intermittent colicky abdominal pain; abdomen tympanitic; temperature and pulse

normal. No abdominal tenderness. Gave soapsuds, enema, liquid diet, castor oil, 1 ounce. Diagnosis: Acute intestinal indigestion. At 4 p. m., temperature, 100; pulse, 90, and of good quality; pain, as before; slight localization of pain over McBurney's point. Abdomen slightly tympanitic. Return of enema good, constipated mass. Treatment: Ice bag to right iliac fossa, liquid diet. Diagnosis: Acute appendicitis. Five a. m. next day: patient suffering with sharp shooting pains in vulva, in addition to abdominal pains, still same character as before. Catheterized and obtained 4 ounces clear straw colored urine. Temperature, 102; pulse, 110, weak and compressible; marked tenderness over McBurney's point; *slight rigidity* of right rectus. On consultation immediate operation advised. On operation, Sutton found at the distal end of the appendix a ruptured abscess, firmly *adherent to the posterior* wall of the bladder, and a beginning *peritonitis*. *As the vulva* and bladder are supplied in part by the sacral plexus, it is easy to understand why such a complicating symptom should arise. The diagnosis was also *complicated* by the ovarian pain. A bimanual examination was not *advisable as the patient* was a virgin. Sutton believes the symptom of a sharp shooting pain in the vulva to be *diagnostic* of an adhesion of the posterior wall of the bladder.

8 *Splenectomy in Kala-Azar. S. Cochran.
9 Continued Fever of Korea. H. H. Weir.
10 Roentgen-Ray Experiences in Mission Hospital. A. F. Cole.

7. **Splenomegaly.**—Half the cases seen by Whyte occurred between the ages of 16 and 25 years, when *the patient* became aware of a lump in the position of the spleen. Forty per cent. told of relatives who were suffering from enlarged spleen, etc., but it was noted that this percentage varied with the district *from* which the patient came, namely, eighteen patients were distributed over three districts and only three of these (17 per cent.) had relatives affected, whereas of thirty-eight patients who came from one single district, in as many as twenty-four cases (*63 per cent.*) at least one relative was affected. The duration of illness up to the time the patient came to the hospital varied between a few months and (in one case only) thirty years. In 28 per cent. of the cases the illness had lasted for ten or more years. Eighty-eight per cent. of the patients remembered having had attacks of fever, and in two thirds of these cases the form of infection was either simple or double tertian, the remainder being cases of quartan fever. Edema or ascites had been present, or was found when the patients *came to* the hospital, in 62 per cent. of the cases. Hemorrhage usually from the bowel or the nose was recorded in 61 per cent. of the cases. Diarrhea was recorded in 50 per cent. of the cases. The erythrocytes varied in number from two and a *half* to four millions per cubic millimeter in more than half the cases. The majority of the remaining cases showed between four and five millions, though a few (11 per cent.) had less than two and a half millions. The color index varied *in different* cases from 0.6 to 1.3, but in two thirds of the cases it did *not* exceed 0.9. Nucleated red cells were found in one half the cases whose total red count was less than two and a half million, and in only 6 per cent. of the cases with *more* than four million cells. In the intermediate group normoblasts were found *in 30 per cent. of the cases.* Poikilocytes were noted in 27 per cent. of the cases examined. Two thirds of the cases had less than 3,000 white cells. The percentage of polynuclears varied from 40 to 80 per cent.; 89 cases having between 55 and 75 per cent.

8. **Splenectomy in Kala-Azar.**—Following *removal* of the *spleen in* three cases Cochran says the *patients showed* an immediate and marked increase in hemoglobin and the leukopenia was abolished, there being a tendency to a moderate leukocytosis. One *patient survived only* seventeen days. The other two are now in considerably better health than before the operation. In one *of them* the liver was shrunk to normal size from a *previous marked hypertrophy.* Both have *added weight.* The temperature curve in both is more nearly normal than before the *operation*. Parasites are still easily found, though in one of the cases the number seems smaller.

19 *"Boomerang Leg"; Bone Disease Occurring Among Australian Aboriginals. A. Breinl and H. Priestley.
20 Flagellate Forms of Leishmania Donovani in Tissues of Experimentally Infected Dog. C. M. Wenyon.

19. **"Boomerang Leg."**—This *disease* has for sometime been known as "boomerang leg," on account of *the* similarity of the shape of the legs to that of a boomerang. *It affects* young

natives of both sexes and the resulting deformity persists throughout their life, and in every case seen both legs were affected. The onset seems to be gradual; the children complain at first of pains in the shins, sufficiently severe to prevent them from walking. The skin over the tibia is tender to pressure, but there is no swelling noticeable. These pains become less severe in the course of time, the children begin to use their legs again, and the tibiae and fibulae bend forward gradually and assume the characteristic shape. In consequence of this the center of gravity of the body is displaced forward, the patient becomes flatfooted, and the gait shuffling. The deformed bones gradually increase in thickness, but retain their altered shape. The history of the disease in conjunction with the appearance of the bone suggests that "boomerang leg" is the result of a chronic osteomyelitis of both tibiae. It takes, at first, the form of a rarefying osteitis, corresponding clinically to the early and painful stages of the disease and giving rise to the softening of the bone and the characteristic deformity. This phase is followed later by a condensing osteitis, in cases in which the increased activity of the osteoblasts leads to a progressive thickening of the lamellae, to bony metaplasia of the fibrosed marrow, and to the reduction of the marrow spaces. A simultaneous progressive periosteal new development causes the increase in the thickness of the shaft. The etiology of "boomerang leg" is unknown, but syphilis and tuberculosis can be excluded.

23. **Spasmodic Symptoms in Rheumatism.**—Among the symptoms discussed by Poynton under this head are migraine, muscular spasm, paroxysmal sensory symptoms and anginal attacks. He points out that a damaged heart is made worse by an acute rheumatic attack; then the development of attacks of cardiac pain, becoming at times frequent; steady increase in the predominance of symptoms of a functional or hysterical character; remarkable intervals of freedom; and a final abrupt termination of the illness, as was well illustrated in a case cited by Poynton. The necropsy showed a large heart (27 ounces); the pericardium was generally adherent. There was myocardial fibrosis with endocardial thickening of the membrana septi, and old-standing thickening of the aortic and mitral valves. The aorta, the openings of the coronary vessels, and the coronary vessels themselves were not apparently diseased. An electrocardiogram taken at a time when the attacks were frequent [illegible] demonstrated that there was hypertrophy of the left ventricle. Irregularities of rhythm were conspicuous by their absence throughout.

25. **Treatment of Septic Compound Fractures.**—The method of treatment adopted by Pennell is to make a large incision over the site of the fracture, define the ends of bone, remove any small detached portions of bone and shrapnel, and after placing the two or more main fragments in position, either fix them with a Lane's plate, suture them with silkworm gut, or, in cases in which there is much loss of bone, transpose a graft from the tibia or fibula. If the condition is fairly clean Pennell sews up the muscle and fasciae, leaving only a small rubber drain down to the plate. If it is septic he makes no attempt to "bury" the plate or fixing apparatus. Active antiseptic treatment is instituted.

26. **Intestinal Drainage in Septic Peritonitis.**—The rational treatment of this toxemia in Nyulasy's opinion is the removal of unabsorbed intestinal toxin and the prevention of its further production. Both these ends may be secured by intestinal drainage, provided the peritoneal cavity is not charged with excessive poison and that the focal factor is eliminated. The following is a summary of Nyulasy's treatment: If the focal factor has been eliminated, free toxic fluid mopped away, septic necrotic areas drained, the Fowler position employed, saline freely administered, and early purgation given a trial, but the patient nevertheless continues to deteriorate from toxemia due to paralytic ileus, then intestinal drainage should be instituted. If, at the primary operation, drainage of the septic focus in the abdomen has not been employed and the patient deteriorates, a drainage tube may now be introduced; if the patient does not then rapidly improve, but continues to go down hill, intestinal drainage may now be instituted under local anesthesia. If, when the patient is first seen, the evidence of toxemia from paralytic ileus is positive, and especially if lividity is obvious, then intestinal drainage should form part of the primary operation.

30. **Cases Treated as Paratyphoid.**—Paratyphoid (A and B) in the British expeditionary force, according to Robinson's observation, is a disease much shorter and milder than typhoid, as met with in civilian practice and in the South African campaign. Its onset may be gradual or moderately sudden. Headache and abdominal pain are the most constant symptoms. Shiverings at the onset; cough, pains in the limbs and back, diarrhea, constipation, nosebleeding are the next commonest symptoms; all these are met with in about 30 to 60 per cent. of cases. Vomiting at onset and sore throat later are by no means rare. Definite rose spots in successive crops are found in about 60 per cent. of cases. The abdominal reflex is absent in rather under 50 per cent. The pulse rate is extraordinarily slow, even more so than in typhoid. Relapses of brief duration are not uncommon. Several complications occur more rarely and are the counterparts of those associated with typhoid. The paratyphoid bacillus (A or B) is frequently isolable from the feces, but in many cases not until after the symptoms have subsided; one negative finding should not be accepted as conclusive. It is also occasionally isolable from the blood, urine and from metastatic abscesses. Distinct help in diagnosis is obtainable from repeated quantitative Widal reactions, but much experience is required for their interpretation, and they must be read in conjunction with the clinical evidence and with the history of previous inoculation. On the assumption that this disease is of the enteric group, the same precautions as in the case of true typhoid are indicated against its spread. In particular, carriers must be watched, for bacilli may be present in their urine and feces after all symptoms of illness have subsided.

40. **Magnesium Chlorid in Therapeutics.**—Rosenblith relates clinical experiences which have led him to the same conclusions as to the efficacy of magnesium chlorid that Delbet has reached by experimental research. Rosenblith gave it by subcutaneous injection in April, 1913, to relieve a very painful case of deforming rheumatism, and the results were extremely encouraging. In the last few months he has been using it

in dressing wounds, and with most excellent results. It seems to increase the opsonic index and generate substances antagonistic to proliferation of bacteria.

42. **Magnet for Extraction of Foreign Bodies.**—Léorat relates that the first known use of the magnet for extraction of a scrap of metal in the tissues dates from two thousand years before Christ, as recorded in one of the Vedas, the book of the Brahmins. The eye infirmary at Lyons has been fitted up as a base hospital, and the giant magnet, designed to extract scraps of metal from the eyes, has been found very useful in locating and extracting scraps of shells and bullets in the seat, thigh, neck and back, as well as in the eyes. One man had been showered with small scraps from an exploding shell, and many of them buried deep in the tissues were drawn out by the magnet alone. At one point five scraps were thus extracted through the single hole through which they had entered. In two other cases a piece of a needle or pin was thus drawn out. He gives some illustrations which show how the size, shape and depth of the foreign body can be approximately estimated from the shape of the protuberance that forms above it when the magnet is applied to the region. The more of a peak, naturally, the nearer to the surface. The base of the protuberance should be outlined; it is circular if the needle, for example, stands perpendicular; it is an ellipse if the needle lies parallel to the skin, and it is egg-shaped if the needle lies slanting. Bird shot is often made of iron, and hence is magnetic, and nickel-coated bullets also respond to the magnet. He suggests the possibility of making a magnet long and thin that might be introduced into the esophagus, stomach or air passages, and thus draw out metal foreign bodies.

45. **Mud and Brine Baths.**—This long study of the "limans" of the Black Sea concludes with Borisoff's warning that acute diseases should never be given treatment with mineral mud or brine baths as they are exclusively for chronic affections. In his experience with over 10,000 patients taking the baths, he found that the chronic affection always showed a phase of aggravation under the influence of the baths. That is to say, the chronic affection developed an acute phase, and the defensive forces then rallied better and often conquered the trouble without further ado. The technic, therefore, of the mud and brine baths health resorts in question aims to transform a chronic into an acute affection. The strength of the patient must be sustained, all depressing factors avoided, and constant medical supervision is imperative, especially when the nervous or cardiovascular system is impaired. Two diabetics taking the mud baths without medical advice developed fatal coma.

46. **Blister Cupping.**—Aubert expatiates on the benefit from revulsion in pulmonary edema, and relates that he has thus tided an elderly physician of 75 through repeated attacks of pulmonary edema during the last three years. The drawbacks of cantharidin blisters are avoided by using an ordinary tumbler, with a lighted, crushed up piece of newspaper inside, applied to the skin in the dorsolumbar region. The tumbler is pressed firmly into the skin and left there for an hour and a half or two hours. Multiple blisters form under it, and they continue to secrete for about a week. He has had no opportunity to apply the measure in affections other than pulmonary edema, but it works so well in this that he would not hesitate to use it for congestion of the lungs or viscera, and attacks of pain in the kidney, along the sciatic nerve or elsewhere. The cupping glass does not get so good a hold on the abdomen as on the back; the secret of success is a good hold and an hour and a half to two hours' application. He has his patients with pulmonary edema sit up in a comfortable arm chair, with several shawls thrown over the legs and trunk, or a wide dressing gown that can be readily drawn out of the way, to permit this cupping blister revulsion.

No. 5, pp. 93-108

55 Epidemic Tetragenemia; Thirty-Five Cases. F. Trémolières and P. Loew.

49. **Partial Tetanus.**—Courtellemont's patient was a man of 65 who developed attenuated partial and chronic tetanic contracture of the leg after he had stepped on the tooth of a rake and inflicted a slight wound. The first symptoms were observed about fifteen days after the accident, and except for a slight and transient tendency to trismus the disturbances were apparently merely a spastic monoplegia. A painful cramp sometimes developed in the leg and foot affected when he tried to move them. Under epidural injections of antitetanus serum and chloral the symptoms gradually subsided to a complete cure by the end of the sixth week. In connection with this case Courtellemont discusses the literature on partial and atypical tetanus, emphasizing that however unusual the combination or sequence of symptoms, the underlying tetanus is the same disease in all and requires the same treatment.

51. **Massage and Exercise in Treatment of Skin Affections Persisting After Wounds.**—Debat relates that in many cases the dermatitis was the result of corrosion from the antiseptics used in dressing the wounds or of maceration from a moist dressing with boiled water. The tissues become so torpid that they show no inclination to heal. The injury of nerves and vessels in the region may cooperate in the delay in the healing of the dermatitis as also the immobilization of the part. Both of these factors are combated by intermittently stimulating the skin with a 9 per thousand salt solution and exposing the region to the air, as soon as possible having the muscles massaged and exercised. He reports some typical cases showing the rapid healing under such measures of dermatitis long resisting ordinary treatment.

52. **Ambulance and Hospital Number.**—This large number is profusely illustrated and describes and shows the ambulances at work, the hospitals and dressing stations, base hospitals, etc., the sanitary trains, the stretchers in use and the dogs trained to seek for the wounded. The last two of the twelve articles by various writers are descriptions by Camus of the physiotherapeutic institutes at Paris and by Claude of the regional neurologic centers which have been established at various points. Claude states that specialist care and hospital treatment for the neurologic cases has been organized at several points in Paris, and at Lyons, Bourges, Bordeaux, Toulouse, Nancy, Rennes, Marseilles, Nantes and Tours. Other regional neurologic hospitals are to be installed as needed, the results having abundantly proved their usefulness.

61. **Influence of Emotions and Drugs on the Carbon Dioxid Tension of the Alveolar Air.**—Beckmann found that emotional factors had a depressing influence. This must entail a drop in the concentration of hydrogen ions throughout the entire body. This in turn must affect the functioning of numerous organs. Certain drugs are able to influence the tension, morphin increasing and cola reducing it.

62. **Eosinophil Myocarditis.**—Liebmann found accumulations of eosinophil elements in the myocardium at necropsy of a girl of 12 who had succumbed to diphtheria. The findings in the heart muscle were like those Stäubli and Hübner have reported from cases of trichinosis. Tanaka in 1912 reported eosinophils as a constant finding in four out of fifteen diphtheria hearts, but never in such profusion as in the case here described, with a colored plate. In this case the eosinophils were grouped also in such a way as to suggest that the affection represents a new and rare type of diphtheritic myocarditis. Destruction of muscle tissue cannot be the only factor involved. Liebmann is making a special study of the heart in infectious diseases, and this first communication is to be followed by others.

69. Practically the same article was summarized in these columns, November 6, p. 1682.

71. **Mechanism of Injury from Getting Chilled.**—Aufrecht presents an imposing array of testimony culled from old and modern writers to reaffirm the important part played by getting chilled in the genesis of various diseases and morbid processes. He then reports various experiments on rabbits, all of which confirms his assumption that the chilling causes coagulation of fibrin in the blood stream in the part chilled. The cause of the coagulation is the injury done to the white corpuscles by the cold. The coagulation obstructs the flow through the peripheral vessels involved and the blood is liable to back up into the liver, kidneys and gastric mucosa. The most striking changes were found in the lungs, the coagulation of fibrin entailing microscopic hemorrhage into the interstitial tissue. This occurred in a pronounced form when the hind part of the rabbit was thrice dipped into ice water for ten minutes. The blood chilled in this way passes in the directest way to the arterial circulation in the lungs. The obstruction of vessels by the coagulated fibrin after chilling may be transitory and harmless, but, on the other hand, it may provide a culture medium for germs and explain pneumonia developing after exposure to cold. The hyperemia in the internal organs may also cooperate in the disturbances following chilling.

81 The Blood Count and Differential Staining in Counting Chamber. (Zur Blutkörperchenzählung und zur Differentialkammerfärbung.) G. C. van Walsem.

73. **Treatment of Dysentery.**—Hirsch reviews the general principles for prevention and treatment of dysentery, and emphasizes that there are not only severe infection and intoxication but serious lesions in the lining of the bowel, and the patient is suffering likewise from lack of water, lack of nourishment, and from the constant draining away of salts. All of these should be regarded in treatment. He advocates one or two tablespoonfuls of castor oil daily at first, supplemented after a few days with repeated small doses of calomel. He has found rectal injections of kaolin or of animal charcoal (one heaping tablespoonful to a liter of warm salt solution) effectual in reducing tenesmus. He generally makes the injection at night and then gives a little opium to ensure a few hours' rest. He does not approve of either kaolin or charcoal by the mouth; they adsorb the digestive ferments and ruin the appetite. Saline infusion combats the loss both of water and of salt.

76. **Abortive Forms of Meningitis.**—Hochhaus remarks that the abortive forms seldom come to the notice of physicians, and yet they are of great epidemiologic importance as sources of infection of others. During the first six months of this year there were thirty-two cases of meningitis at Cologne and twenty-four of these passed under his observation. In all there were pains at the back of the neck, headache, vomiting, stiff neck and a chill; in a few cases the nose and throat secretions gave positive bacteriologic findings. There were also sore throat and bronchitis in most cases. These symptoms all rapidly retrogressed in the sixteen abortive cases and the men felt quite well. The diagnosis was based mainly on the fact that the men had been living with those who had developed severe epidemic meningitis. It is wise when the latter is prevalent to have the nasopharyngeal secretions examined from all those who present any symptoms on the part of the air passages and pains in the limbs.

88 Open Treatment of Wounds. (Offene Wundbehandlung.) Schede.

85. **Blocking the Brachial Plexus.**—Schepelmann states that in his application of Kulenkampff's technic in 300 cases he observed unpleasant by-effects in seven cases, that is, in 2.3 per cent. This included four cases of interference with the breathing on account of injury of the pleura, one case of pneumothorax, and two of brain symptoms, alarming at

first but rapidly subsiding completely. He never witnessed any harm from repeating the plexus anesthesia at weekly intervals, as he had occasion to do in mobilizing some stiff joints. With improved technic and patient waiting, the anesthesia is satisfactory with extremely rare exceptions. He warns, however, that the plexus should never be blocked on both sides. The above statistics do not include nineteen cases presenting what he calls "Horner's syndrome," which he remarks is entirely harmless. They do not include either a case of paresis of the fingers from the constricting band.

91 *Bacterial Affections of the Urinary Organs in Infants. (Sog. Pyelocystitis im Säuglingsalter.) H. L. Kowitz.
92 *Invagination of the Intestines in Infants and Small Children. (Darminvaginationen im Kindesalter.) H. Wollin (Prague).

90. **Transmissibility of Exfoliating Dermatitis of the Newly Born.**—Wolf encountered within two weeks recently three cases of exfoliative dermatitis in newly born infants, fatal by the ninth to the seventeenth day. The clinical picture was the same in all, and each had been breast fed. Rittershain had 297 cases of the kind at Prague in ten years' experience. He and others regard it as an affection developing only in early infancy, noncontagious, and to be sharply distinguished from pemphigus of the new-born. Others regard pemphigus of the newly born and exfoliating dermatitis of the newly born as the same process, differing merely in its intensity. Wolf has been unable to find in the literature any history of direct transmission from skin to skin but has met with a case of this kind in practice. The mother of one of the three infants mentioned above developed an apparently identical process in the right breast at the point where the child had lain to nurse. The clinical picture was unmistakably the same, after an incubation period of ten days. The general health was not impaired, and under eight days' hospital treatment the condition improved to a practical cure and the woman has not been seen since. A peculiarity of the case was the presence of two hard tumors in the depths of the affected region. One was as large as a hen's egg, the other not so large. They retrogressed without softening, but the local painfulness prevented investigation. They suggest, however, that certain special factors are involved in the production of the exfoliating dermatitis.

91. **Bacterial Affections of the Urinary Organs in Infants.**—Kowitz has examined forty infants under 2 with some affection of this kind. There were about as many boy as girl babies in the series, and the connection with gastro-intestinal disturbances and the bacteriologic findings indicated that bacilli of the colon group, brought by the blood, were responsible for the processes in the various cases. He says that the terms cystitis or pyelitis are not applicable. A more accurate descriptive term would be bacterial nephritis or colinephritis in small children. In 37 of his 40 cases bacteria were found in pure cultures; mixed infection in only 3. Among the pure cultures, colon bacilli were found alone in 24 cases, paracolon bacilli in 10, and staphylococci alone in 3. In these latter cases the infants had furunculosis or eczema. In the 3 cases of mixed infection colon bacilli were present. In the entire 40 cases members of the colon family were found in 92.5 per cent.; this proved conclusively, he thinks, that the germs came originally from the bowel. It is astonishing, he remarks, that so little attention has been paid to the blood in studying disease of the urinary apparatus in small children, especially in "pyelitis in infants." Bahr found bacilli in the blood in 117 of 120 cases of digestive disturbances in infants, in 65 during life, and the colon bacillus predominated far above all others. The blood count in the few cases in which he could make it suggests the importance of research in this line.

In 5 cases Kowitz could trace the development of the urinary affection. First there was albumin in the urine and bacteria soon appeared also in the urine. Then after an interval of five or six days, pus and epithelial cells, and sometimes tube-casts and red blood corpuscles were also found in the urine. With ascending infection the sequence would have been reversed. The cases are grouped and tabulated under various headings, the tables filling six pages. The blood count in twelve cases showed leukocytosis from 10,000 to 20,000 in all but 4; the small lymphocytes ranged from 20 to 72.7, the large from 0.7 to 8; the polynuclears from 15 to 53.7; the eosinophils from 0 to 6, and the mononuclears from 0.3 to 11. The corresponding standard figures for infants are (Japha) 12,000; 25 to 35; 50 to 55; eosinophils 2 to 7 and mononuclears 8 to 15. Pfaundler's figures for infants are: lymphocytes, 22; polynuclears, 51; eosinophils, 4; and mononuclears, 12.

92. **Invagination of the Intestines in Children.**—Wollin analyzes twenty cases from the Prague children's clinic, saying that the outcome confirms the gravity of the prognosis the younger the child. Only three of the thirteen infants less than 1 year old survived, while the seven older than this all recovered. The younger the child, the more difficult the diagnosis, as a rule, and the longer the delay before the operation.

Medizinische Klinik, Berlin

September 26, XI, No. 39, pp. 1065-1092

93 Psoriasis and Allied Diseases. J. Jadassohn. Concluded in No. 40.
94 *Abnormal Mammary Secretion. (Zur Pathologie der Brustdrüsensekretion.) E. Ebeler.
95 Serotherapy of Typhoid B. Fellner.
96 *Relapsing Fever (Ruckfallfieber.) L. R. v. Korczynski. Commenced in No. 38.

98 Prognosis in Typhoid from Bacteriologic Findings. O. Landsberger.
99 Sterilization of Clothing. (Bekämpfung der Kleiderläuse durch trockne Hitze.) A. Hartmann.

94. **Pathology of Mammary Secretion.**—Ebeler had his attention called to this subject in 1912 by the case of a woman of 50 from whose breasts there oozed a watery fluid after a laparotomy for myomatous uterus and ovarian cysts. Since then he has examined for mammary secretion in various gynecologic affections, and reports here positive findings in 87 cases. The secretion ranged from a watery fluid to actual milk in the different cases and sometimes in the same case at different times. Genital tumors seem to have a particularly stimulating action on the secreting glands in the breast. He lists 12 positive cases with uterine myoma, 5 with ovarian cysts, 6 with pyosalpinx, 10 with cancer of the uterus, and 11 with retroflexion, 9 with prolapse of genital organs or bladder, 12 with inflammatory processes in the uterus, and 22 with other affections, such as hernia, mammary cancer, tuberculous peritonitis, etc. These different series included women who had never been pregnant, but all were over 20, except one girl of 16 with appendicitis, one of 17 with probable renal tuberculosis, and one of 19 with movable retroflexion of the uterus. In 24.13 per cent. of his 87 cases the women had never been pregnant; a number were virgins and 11 were past the menopause. One was a woman of 82 with prolapse of the vagina. The proportion of cases of colostrum secretion outside of a pregnancy is largest with genital tumors. Klein reported this year the case of a woman of 51, in the menopause for a year, with profuse secretion of milk in both breasts accompanying a sarcoma of the uterus. When the breasts are examined more systematically in the nonpregnant, such cases will be found more common than is recognized at present. A mammary secretion of colostrum therefore cannot be regarded as of so much import in the diagnosis of pregnancy as has hitherto been accepted.

96. **Relapsing Fever.**—Korczynski has had considerable experience with relapsing fever recently in the eastern seat of war, and states that there was but one attack in 76 per cent. of seventy-five cases, while the other patients had one relapse. He says that salvarsan must be regarded as the sovereign remedy, but it must be given in large doses, 0.9 gm. for adults and from 0.45 to 0.6 gm. for youths. Heart tonics generally are needed. If such large doses of salvarsan seem contraindicated, smaller, repeated doses might be tried.

103. **Blood Findings After Inoculation Against Typhoid.**—Ziersch examined daily the blood of forty-five soldiers who had been inoculated three times. No regularity in the response to the agglutination test could be detected during the following months. A positive response was obtained in eighteen, and a negative in twenty-seven. The leukocyte count ranged about 4,900 to 5,700. The differential blood count kept like that of typhoid except that the eosinophils did not disappear as with typhoid.

105. **Differential Diagnosis of Syphilis.**—Hubert relates that during the last three years every patient at the first medical clinic at Munich has been examined for possible syphilis. The previous history in each case, the physical findings, and the response to the Wassermann test were correlated, the results demonstrating that 8.8 per cent. of the 8,652 patients applying to the clinic were infected, although fully 52 per cent. of the 405 men and 75 per cent. of the 354 women infected were unaware of it. This lack of any previous history or suspicion of syphilis may prove misleading in treatment of cardiovascular affections, apoplexy or headache. Hubert was also impressed with the prevalence of latent syphilis, and the importance of serodiagnosis for revealing unsuspected syphilis in such a large proportion of the general public. He found also that quite a large proportion of the patients denied syphilis, in deliberate falsehood. In the cases of tabes, the Wassermann reaction alone cleared up the diagnosis in 56 per cent. of the men and in 65 per cent. of the women. The anamnesis supplemented the Wassermann only in 75 per cent. in the male tabetics and in 68 per cent. of the women. The experiences related confirm the value of the routine Wassermann test in general hospital practice.

106. **Relation of Life to Light.**—Schanz cites recent authorities to sustain the results of his own research which has demonstrated that insects and the dwellers in the sea are all color blind. They see everything gray in gray. As Hess has established, only vertebrates living in air are able to distinguish colors. This demolishes the old conception that the colors of the flowers serve to attract and guide insects. The brilliant coloring of the sea dwellers is obscured to the eye of man at a depth of a few feet, and the light penetrating the water changes its color as it descends lower and lower; the red and yellow rays being absorbed more than the blue or green. The sea dwellers look red and yellow to us because their integument is so constituted that they are able to absorb the rays which are able to penetrate to them, and thus they can utilize the light which reaches them. The coloring matters in their integument thus serve as photocatalyzers, the same as the hematoporphyrin in the back of the earthworm. He explains further that light modifies albumin, changing it from a readily soluble into a much less soluble form. There are many substances which retard or hasten this change. The most common substance of the kind is chlorophyl, with whose photocatalyzing properties we are all familiar. In certain animals the entire integument is sensitive to the action of light, thus forming an apparatus for the perception of light as it is provided with some photocatalyzing element. This seems to be the case with the sea dwellers: In others, like the earthworm, this element is restricted to some part of the creature. In the higher animals this localization is still more specialized, and the eye develops. There is much to sustain the assumption, he adds, that the act of seeing in the higher animals is at bottom the same photocatalytic process which we observe going on everywhere throughout all living beings.

107. **Serodiagnosis and Psychiatry.**—Kafka concludes his discussion of this subject with the remark that the ninhydrin reaction must be studied further, tranquilly and objectively, as the results already obtained show promise of great usefulness. To date, however, the method has no actually practical value in psychiatry. He urges simultaneous study of other methods working toward the same aims, to control and supplement the findings with the dialysis method, mentioning P. Hirsch's "interferometry" in particular for this purpose. Even with all these restrictions, however, the Abderhalden technic may already yield important information to fill gaps in our knowledge of the case, especially in differentiating between dementia praecox and uncomplicated cases of manic depressive insanity or psychoneuroses; also between epilepsy and hysteria, between paralysis and cerebral syphilis, between organic affections of the central nervous system and neuroses. The cases of glandular imbecility and idiocy will be recognized better. Chief in interest, however, is the light thrown on the pathogenesis of nervous and mental affections.

111. **Dangers of Oxygen in Treatment of Gas Phlegmons, Etc.**—Borchers injected a 3 per cent. hydrogen dioxid solution subcutaneously and intramuscularly in a case of extensive gas phlegmon after exarticulation of the shoulder. The prompt recovery he ascribed to the nascent oxygen, and was confirmed in this view by the prompt recovery in two other similar cases. In the fourth case, however, breathing stopped at once on injection of the dioxid solution into the stump of the arm after amputation. This makes the fifth case on record of sudden death from this cause, and it warns of the dangers of injecting oxygen into the tissues. He presents evidence further that the prognosis of gas phlegmons is not so grave as has been hitherto assumed. Under simple multiple small incisions the infected lymph stream is diverted outward, and the infection is conquered. Of course these remarks as to the danger of oxygen do not apply to rinsing the wound with nascent oxygen. This is the best mechanical cleansing method at our disposal to date, and does no harm where the oxygen can escape freely.

112. **Preventive Injection of Antitetanus Serum.**—Wolf relates that after the German authorities decreed that every wounded soldier is to be given a preventive injection of antitetanus serum, the number of cases of tetanus dropped off to almost zero. In one case tetanus developed thirty hours after the injury, notwithstanding the preventive injection. Although the incubation was so brief the tetanus ran a very mild course. There is every reason to assume that without the preventive injection this case would have terminated fatally. The experiences related indicate that the preventive injections are an almost certain protection against lockjaw; also that the injection need not be made at once; even delay till the next day does not detract from its efficacy. It is not necessary, he adds, to give the preventive injection to every wounded man; it is enough to give it after shrapnel

d grenade wounds. When there are a number of scattered ounds, soiled with horse manure, the foci of infection being merous the patient requires a double dose of the antitanus serum.

130. **Tuberculin Treatment of Children.**—Koch is assistant at the children's clinic at Vienna in charge of von Pirquet, and he here gives a detailed description of forty-five children given systematic courses of tuberculin treatment. He reports excellent and encouraging results, but emphasizes the changes he has introduced into the method of tuberculin treatment for children. He gives the tuberculin in a larger amount of fluid than others use, up to 10 or 20 c.c., believing that the tuberculin diffuses better in this way. He also changes the site of the injections, and increases the doses by geometrical progression. Only two strengths are required, 1:100,000 and 1:10,000. He begins with 1/1,000 mg. and increases to the final dose at 1,000 mg. This is reached usually in seven, thirteen or twenty-five doses, giving two injections a week. He adds that the terminal dose can be repeated as long as it seems necessary to continue the course. In seven cases the treatment had to be discontinued as periods of high fever set in. All the other little patients bore the treatment well and improved under it. The children were of all ages, but most were between 3 and 9. The most unfavorable age for the treatment is the first three years, and the eleventh, thirteenth and fourteenth years. The duration of treatment averaged only eleven weeks.

131. **Initial Fever of Tuberculosis.**—Koch relates that he had three children under observation who developed tuberculosis under his eyes, the exact date of their exposure to contagion being known. The children were tested regularly for the skin tuberculin reaction afterward. The response became positive at the same time that fever developed and kept up, and this was in each case during the seventh week after infection. The initial fever was the only clinical sign that anything was wrong, but from the first it displayed the characteristics of the fever of tuberculosis.

137 *Cholera Traced to the Market Place. (Se e come un mercato possa essere o divenire centro o veicolo d'infezione colerica.) M. Ciosefi.
138 *Case of Simple Traumatic Polyuria. A. Cardarelli.

137. **Epidemic of Cholera.**—Ciosefi relates that at Trieste nineteen cases of cholera developed at scattered points throughout the city, all in the course of ten days, and with no apparent connection between the cases. There were thus several remote foci. The water, milk, and similar sources of infection could be excluded, the only tenable explanation being that some carrier had been in the central fruit and vegetable market, and had infected some of the fruits and vegetables by handling them. The populace has been educated by the authorities to cook fruits and vegetables and eat none raw, so that infection could not have occurred from uncooked fruits or vegetables. The dealers, however, handling the goods, thus became infected secondarily, and carried the infection home. Some person connected with the market or working nearby was discovered in the environment in all the cholera cases.

138. **Traumatic Polyuria.**—In the case reported by Cardarelli a boy of 15 fell from a height of nearly 50 feet and suffered several fractures, and concussion of the brain. For twenty days he was unconscious or delirious, and not until after the fortieth day was the brain working apparently normally once more. He had much headache and thirst and voided from 17 to 18 liters of urine in the twenty-four hours. The traumatism seems ample to explain the polyuria, and under treatment with hypophysis extract the youth seems to be improving. The urine voided does not total over 8 or 9 liters now. Cardarelli thinks that it is not necessary to incriminate hysteria in this case although hysteria is often responsible for transient polyuria. He saw a case not long ago in which a young woman with pronounced stigmata of hysteria voided 22 liters of urine. In another case a boy of 11, after a severe fright, passed no urine for four weeks although apparently entirely healthy, and the anuria then stopped as suddenly as it had begun.

142 *Multiple Myelomas with Bence-Jones Albumosuria. (La malattia di Kahler-Bozzolo con illustrazione di un nuovo caso.) A. Martiri. To be continued.

140. **Interaction of Microbian Toxins.**—Mahokian reports experiences showing that tetanus and diphtheria toxins influence each other, the former attenuating the action of the latter when injected into guinea-pigs. On the other hand, diphtheria toxin enhances the toxic action of tetanus toxin. When tetanus toxin was injected along with diphtheria antitoxin, the curative influence of the latter was enhanced, but the exact opposite was observed with antitetanus serum. Microbes seemed to acquire greater virulence when some of their own toxin, and sometimes an alien toxin, was added to the culture medium. Experiments with the toxin from leprosy bacilli and from tubercle bacilli gave results suggesting that the secretions of the former were less diffusible than of the latter, which might be one reason why the former is harder to cultivate.

141. **Acute Raynaud's Disease Associated with Paralysis.**—Alessandri and Mingazzini encountered a number of cases of this kind among persons injured in the last great earthquake in Italy. Six of the patients died; in three the disturbances progressed to gangrene compelling amputation. The other patients recovered more or less completely

although the paralysis persisted in most. Trophic vasomotor disturbances were evidently the main factor in some cases and acute inflammation of peripheral nerves in others. The latter group is much less serious. All the patients had been buried under the ruins for from one to three days, exposed to cold, wet and fright.

142. **Multiple Myelomas.**—Martiri reviews the literature on the syndrome described by Kahler and first diagnosed in the living subject by Bozzolo. He has compiled 204 cases and adds another to the list. His patient was a man of 55, a great smoker and drinker, who developed occipital headache in 1913, subcontinuous, a little worse at night, with occasional dizziness, all improving under treatment for neuralgia. A few months later pains and tenderness in the right ribs became so intense that the man could not get up for a few days, but they gradually improved although the pains could be elicited anew by bending the trunk. Later, pains in the knee prevented walking. A tumor could be felt on the sternum, painful on pressure, but there was never any fever. The urine contained from 0.15 to 1 per thousand Bence-Jones bodies, and the diagnosis of Kahler-Bozzolo's disease was confirmed by the practically spontaneous rupture of the femur. The course was progressive, the man dying in coma about a year after the first symptoms. The variability of the seat of the pains from day to day is a striking feature of this disease, but the pains always cling to the bones, and nocturnal exacerbations are common. In some cases the complaints seemed to be so out of proportion to the slight objective findings that simulation was suspected. The discussion of the disease, of the Bence-Jones albumose and its determination, etc., fill thirty pages in this installment of Martiri's article.

143 *Pathologic Obesity in Two Infants. (L'obesita mostruosa nei bambini lattanti.) L. Ferrannini. Commenced in No. 39.
144 Catalase in Organs with an Internal Secretion. F. Galdi.

143. **Extreme Obesity in Infants.**—In this concluding half of his article Ferrannini summarizes his conclusions in the statement that disturbances in the glands with an internal secretion are undoubtedly responsible for pathologic obesity in infants, as at any age. The influence of the nervous system and of infections and intoxications is felt through structural or functional changes or both in the glands with an internal secretion. In the two cases of which an illustrated description is given, probably more than one of these glands was involved as the syndrome was extremely pronounced and complex. The pancreas and the thyroid can probably be excluded as also the genital glands, on account of the age of the little patients. The pituitary body, the pineal gland and the suprarenals are probably the ones involved, the last two only secondarily.

153 *Acute Necrosis of Pancreas. V. P. Nedokhleboff.

147. **Cultivation of Cholera Vibriones.**—Krich found Ottolenghi's medium for cultivation of cholera vibriones more suitable than pepton-water. Fresh ox gall is filtered through paper and then 3 c.c. of the filtrate is mixed with 100 c.c. of 1:1,000 solution of soda crystals and 1:1,000 of potassium nitrate. The mixture is placed in test tubes and sterilized at 115 C. for fifteen or twenty minutes. Krich had the opportunity of studying this method on cholera patients simultaneously with the pepton-water medium. The parallel experiments showed the advantages of the gall medium. The latter would produce a luxuriant growth of cholera vibriones [illegible] when the pepton-water medium would show no growth whatever. The technic was as follows: 1 c.c. of feces was place in a glass with 30 c.c. of alkaline gall prepared according t Ottolenghi. Six or twelve hours later a reinoculation wa made on slanting agar, rendered solid by addition of 1.5 pe cent. of agar to 10 c.c. of gall. The specimens were staine with acid fuchsin, after fixation in an alcoholic solution mercuric chlorid, or a 1:1,000 solution.

148. **Hemolytic Serums.**—Krichevsky showed that the connective tissue of animals, as for instance, the fat of a guinea pig, contains an antigen which produces a hemolysin against sheep red blood corpuscles. The cause being in the nuclei, he concluded that nucleated erythrocytes, which are found in a hen, for instance, should also possess this ability of producing hemolysins against sheep erythrocytes. As the organs of a hen contain such an antigen, he chose the erythrocytes of this animal for his experiments. They were injected into rabbits and the latter's serum proved afterward hemolyti for sheep red cells. Therefore he comes to the conclusio that the hen's erythrocytes contain the same heterogenou antigen—which produces hemolysis of sheep cells—as th organs. The obtained heterogenous serum possesses hig hemolytic properties; 1,000 hemolytic units in 1 c.c. for shee cells, but it is inactive against the cells of the hen that gav the antigen. Therefore, Krichevsky thinks that specificity antibodies does not exist, because rabbits injected with hen' red cells produce a hemolysin not against the latter, bu against sheep cells. However, the serum of a hen contain agglutinogens as shown by the fact that immunization rabbits generates in their serum a large amount of agglutinins against the erythrocytes of hens. Thus, the erythrocytes of the latter contain not only heterogenous hemolysin but also heterogenous agglutinins. The experiments als showed that rabbit's serum immunized by hen cells does no contain hemolysins against beef erythrocytes either, and tha the connective tissue of animals (guinea-pig, for instance contains a heterogenous sheep antigen—rabbits injected wi fat from a guinea-pig give a serum that dissolves the shee erythrocytes.

150. **Wounds Caused by Earth.**—Wounds caused by eart are the by-effects of the action of projectiles. Explodin bullets and shells drive small particles of dirt into the ski The neck, face and other exposed portions of the body a usually affected. The mildest form is "tattooed skin" whic appears as if covered with dirt which cannot be remove either with soap or benzin, as the smallest particles of th dirt have been driven into the skin. It becomes swolle parchment-like, and either peels or small necrotic foci for Venous thrombi sometimes develop. With the second for abrasions with cyanosis and swelling, deep necrosis ma occur or thrombophlebitis. The third variety is the formatio of real wounds with irregular edges and subcutaneous hemorrhages; the wound is full of pieces of earth, stones or dir In one case one and a half pounds of dirt were found in th wound. Such wounds may be the cause of general sepsi Earth wounds may be complicated with brain concussion fractures of bones and contusions of viscera. In milder case there may be dizziness, headache, general pallor or redne of the face, neck and chest. In other cases the explosio caused psychic disturbances. In all he had forty-five cas of "dirt wounds" among 2,000 patients (2.25 per cent.). T wounds are superficial, but badly infected. The treatm therefore, consists in prevention of sepsis. By the sixth or ninth day as a rule the soldiers wounded in this way could be sent back to the interior without danger.

153. **Acute Necrosis of Pancreas.**—Nedokhleboff advocates early operative treatment of acute necrosis of the pancreas. It can be diagnosed by the following symptoms: adipositas, sudden onset with a severe shock, stormy course, localization of pain in the epigastrium, meteorism in the region of the stomach, absence of muscular defence, prolonged vomiting of bile, the contrast between the collapsed state and the good pulse, cyanosis and dyspnea without corresponding changes in the heart and lungs. All these symptoms were present in a case reported in detail. This patient was a 19 year old [illegible] after a successful operation.
